

1. Ice Manual	15
1.1 Ice Overview	17
1.1.1 Ice Architecture	18
1.1.1.1 Terminology	19
1.1.1.2 Slice (Specification Language for Ice)	26
1.1.1.3 Overview of the Language Mappings	27
1.1.1.4 Client and Server Structure	28
1.1.1.5 Overview of the Ice Protocol	30
1.1.2 Ice Services Overview	31
1.1.3 Architectural Benefits of Ice	33
1.2 Hello World Application	34
1.2.1 Writing a Slice Definition	35
1.2.2 Writing an Ice Application with C++	36
1.2.3 Writing an Ice Application with C-Sharp	43
1.2.4 Writing an Ice Application with Java	50
1.2.5 Writing an Ice Application with JavaScript	57
1.2.6 Writing an Ice Application with Objective-C	60
1.2.7 Writing an Ice Application with PHP	67
1.2.8 Writing an Ice Application with Python	70
1.2.9 Writing an Ice Application with Ruby	75
1.2.10 Writing an Ice Application with Visual Basic	78
1.3 The Slice Language	86
1.3.1 Slice Compilation	87
1.3.2 Slice Source Files	90
1.3.3 Lexical Rules	93
1.3.4 Modules	95
1.3.5 Basic Types	97
1.3.6 User-Defined Types	99
1.3.6.1 Enumerations	100
1.3.6.2 Structures	102
1.3.6.3 Sequences	104
1.3.6.4 Dictionaries	106
1.3.7 Constants and Literals	108
1.3.8 Interfaces, Operations, and Exceptions	112
1.3.8.1 Operations	113
1.3.8.2 User Exceptions	118
1.3.8.3 Run-Time Exceptions	123
1.3.8.4 Proxies for Ice Objects	128
1.3.8.5 Interface Inheritance	130
1.3.9 Classes	138
1.3.9.1 Simple Classes	139
1.3.9.2 Class Inheritance	141
1.3.9.3 Class Inheritance Semantics	143
1.3.9.4 Classes as Unions	145
1.3.9.5 Self-Referential Classes	146
1.3.9.6 Classes Versus Structures	149
1.3.9.7 Classes with Operations	150
1.3.9.8 Architectural Implications of Classes	152
1.3.9.9 Classes Implementing Interfaces	154
1.3.9.10 Class Inheritance Limitations	157
1.3.9.11 Pass-by-Value Versus Pass-by-Reference	158
1.3.9.12 Passing Interfaces by Value	160
1.3.9.13 Classes with Compact Type IDs	161
1.3.10 Forward Declarations	162
1.3.11 Optional Data Members	163
1.3.12 Type IDs	166
1.3.13 Operations on Object	167
1.3.14 Local Types	169
1.3.15 Names and Scoping	170
1.3.16 Metadata	181
1.3.17 Serializable Objects	182
1.3.18 Deprecating Slice Definitions	184
1.3.19 Using the Slice Compilers	185
1.3.20 Slice Checksums	187
1.3.21 Generating Slice Documentation	188
1.3.22 Slice Keywords	194
1.3.23 Slice Metadata Directives	195
1.3.24 Slice for a Simple File System	203
1.4 Language Mappings	207
1.4.1 C++ Mapping	208
1.4.1.1 Client-Side Slice-to-C++ Mapping	209
1.4.1.1.1 C++ Mapping for Identifiers	210

1.4.1.1.2 C++ Mapping for Modules	211
1.4.1.1.3 C++ Mapping for Built-In Types	212
1.4.1.1.4 C++ Mapping for Enumerations	215
1.4.1.1.5 C++ Mapping for Structures	216
1.4.1.1.6 C++ Mapping for Sequences	221
1.4.1.1.7 C++ Mapping for Dictionaries	225
1.4.1.1.8 C++ Mapping for Constants	227
1.4.1.1.9 C++ Mapping for Exceptions	229
1.4.1.1.10 C++ Mapping for Interfaces	234
1.4.1.1.11 C++ Mapping for Operations	243
1.4.1.1.12 C++ Mapping for Optional Values	253
1.4.1.1.13 C++ Mapping for Classes	256
1.4.1.1.14 Smart Pointers for Classes	265
1.4.1.1.15 Asynchronous Method Invocation (AMI) in C++	279
1.4.1.1.16 Using Slice Checksums in C++	294
1.4.1.1.17 Example of a File System Client in C++	295
1.4.1.2 Server-Side Slice-to-C++ Mapping	300
1.4.1.2.1 The Server-Side main Function in C++	301
1.4.1.2.2 Server-Side C++ Mapping for Interfaces	313
1.4.1.2.3 Parameter Passing in C++	316
1.4.1.2.4 Raising Exceptions in C++	318
1.4.1.2.5 Object Incarnation in C++	319
1.4.1.2.6 Asynchronous Method Dispatch (AMD) in C++	324
1.4.1.2.7 Example of a File System Server in C++	329
1.4.1.3 Customizing the C++ Mapping	348
1.4.1.3.1 The C++ Stream Helpers	349
1.4.1.3.2 The <code>cpp:type</code> and <code>cpp:view-type</code> Metadata Directives	357
1.4.1.4 Version Information in C++	370
1.4.1.5 <code>slice2cpp</code> Command-Line Options	371
1.4.1.6 C++ Strings and Character Encoding	378
1.4.1.6.1 Installing String Converters	379
1.4.1.6.2 UTF-8 Conversion	381
1.4.1.6.3 String Parameters in Local Calls	382
1.4.1.6.4 Built-in String Converters	383
1.4.1.6.5 String Conversion Convenience Functions	384
1.4.1.6.6 The <code>iconv</code> String Converter	386
1.4.1.6.7 The Ice String Converter Plug-in	387
1.4.1.6.8 Custom String Converter Plug-ins	389
1.4.1.7 The C++ Utility Library	390
1.4.1.7.1 Threads and Concurrency with C++	391
1.4.1.7.2 The C++ <code>AbstractMutex</code> Class	425
1.4.1.7.3 The C++ <code>Cache</code> Template	428
1.4.1.7.4 The C++ <code>Exception</code> Class	430
1.4.1.7.5 The C++ <code>generateUUID</code> Function	431
1.4.1.7.6 The C++ <code>Handle</code> Template	432
1.4.1.7.7 The C++ <code>Handle</code> Template Adaptors	436
1.4.1.7.8 The C++ <code>ScopedArray</code> Template	443
1.4.1.7.9 The C++ <code>Shared</code> and <code>SimpleShared</code> Classes	446
1.4.1.7.10 The C++ <code>Time</code> Class	447
1.4.1.7.11 The C++ <code>Timer</code> and <code>TimerTask</code> Classes	451
1.4.2 C-Sharp Mapping	453
1.4.2.1 Client-Side Slice-to-C-Sharp Mapping	454
1.4.2.1.1 C-Sharp Mapping for Identifiers	455
1.4.2.1.2 C-Sharp Mapping for Modules	456
1.4.2.1.3 C-Sharp Mapping for Built-In Types	458
1.4.2.1.4 C-Sharp Mapping for Enumerations	459
1.4.2.1.5 C-Sharp Mapping for Structures	460
1.4.2.1.6 C-Sharp Mapping for Sequences	466
1.4.2.1.7 C-Sharp Mapping for Dictionaries	470
1.4.2.1.8 C-Sharp Collection Comparison	472
1.4.2.1.9 C-Sharp Mapping for Constants	473
1.4.2.1.10 C-Sharp Mapping for Exceptions	476
1.4.2.1.11 C-Sharp Mapping for Interfaces	481
1.4.2.1.12 C-Sharp Mapping for Operations	489
1.4.2.1.13 C-Sharp Mapping for Classes	498
1.4.2.1.14 C-Sharp Mapping for Optional Values	509
1.4.2.1.15 Serializable Objects in C-Sharp	511
1.4.2.1.16 C-Sharp Specific Metadata Directives	513
1.4.2.1.17 Asynchronous Method Invocation (AMI) in C-Sharp	514
1.4.2.1.18 <code>slice2cs</code> Command-Line Options	530
1.4.2.1.19 Using Slice Checksums in C-Sharp	531
1.4.2.1.20 Example of a File System Client in C-Sharp	532

1.4.2.2 Server-Side Slice-to-C-Sharp Mapping	537
1.4.2.2.1 The Server-Side main Method in C-Sharp	538
1.4.2.2.2 Server-Side C-Sharp Mapping for Interfaces	545
1.4.2.2.3 Parameter Passing in C-Sharp	549
1.4.2.2.4 Raising Exceptions in C-Sharp	551
1.4.2.2.5 Tie Classes in C-Sharp	552
1.4.2.2.6 Object Incarnation in C-Sharp	556
1.4.2.2.7 Asynchronous Method Dispatch (AMD) in C-Sharp	560
1.4.2.2.8 Example of a File System Server in C-Sharp	565
1.4.2.3 The .NET Utility Library	576
1.4.3 Java Mapping	578
1.4.3.1 Client-Side Slice-to-Java Mapping	579
1.4.3.1.1 Java Mapping for Identifiers	580
1.4.3.1.2 Java Mapping for Modules	581
1.4.3.1.3 Java Mapping for Built-In Types	582
1.4.3.1.4 Java Mapping for Enumerations	583
1.4.3.1.5 Java Mapping for Structures	585
1.4.3.1.6 Java Mapping for Sequences	588
1.4.3.1.7 Java Mapping for Dictionaries	589
1.4.3.1.8 Java Mapping for Constants	590
1.4.3.1.9 Java Mapping for Exceptions	592
1.4.3.1.10 Java Mapping for Interfaces	596
1.4.3.1.11 Java Mapping for Operations	605
1.4.3.1.12 Java Mapping for Classes	615
1.4.3.1.13 Java Mapping for Optional Data Members	624
1.4.3.1.14 Serializable Objects in Java	628
1.4.3.1.15 Customizing the Java Mapping	630
1.4.3.1.16 Asynchronous Method Invocation (AMI) in Java	642
1.4.3.1.17 Using the Slice Compiler for Java	655
1.4.3.1.18 slice2java Command-Line Options	656
1.4.3.1.19 Using Slice Checksums in Java	657
1.4.3.1.20 Example of a File System Client in Java	658
1.4.3.2 Server-Side Slice-to-Java Mapping	663
1.4.3.2.1 The Server-Side main Method in Java	664
1.4.3.2.2 Server-Side Java Mapping for Interfaces	671
1.4.3.2.3 Parameter Passing in Java	675
1.4.3.2.4 Raising Exceptions in Java	678
1.4.3.2.5 Tie Classes in Java	680
1.4.3.2.6 Object Incarnation in Java	685
1.4.3.2.7 Asynchronous Method Dispatch (AMD) in Java	689
1.4.3.2.8 Example of a File System Server in Java	694
1.4.3.3 The Java Utility Library	705
1.4.3.4 Custom Class Loaders	708
1.4.3.5 Java Interrupts	709
1.4.4 JavaScript Mapping	711
1.4.4.1 Asynchronous APIs in JavaScript	713
1.4.4.2 Client-Side Slice-to-JavaScript Mapping	714
1.4.4.2.1 JavaScript Mapping for Identifiers	715
1.4.4.2.2 JavaScript Mapping for Modules	716
1.4.4.2.3 JavaScript Mapping for Built-In Types	718
1.4.4.2.4 JavaScript Mapping for Enumerations	719
1.4.4.2.5 JavaScript Mapping for Structures	721
1.4.4.2.6 JavaScript Mapping for Sequences	723
1.4.4.2.7 JavaScript Mapping for Dictionaries	724
1.4.4.2.8 JavaScript Mapping for Constants	727
1.4.4.2.9 JavaScript Mapping for Exceptions	729
1.4.4.2.10 JavaScript Mapping for Interfaces	732
1.4.4.2.11 JavaScript Mapping for Operations	739
1.4.4.2.12 JavaScript Mapping for Classes	755
1.4.4.2.13 slice2js Command-Line Options	762
1.4.4.3 Server-Side Slice-to-JavaScript Mapping	763
1.4.4.3.1 Server-Side JavaScript Mapping for Interfaces	764
1.4.4.3.2 Parameter Passing in JavaScript	767
1.4.4.3.3 Raising Exceptions in JavaScript	769
1.4.4.3.4 Object Incarnation in JavaScript	770
1.4.4.3.5 Asynchronous Method Dispatch (AMD) in JavaScript	774
1.4.5 Objective-C Mapping	778
1.4.5.1 Client-Side Slice-to-Objective-C Mapping	779
1.4.5.1.1 Objective-C Mapping for Modules	780
1.4.5.1.2 Objective-C Mapping for Identifiers	782
1.4.5.1.3 Objective-C Mapping for Built-In Types	784
1.4.5.1.4 Objective-C Mapping for Enumerations	785

1.4.5.1.5 Objective-C Mapping for Structures	786
1.4.5.1.6 Objective-C Mapping for Sequences	790
1.4.5.1.7 Objective-C Mapping for Dictionaries	794
1.4.5.1.8 Objective-C Mapping for Constants	796
1.4.5.1.9 Objective-C Mapping for Exceptions	798
1.4.5.1.10 Objective-C Mapping for Interfaces	806
1.4.5.1.11 Objective-C Mapping for Operations	811
1.4.5.1.12 Objective-C Mapping for Local Interfaces	823
1.4.5.1.13 Objective-C Mapping for Classes	824
1.4.5.1.14 Objective-C Mapping for Interfaces by Value	835
1.4.5.1.15 Objective-C Mapping for Optional Data Members	836
1.4.5.1.16 Asynchronous Method Invocation (AMI) in Objective-C	837
1.4.5.1.17 slice2objc Command-Line Options	847
1.4.5.1.18 Example of a File System Client in Objective-C	848
1.4.5.2 Server-Side Slice-to-Objective-C Mapping	853
1.4.5.2.1 The Server-Side main Function in Objective-C	854
1.4.5.2.2 Server-Side Objective-C Mapping for Interfaces	857
1.4.5.2.3 Parameter Passing in Objective-C	861
1.4.5.2.4 Raising Exceptions in Objective-C	863
1.4.5.2.5 Object Incarnation in Objective-C	864
1.4.5.2.6 Example of a File System Server in Objective-C	868
1.4.6 PHP Mapping	883
1.4.6.1 Client-Side Slice-to-PHP Mapping	884
1.4.6.1.1 PHP Mapping for Identifiers	885
1.4.6.1.2 PHP Mapping for Modules	886
1.4.6.1.3 PHP Mapping for Built-In Types	887
1.4.6.1.4 PHP Mapping for Enumerations	888
1.4.6.1.5 PHP Mapping for Structures	890
1.4.6.1.6 PHP Mapping for Sequences	892
1.4.6.1.7 PHP Mapping for Dictionaries	893
1.4.6.1.8 PHP Mapping for Constants	894
1.4.6.1.9 PHP Mapping for Exceptions	896
1.4.6.1.10 PHP Mapping for Interfaces	900
1.4.6.1.11 PHP Mapping for Operations	907
1.4.6.1.12 PHP Mapping for Classes	914
1.4.6.1.13 slice2php Command-Line Options	922
1.4.6.1.14 Application Notes for PHP	923
1.4.6.1.15 Using Slice Checksums in PHP	930
1.4.6.1.16 Example of a File System Client in PHP	931
1.4.7 Python Mapping	936
1.4.7.1 Client-Side Slice-to-Python Mapping	937
1.4.7.1.1 Python Mapping for Identifiers	938
1.4.7.1.2 Python Mapping for Modules	939
1.4.7.1.3 Python Mapping for Built-In Types	940
1.4.7.1.4 Python Mapping for Enumerations	941
1.4.7.1.5 Python Mapping for Structures	944
1.4.7.1.6 Python Mapping for Sequences	946
1.4.7.1.7 Python Mapping for Dictionaries	949
1.4.7.1.8 Python Mapping for Constants	950
1.4.7.1.9 Python Mapping for Exceptions	952
1.4.7.1.10 Python Mapping for Interfaces	956
1.4.7.1.11 Python Mapping for Operations	963
1.4.7.1.12 Python Mapping for Classes	970
1.4.7.1.13 Asynchronous Method Invocation (AMI) in Python	978
1.4.7.1.14 Code Generation in Python	987
1.4.7.1.15 Using Slice Checksums in Python	997
1.4.7.1.16 Example of a File System Client in Python	998
1.4.7.2 Server-Side Slice-to-Python Mapping	1003
1.4.7.2.1 The Server-Side main Program in Python	1004
1.4.7.2.2 Server-Side Python Mapping for Interfaces	1010
1.4.7.2.3 Parameter Passing in Python	1013
1.4.7.2.4 Raising Exceptions in Python	1015
1.4.7.2.5 Object Incarnation in Python	1016
1.4.7.2.6 Asynchronous Method Dispatch (AMD) in Python	1020
1.4.7.2.7 Example of a File System Server in Python	1024
1.4.8 Ruby Mapping	1034
1.4.8.1 Client-Side Slice-to-Ruby Mapping	1035
1.4.8.1.1 Ruby Mapping for Identifiers	1036
1.4.8.1.2 Ruby Mapping for Modules	1037
1.4.8.1.3 Ruby Mapping for Built-In Types	1038
1.4.8.1.4 Ruby Mapping for Enumerations	1039
1.4.8.1.5 Ruby Mapping for Structures	1042

1.4.8.1.6 Ruby Mapping for Sequences	1044
1.4.8.1.7 Ruby Mapping for Dictionaries	1046
1.4.8.1.8 Ruby Mapping for Constants	1047
1.4.8.1.9 Ruby Mapping for Exceptions	1049
1.4.8.1.10 Ruby Mapping for Interfaces	1053
1.4.8.1.11 Ruby Mapping for Operations	1060
1.4.8.1.12 Ruby Mapping for Classes	1067
1.4.8.1.13 Code Generation in Ruby	1076
1.4.8.1.14 The main Program in Ruby	1082
1.4.8.1.15 Using Slice Checksums in Ruby	1088
1.4.8.1.16 Example of a File System Client in Ruby	1089
1.5 Properties and Configuration	1094
1.5.1 Properties Overview	1095
1.5.2 Configuration File Syntax	1097
1.5.3 Setting Properties on the Command Line	1100
1.5.4 Using Configuration Files	1101
1.5.5 Alternate Property Stores	1103
1.5.6 Command-Line Parsing and Initialization	1104
1.5.7 The Properties Interface	1107
1.5.8 Reading Properties	1109
1.5.9 Setting Properties	1111
1.5.10 Parsing Properties	1116
1.6 Communicator and other Core Local Features	1121
1.6.1 Communicators	1122
1.6.2 Communicator Initialization	1126
1.6.3 Object Identity	1128
1.6.4 Plug-in Facility	1132
1.6.4.1 Plug-in API	1133
1.6.4.2 Plug-in Configuration	1137
1.6.4.3 Advanced Plug-in Topics	1138
1.7 Client-Side Features	1141
1.7.1 Proxies	1142
1.7.1.1 Obtaining Proxies	1143
1.7.1.2 Proxy Methods	1146
1.7.1.3 Proxy Endpoints	1151
1.7.1.4 Filtering Proxy Endpoints	1152
1.7.1.5 Proxy Defaults and Overrides	1153
1.7.1.6 Proxy-Based Load Balancing	1155
1.7.1.7 Indirect Proxy with Object Adapter Identifier	1157
1.7.1.8 Well-Known Proxy	1158
1.7.1.9 Proxy and Endpoint Syntax	1159
1.7.2 Request Contexts	1166
1.7.2.1 Explicit Request Contexts	1167
1.7.2.2 Per-Proxy Request Contexts	1169
1.7.2.3 Implicit Request Contexts	1171
1.7.2.4 Design Considerations for Request Contexts	1173
1.7.3 Invocation Timeouts	1175
1.7.4 Automatic Retries	1177
1.7.5 Oneway Invocations	1181
1.7.6 Datagram Invocations	1185
1.7.7 Batched Invocations	1188
1.8 Server-Side Features	1194
1.8.1 Object Adapters	1195
1.8.1.1 The Active Servant Map	1196
1.8.1.2 Creating an Object Adapter	1198
1.8.1.3 Servant Activation and Deactivation	1199
1.8.1.4 Object Adapter States	1201
1.8.1.5 Object Adapter Endpoints	1204
1.8.1.6 Creating Proxies with an Object Adapter	1208
1.8.1.7 Using Multiple Object Adapters	1210
1.8.2 The Current Object	1211
1.8.3 Servant Locators	1213
1.8.3.1 The ServantLocator Interface	1214
1.8.3.2 Threading Guarantees for Servant Locators	1216
1.8.3.3 Registering a Servant Locator	1217
1.8.3.4 Servant Locator Example	1219
1.8.3.5 Using Identity Categories with Servant Locators	1223
1.8.3.6 Using Cookies with Servant Locators	1227
1.8.4 Default Servants	1229
1.8.5 Dispatch Interceptors	1233
1.9 Client-Server Features	1238
1.9.1 The Ice Threading Model	1239

1.9.1.1 Thread Pools	1240
1.9.1.2 Object Adapter Thread Pools	1243
1.9.1.3 Thread Pool Design Considerations	1244
1.9.1.4 Concurrent Proxy Invocations	1246
1.9.1.5 Nested Invocations	1247
1.9.1.6 Thread Safety	1249
1.9.1.7 Dispatching Invocations to User Threads	1255
1.9.1.8 Blocking API Calls	1271
1.9.2 Connection Management	1272
1.9.2.1 Connection Establishment	1273
1.9.2.2 Active Connection Management	1277
1.9.2.3 Using Connections	1281
1.9.2.4 Connection Closure	1289
1.9.2.5 Bidirectional Connections	1290
1.9.3 Connection Timeouts	1294
1.9.4 Collocated Invocation and Dispatch	1297
1.9.5 Locators	1299
1.9.5.1 Locator Semantics for Clients	1300
1.9.5.2 Locator Configuration for a Client	1303
1.9.5.3 Locator Semantics for Servers	1304
1.9.5.4 Locator Configuration for a Server	1305
1.9.6 Slicing Values and Exceptions	1307
1.9.7 Dynamic Ice	1319
1.9.7.1 Streaming Interfaces	1320
1.9.7.1.1 C++ Streaming Interfaces	1321
1.9.7.1.2 Java Streaming Interfaces	1341
1.9.7.1.3 C-Sharp Streaming Interfaces	1360
1.9.7.2 Dynamic Invocation and Dispatch	1379
1.9.7.2.1 Dynamic Invocation and Dispatch Overview	1380
1.9.7.2.2 Dynamic Invocation and Dispatch in C++	1383
1.9.7.2.3 Dynamic Invocation and Dispatch in Java	1389
1.9.7.2.4 Dynamic Invocation and Dispatch in C-Sharp	1395
1.9.7.3 Asynchronous Dynamic Invocation and Dispatch	1402
1.9.7.3.1 Asynchronous Dynamic Invocation and Dispatch in C++	1403
1.9.7.3.2 Asynchronous Dynamic Invocation and Dispatch in Java	1409
1.9.7.3.3 Asynchronous Dynamic Invocation and Dispatch in C-Sharp	1413
1.9.8 Facets	1416
1.9.9 Versioning	1424
1.9.9.1 Versioning through Incremental Updates	1425
1.9.9.2 Versioning with Facets	1428
1.10 Administration and Diagnostics	1433
1.10.1 Administrative Facility	1434
1.10.1.1 The admin Object	1435
1.10.1.2 Creating the admin Object	1436

Ice Manual

Distributed Programming with Ice

The Internet Communications Engine (Ice) is a modern object-oriented toolkit that enables you to build distributed applications with minimal effort. Ice allows you to focus your efforts on your application logic, and it takes care of all interactions with low-level network programming interfaces. With Ice, there is no need to worry about details such as opening network connections, serializing and deserializing data for network transmission, or retrying failed connection attempts.

The main design goals of Ice are:

- Provide an object-oriented middleware platform suitable for use in heterogeneous environments.
- Provide a full set of features that support development of realistic distributed applications for a wide variety of domains.
- Avoid unnecessary complexity, making the platform easy to learn and to use.
- Provide an implementation that is efficient in network bandwidth, memory use, and CPU overhead.
- Provide an implementation that has built-in security, making it suitable for use over insecure public networks.

In simpler terms, the Ice design goals could be stated as "Let's build a powerful middleware platform that makes the developer's life easier."

The acronym "Ice" is pronounced as a single syllable, like the word for frozen water.

Getting Help with Ice

If you have a question and you cannot find an answer in this manual, you can visit our [developer forums](#) to see if another developer has encountered the same issue. If you still need help, feel free to post your question on the forum, which ZeroC's developers monitor regularly. Note, however, that we can provide only limited free support in our forums. For guaranteed response and problem resolution times, we highly recommend purchasing [commercial support](#).

Feedback about the Manual

We would very much like to hear from you in case you find any bugs (however minor) in this manual. We also would like to hear your opinion on the contents, and any suggestions as to how it might be improved. You can contact us via e-mail at icebook@zeroc.com.

Legal Notices

Many of the designations used by manufacturers and sellers to distinguish their products are claimed as trademarks. Where those designations appear in this book and ZeroC was aware of the trademark claim, the designations have been printed in initial caps or all caps. The authors and publisher have taken care in the preparation of this book, but make no expressed or implied warranty of any kind and assume no responsibility for errors or omissions. No liability is assumed for incidental or consequential damages in connection with or arising out of the use of the information or programs contained herein.

Ice Overview

The following topics provide a high-level overview of Ice:

- [Ice Architecture](#) introduces fundamental concepts and terminology, and outlines how Slice definitions, language mappings, and the Ice run time and protocol work in concert to create clients and servers.
- [Ice Services Overview](#) briefly presents the object services provided by Ice.
- [Architectural Benefits of Ice](#) outlines the benefits that result from the Ice architecture.

Topics

- [Ice Architecture](#)
- [Ice Services Overview](#)
- [Architectural Benefits of Ice](#)

Ice Architecture

Ice is an object-oriented middleware platform. Fundamentally, this means that Ice provides tools, APIs, and library support for building object-oriented client-server applications. Ice applications are suitable for use in heterogeneous environments: client and server can be written in different programming languages, can run on different operating systems and machine architectures, and can communicate using a variety of networking technologies. The source code for these applications is portable regardless of the deployment environment.

Topics:

- [Terminology](#)
- [Slice \(Specification Language for Ice\)](#)
- [Overview of the Language Mappings](#)
- [Client and Server Structure](#)
- [Overview of the Ice Protocol](#)

Terminology

Every computing technology creates its own vocabulary as it evolves. Ice is no exception. However, the amount of new jargon used by Ice is minimal. Rather than inventing new terms, we have used existing terminology as much as possible. If you have used another middleware technology in the past, you will be familiar with much of what follows. (However, we suggest you at least skim the material because a few terms used by Ice *do* differ from the corresponding terms used by other middleware.)

Clients and Servers

The terms *client* and *server* are not firm designations for particular parts of an application; rather, they denote roles that are taken by parts of an application for the duration of a request:

- Clients are active entities. They issue requests for service to servers.
- Servers are passive entities. They provide services in response to client requests.

Frequently, servers are not "pure" servers, in the sense that they never issue requests and only respond to requests. Instead, servers often act as a server on behalf of some client but, in turn, act as a client to another server in order to satisfy their client's request.

Similarly, clients often are not "pure" clients, in the sense that they only request service from an object. Instead, clients are frequently client-server hybrids. For example, a client might start a long-running operation on a server; as part of starting the operation, the client can provide a *callback object* to the server that is used by the server to notify the client when the operation is complete. In that case, the client acts as a client when it starts the operation, and as a server when it is notified that the operation is complete.

Such role reversal is common in many systems, so, frequently, client-server systems could be more accurately described as *peer-to-peer* systems.

Ice Objects

An *Ice object* is a conceptual entity, or abstraction. An Ice object can be characterized by the following points:

- An Ice object is an entity in the local or a remote address space that can respond to client requests.
- A single Ice object can be instantiated in a single server or, redundantly, in multiple servers. If an object has multiple simultaneous instantiations, it is still a single Ice object.
- Each Ice object has one or more *interfaces*. An interface is a collection of named *operations* that are supported by an object. Clients issue requests by invoking operations.
- An operation has zero or more *parameters* as well as a *return value*. Parameters and return values have a specific *type*. Parameters are named and have a direction: in-parameters are initialized by the client and passed to the server; out-parameters are initialized by the server and passed to the client. (The return value is simply a special out-parameter.)
- An Ice object has a distinguished interface, known as its *main interface*. In addition, an Ice object can provide zero or more alternate interfaces, known as *facets*. Clients can select among the facets of an object to choose the interface they want to work with.

- Each Ice object has a unique *object identity*. An object's identity is an identifying value that distinguishes the object from all other objects. The Ice object model assumes that object identities are globally unique, that is, no two objects within an Ice communication domain can have the same object identity.

In practice, you need not use object identities that are globally unique, such as [UUIDs](#), only identities that do not clash with any other identity within your domain of interest. However, there are architectural advantages to using globally unique identifiers, which we explore in our discussion of [object life cycle](#).

Proxies

For a client to be able to contact an Ice object, the client must hold a *proxy* for the Ice object. A *proxy* is an artifact that is local to the client's address space; it represents the (possibly remote) Ice object for the client. A proxy acts as the local ambassador for an Ice object: when the client invokes an operation on the proxy, the Ice run time:

1. Locates the Ice object
2. Activates the Ice object's server if it is not running
3. Activates the Ice object within the server
4. Transmits any in-parameters to the Ice object
5. Waits for the operation to complete
6. Returns any out-parameters and the return value to the client (or throws an exception in case of an error)

A proxy encapsulates all the necessary information for this sequence of steps to take place. In particular, a proxy contains:

- Addressing information that allows the client-side run time to contact the correct server
- An object identity that identifies which particular object in the server is the target of a request
- An optional facet identifier that determines which particular facet of an object the proxy refers to

Stringified Proxies

The information in a proxy can be expressed as a string. For example, the string:

```
SimplePrinter:default -p 10000
```

is a human-readable representation of a proxy. The Ice run time provides API calls that allow you to convert a proxy to its stringified form and vice versa. This is useful, for example, to store proxies in database tables or text files.

Provided that a client knows the identity of an Ice object and its addressing information, it can create a proxy "out of thin air" by supplying that information. In other words, no part of the information inside a proxy is considered opaque; a client needs to know only an object's identity, addressing information, and (to be able to invoke an operation) the object's type in order to contact the object.

Direct Proxies

A *direct proxy* is a proxy that embeds an object's identity, together with the address at which its server runs. The address is completely specified by:

- a protocol identifier (such TCP/IP or UDP)
- a protocol-specific address (such as a host name and port number)

To contact the object denoted by a direct proxy, the Ice run time uses the addressing information in the proxy to contact the server; the identity of the object is sent to the server with each request made by the client.

Indirect Proxies

An *indirect proxy* has two forms. It may provide only an object's identity, or it may specify an identity together with an object adapter identifier. An object that is accessible using only its identity is called a well-known object, and the corresponding proxy is a [well-known proxy](#). For example, the string:

```
SimplePrinter
```

is a valid proxy for a well-known object with the identity `SimplePrinter`.

An indirect proxy that includes an object adapter identifier has the stringified form

```
SimplePrinter@PrinterAdapter
```

Any object of the object adapter can be accessed using such a proxy, regardless of whether that object is also a well-known object.

Notice that an indirect proxy contains no addressing information. To determine the correct server, the client-side run time passes the proxy information to a [location service](#). In turn, the location service uses the object identity or the object adapter identifier as the key in a lookup table that contains the address of the server and returns the current server address to the client. The client-side run time now knows how to contact the server and dispatches the client request as usual.

The entire process is similar to the mapping from Internet domain names to IP address by the Domain Name Service (DNS): when we use a domain name, such as `www.zeroc.com`, to look up a web page, the host name is first resolved to an IP address behind the scenes and, once the correct IP address is known, the IP address is used to connect to the server. With Ice, the mapping is from an object identity or object adapter identifier to a protocol-address pair, but otherwise very similar. The client-side run time knows how to contact the location service via configuration (just as web browsers know which DNS server to use via configuration).

Direct Versus Indirect Binding

The process of resolving the information in a proxy to protocol-address pair is known as *binding*. Not surprisingly, *direct binding* is used for direct proxies, and *indirect binding* is used for indirect proxies.

The main advantage of indirect binding is that it allows us to move servers around (that is, change their address) without invalidating existing proxies that are held by clients. In other words, direct proxies avoid the extra lookup to locate the server but no longer work if a server is moved to a different machine. On the other hand, indirect proxies continue to work even if we move (or *migrate*) a server.

Fixed Proxies

A *fixed proxy* is a proxy that is bound to a particular connection: instead of containing addressing information or an adapter name, the proxy contains a connection handle. The connection handle stays valid only for as long as the connection stays open so, once the connection is closed, the proxy no longer works (and will never work again). Fixed proxies cannot be marshaled, that is, they cannot be passed as parameters on operation invocations. Fixed proxies are used to allow [bidirectional communication](#), so a server can make callbacks to a client without having to open a new connection.

Routed Proxies

A *routed proxy* is a proxy that forwards all invocations to a specific target object, instead of sending invocations directly to the actual target. Routed proxies are useful for implementing services such as [Glacier2](#), which enables clients to communicate with servers that are behind a firewall.

Replication

In Ice, *replication* involves making object adapters (and their objects) available at multiple addresses. The goal of replication is usually to provide redundancy by running the same server on several computers. If one of the computers should happen to fail, a server still remains available on the others.

The use of replication implies that applications are designed for it. In particular, it means a client can access an object via one address and obtain the same result as from any other address. Either these objects are stateless, or their implementations are designed to synchronize with a database (or each other) in order to maintain a consistent view of each object's state.

Ice supports a limited form of replication when a proxy specifies multiple addresses for an object. The Ice run time selects one of the addresses at random for its [initial connection attempt](#) and tries all of them in the case of a failure. For example, consider this proxy:

```
SimplePrinter:tcp -h server1 -p 10001:tcp -h server2 -p 10002
```

The proxy states that the object with identity `SimplePrinter` is available using TCP at two addresses, one on the host `server1` and another on the host `server2`. The burden falls to users or system administrators to ensure that the servers are actually running on these computers at the specified ports.

Replica Groups

In addition to the proxy-based replication described above, Ice supports a more useful form of replication known as *replica groups* that requires the use of a [location service](#).

A replica group has a unique identifier and consists of any number of object adapters. An object adapter may be a member of at most one replica group; such an adapter is considered to be a *replicated object adapter*.

After a replica group has been established, its identifier can be used in an indirect proxy in place of an adapter identifier. For example, a replica group identified as `PrinterAdapters` can be used in a proxy as shown below:

```
SimplePrinter@PrinterAdapters
```

The replica group is treated by the location service as a "virtual object adapter." The behavior of the location service when resolving an indirect proxy containing a replica group id is an implementation detail. For example, the location service could decide to return the addresses of all object adapters in the group, in which case the client's Ice run time would select one of the addresses at random using the limited form of replication discussed earlier. Another possibility is for the location service to return only one address, which it decided upon using some heuristic.

Regardless of the way in which a location service resolves a replica group, the key benefit is indirection: the location service as a middleman can add more intelligence to the binding process.

Servants

As we mentioned, an [Ice Object](#) is a conceptual entity that has a type, identity, and addressing information. However, client requests ultimately must end up with a concrete server-side processing entity that can provide the behavior for an operation invocation. To put this differently, a client request must ultimately end up executing code inside the server, with that code written in a specific programming language and executing on a specific processor.

The server-side artifact that provides behavior for operation invocations is known as a *servant*. A servant provides substance for (or *incarnates*) one or more Ice objects. In practice, a servant is simply an instance of a class that is written by the server developer and that is registered with the server-side run time as the servant for one or more Ice objects. Methods on the class correspond to the operations on the Ice object's interface and provide the behavior for the operations.

A single servant can incarnate a single Ice object at a time or several Ice objects simultaneously. If the former, the identity of the Ice object incarnated by the servant is implicit in the servant. If the latter, the servant is provided the identity of the Ice object with each request, so it can decide which object to incarnate for the duration of the request.

Conversely, a single Ice object can have multiple servants. For example, we might choose to create a proxy for an Ice object with two different addresses for different machines. In that case, we will have two servers, with each server containing a servant for the same Ice object. When a client invokes an operation on such an Ice object, the client-side run time sends the request to exactly one server. In other words, multiple servants for a single Ice object allow you to build redundant systems: the client-side run time attempts to send the request to one server and, if that attempt fails, sends the request to the second server. An error is reported back to the client-side application code only if that second attempt also fails.

At-Most-Once Semantics

Ice requests have *at-most-once* semantics: the Ice run time does its best to deliver a request to the correct destination and, depending on the exact circumstances, may retry a failed request. Ice guarantees that it will either deliver the request, or, if it cannot deliver the request, inform the client with an appropriate exception; under no circumstances is a request delivered twice, that is, retries are attempted only if it is known that a previous attempt definitely failed.

One exception to this rule are datagram invocations over UDP transports. For these, duplicated UDP packets can lead to a violation of at-most-once semantics.

At-most-once semantics are important because they guarantee that operations that are not *idempotent* can be used safely. An idempotent

operation is an operation that, if executed twice, has the same effect as if executed once. For example, `x = 1`; is an idempotent operation: if we execute the operation twice, the end result is the same as if we had executed it once. On the other hand, `x++`; is not idempotent: if we execute the operation twice, the end result is not the same as if we had executed it once.

Without at-most-once semantics, we can build distributed systems that are more robust in the presence of network failures. However, realistic systems require non-idempotent operations, so at-most-once semantics are a necessity, even though they make the system less robust in the presence of network failures. Ice permits you to mark individual operations as idempotent. For such operations, the Ice run time uses a more aggressive error recovery mechanism than for non-idempotent operations.

Synchronous Method Invocation

By default, the request dispatch model used by Ice is a synchronous remote procedure call: an operation invocation behaves like a local procedure call, that is, the client thread is suspended for the duration of the call and resumes when the call completes (and all its results are available).

Asynchronous Method Invocation

Ice also supports *asynchronous method invocation* (AMI): a client can invoke operations *asynchronously*, which means the client's calling thread does not block while waiting for the invocation to complete. The client passes the normal parameters and, depending on the language mapping, might also pass a callback that the client-side run time invokes upon completion, or the invocation might return a future that the client can eventually use to obtain the results.

The server cannot distinguish an asynchronous invocation from a synchronous one — either way, the server simply sees that a client has invoked an operation on an object.

Asynchronous Method Dispatch

Asynchronous method dispatch (AMD) is the server-side equivalent of AMI. For synchronous dispatch (the default), the server-side run time up-calls into the application code in the server in response to an operation invocation. While the operation is executing (or sleeping, for example, because it is waiting for data), a thread of execution is tied up in the server; that thread is released only when the operation completes.

With asynchronous method dispatch, the server-side application code is informed of the arrival of an operation invocation. However, instead of being forced to process the request immediately, the server-side application can choose to delay processing of the request and, in doing so, releases the execution thread for the request. The server-side application code is now free to do whatever it likes. Eventually, once the results of the operation are available, the server-side application code makes an API call to inform the server-side Ice run time that a request that was dispatched previously is now complete; at that point, the results of the operation are returned to the client.

Asynchronous method dispatch is useful if, for example, a server offers operations that block clients for an extended period of time. For example, the server may have an object with a `get` operation that returns data from an external, asynchronous data source and that blocks clients until the data becomes available. With synchronous dispatch, each client waiting for data to arrive ties up an execution thread in the server. Clearly, this approach does not scale beyond a few dozen clients. With asynchronous dispatch, hundreds or thousands of clients can be blocked in the same operation invocation without tying up any threads in the server.

Synchronous and asynchronous method dispatch are transparent to the client, that is, the client cannot tell whether a server chose to process a request synchronously or asynchronously.

Oneway Method Invocation

Clients can invoke an operation as a *oneway* operation. A oneway invocation has "best effort" semantics. For a oneway invocation, the client-side run time hands the invocation to the local transport, and the invocation completes on the client side as soon as the local transport has buffered the invocation. The actual invocation is then sent asynchronously by the operating system. The server does not reply to oneway invocations, that is, traffic flows only from client to server, but not vice versa.

Oneway invocations are unreliable. For example, the target object may not exist, in which case the invocation is simply lost. Similarly, the operation may be dispatched to a servant in the server, but the operation may fail (for example, because parameter values are invalid); if so, the client receives no notification that something has gone wrong.

Oneway invocations are possible only on [operations](#) that do not have a return value, do not have out-parameters, and do not throw user exceptions.

To the application code on the server-side, oneway invocations are transparent, that is, there is no way to distinguish a twoway invocation from a oneway invocation.

Oneway invocations are available only if the target object offers a stream-oriented transport, such as TCP/IP or SSL.

Note that, even though oneway operations are sent over a stream-oriented transport, they may be processed out of order in the server. This can happen because each invocation may be dispatched in its own thread: even though the invocations are *initiated* in the order in which the invocations arrive at the server, this does not mean that they will be *processed* in that order — the vagaries of thread scheduling can result in a oneway invocation completing before other oneway invocations that were received earlier.

Batched Oneway Method Invocation

Each oneway invocation sends a separate message to the server. For a series of short messages, the overhead of doing so is considerable: the client- and server-side run time each must switch between user mode and kernel mode for each message and, at the networking level, each message incurs the overheads of flow-control and acknowledgement.

Batched oneway invocations allow you to send a series of oneway invocations as a single message: every time you invoke a batched oneway operation, the invocation is buffered in the client-side run time. Once you have accumulated all the oneway invocations you want to send, you make a separate API call to send all the invocations at once. The client-side run time then sends all of the buffered invocations in a single message, and the server receives all of the invocations in a single message. This avoids the overhead of repeatedly trapping into the kernel for both client and server, and is much easier on the network between them because one large message can be transmitted more efficiently than many small ones.

The individual invocations in a batched oneway message are dispatched by a single thread in the order in which they were placed into the batch. This guarantees that the individual operations in a batched oneway message are processed in order in the server.

Batched oneway invocations are particularly useful for messaging services, such as `IceStorm`, and for fine-grained interfaces that offer `set` operations for small attributes.

Datagram Invocations

Datagram invocations have "best effort" semantics similar to oneway invocations. However, datagram invocations require the object to offer UDP as a transport (whereas oneway invocations require TCP/IP).

Like a oneway invocation, a datagram invocation can be made only if the operation does not have a return value, out-parameters, or user exceptions. A datagram invocation uses UDP to invoke the operation. The operation returns as soon as the local UDP stack has accepted the message; the actual operation invocation is sent asynchronously by the network stack behind the scenes.

Datagrams, like oneway invocations, are unreliable: the target object may not exist in the server, the server may not be running, or the operation may be invoked in the server but fail due to invalid parameters sent by the client. As for oneway invocations, the client receives no notification of such errors.

However, unlike oneway invocations, datagram invocations have a number of additional error scenarios:

- Individual invocations may simply be lost in the network. This is due to the unreliable delivery of UDP packets. For example, if you invoke three operations in sequence, the middle invocation may be lost. (The same thing cannot happen for oneway invocations — because they are delivered over a connection-oriented transport, individual invocations cannot be lost.)
- Individual invocations may arrive out of order. Again, this is due to the nature of UDP datagrams. Because each invocation is sent as a separate datagram, and individual datagrams can take different paths through the network, it can happen that invocations arrive in an order that differs from the order in which they were sent.

Datagram invocations are well suited for small messages on LANs, where the likelihood of loss is small. They are also suited to situations in which low latency is more important than reliability, such as for fast, interactive internet applications. Finally, datagram invocations can be used to multicast messages to multiple servers simultaneously.

Batched Datagram Invocations

As for batched oneway invocations, *batched datagram invocations* allow you to accumulate a number of invocations in a buffer and then send the entire buffer as a single datagram by making an API call to flush the buffer. Batched datagrams reduce the overhead of repeated system calls and allow the underlying network to operate more efficiently. However, batched datagram invocations are useful only for batched messages whose total size does not substantially exceed the PDU limit of the network: if the size of a batched datagram gets too large, UDP fragmentation makes it more likely that one or more fragments are lost, which results in the loss of the entire batched message. However, you are guaranteed that either all invocations in a batch will be delivered, or none will be delivered. It is impossible for individual invocations within a batch to be lost.

Batched datagrams use a single thread in the server to dispatch the individual invocations in a batch. This guarantees that the invocations

are made in the order in which they were queued — invocations cannot appear to be reordered in the server.

Run-Time Exceptions

Any operation invocation can raise a *run-time exception*. Run-time exceptions are pre-defined by the Ice run time and cover common error conditions, such as connection failure, connection timeout, or resource allocation failure. Run-time exceptions are presented to the application as native exceptions and so integrate neatly with the native exception handling capabilities of languages that support exception handling.

User Exceptions

A server indicates application-specific error conditions by raising *user exceptions* to clients. User exceptions can carry an arbitrary amount of complex data and can be arranged into inheritance hierarchies, which makes it easy for clients to handle categories of errors generically, by catching an exception that is further up the inheritance hierarchy. Like run-time exceptions, user exceptions map to native exceptions.

Properties

Much of the Ice run time is configurable via *properties*. Properties are name-value pairs, such as `Ice.Default.Protocol=tcp`. Properties are typically stored in text files and parsed by the Ice run time to configure various options, such as the thread pool size, the level of tracing, and various other configuration parameters.

Slice (Specification Language for Ice)

Each [Ice object](#) has an interface with a number of operations. Interfaces, operations, and the types of data that are exchanged between client and server are defined using the *Slice language*. Slice allows you to define the client-server contract in a way that is independent of a specific programming language, such as C++, Java, or C#. The Slice definitions are compiled by a compiler into an API for a specific programming language, that is, the part of the API that is specific to the interfaces and types you have defined consists of generated code.

See Also

- [The Slice Language](#)

Overview of the Language Mappings

The rules that govern how each Slice construct is translated into a specific programming language are known as *language mappings*. For example, for the [C++ mapping](#), a Slice sequence appears as a `std::vector`, whereas, for the [Java mapping](#), a Slice sequence appears as a Java array. In order to determine what the API for a specific Slice construct looks like, you only need the Slice definition and knowledge of the language mapping rules. The rules are simple and regular enough to make it unnecessary to read the generated code to work out how to use the generated API.

Of course, you are free to peruse the generated code. However, as a rule, that is inefficient because the generated code is not necessarily suitable for human consumption. We recommend that you familiarize yourself with the language mapping rules; that way, you can mostly ignore the generated code and need to refer to it only when you are interested in some specific detail.

Currently, Ice provides language mappings for C++, C#, Java, JavaScript, Python, Objective-C, and, for the client side, PHP and Ruby.

Client and Server Structure

Ice clients and servers have the logical internal structure:

Ice Client and Server Structure

Both client and server consist of a mixture of application code, library code, and code generated from Slice definitions:

- The Ice core contains the client- and server-side run-time support for remote communication. Much of this code is concerned with the details of networking, threading, byte ordering, and many other networking-related issues that we want to keep away from application code. The Ice core is provided as a number of libraries that client and server use.
- The generic part of the Ice core (that is, the part that is independent of the specific types you have defined in Slice) is accessed through the Ice API. You use the Ice API to take care of administrative chores, such as initializing and finalizing the Ice run time. The Ice API is identical for clients and servers (although servers use a larger part of the API than clients).
- The proxy code is generated from your Slice definitions and, therefore, specific to the types of objects and data you have defined in Slice. The proxy code has two major functions:
 - It provides a down-call interface for the client. Calling a function in the generated proxy API ultimately ends up sending an RPC message to the server that invokes a corresponding function on the target object.
 - It provides *marshaling* and *unmarshaling* code. Marshaling is the process of serializing a complex data structure, such as a sequence or a dictionary, for transmission on the wire. The marshaling code converts data into a form that is standardized for transmission and independent of the endian-ness and padding rules of the local machine. Unmarshaling is the reverse of marshaling, that is, deserializing data that arrives over the network and reconstructing a local representation of the data in types that are appropriate for the programming language in use.
- The skeleton code is also generated from your Slice definition and, therefore, specific to the types of objects and data you have defined in Slice. The skeleton code is the server-side equivalent of the client-side proxy code: it provides an up-call interface that permits the Ice run time to transfer the thread of control to the application code you write. The skeleton also contains marshaling and unmarshaling code, so the server can receive parameters sent by the client, and return parameters and exceptions to the client.
- The object adapter is a part of the Ice API that is specific to the server side: only servers use object adapters. An object adapter has several functions:
 - The object adapter maps incoming requests from clients to specific methods on programming-language objects. In other words, the object adapter tracks which servants with what object identity are in memory.
 - The object adapter is associated with one or more transport endpoints. If more than one transport endpoint is associated with an adapter, the servants incarnating objects within the adapter can be reached via multiple transports. For example, you can associate both a TCP/IP and a UDP endpoint with an adapter, to provide alternate quality-of-service and performance characteristics.
 - The object adapter is responsible for the creation of proxies that can be passed to clients. The object adapter knows about

the type, identity, and transport details of each of its objects and embeds the correct details when the server-side application code requests the creation of a proxy.

Note that, as far as the process view is concerned, there are only two processes involved: the client and the server. All the run time support for distributed communication is provided by the Ice libraries and the code that is generated from Slice definitions. (For indirect proxies, a [location service](#) is required to resolve proxies to transport endpoints.)

Overview of the Ice Protocol

Ice provides an [RPC protocol](#) that can use either TCP/IP or UDP as an underlying transport. In addition, Ice also allows you to use [SSL](#) as a transport, so all communication between client and server is encrypted.

The Ice protocol defines:

- a number of message types, such as request and reply message types,
- a protocol state machine that determines in what sequence different message types are exchanged by client and server, together with the associated connection establishment and tear-down semantics for TCP/IP,
- encoding rules that determine how each type of data is represented on the wire,
- a header for each message type that contains details such as the message type, the message size, and the protocol and encoding version in use.

Ice also supports compression on the wire: by setting a configuration parameter, you can arrange for all network traffic to be compressed to conserve bandwidth. This is useful if your application exchanges large amounts of data between client and server.

The Ice protocol is suitable for building highly-efficient event forwarding mechanisms because it permits forwarding of a message without knowledge of the details of the information inside a message. This means that messaging switches need not do any unmarshaling and remarshaling of messages — they can forward a message by simply treating it as an opaque buffer of bytes.

The Ice protocol also supports [bidirectional operation](#): if a server wants to send a message to a callback object provided by the client, the callback can be made over the connection that was originally created by the client. This feature is especially important when the client is behind a firewall that permits outgoing connections, but not incoming connections.

Ice Services Overview

The Ice core provides a sophisticated client-server platform for distributed application development. However, realistic applications usually require more than just a remoting capability: typically, you also need a way to start servers on demand, distribute proxies to clients, distribute asynchronous events, configure your application, distribute patches for an application, and so on.

Ice ships with a number of services that provide these and other features. The services are implemented as Ice servers to which your application acts as a client. None of the services use Ice-internal features that are hidden from application developers so, in theory, you could develop equivalent services yourself. However, having these services available as part of the platform allows you to focus on application development instead of having to build a lot of infrastructure first. Moreover, building such services is not a trivial effort, so it pays to know what is available and use it instead of reinventing your own wheel.

- [IceGrid Service](#)
- [IceBox Server](#)
- [IceStorm](#)
- [IcePatch2](#)
- [Glacier2](#)

Freeze and FreezeScript

Ice has a built-in object persistence service, known as *Freeze*. Freeze makes it easy to store object state in a database: you define the state stored by your objects in Slice, and the Freeze compiler generates code that stores and retrieves object state to and from a database. Freeze uses [Berkeley DB](#) as its database.

Ice also offers a tool set collectively called [FreezeScript](#) that makes it easier to maintain databases and to migrate the contents of existing databases to a new schema if the type definitions of objects change.

IceGrid Service

[IceGrid](#) is an implementation of an Ice [location service](#) that resolves the symbolic information in an indirect proxy to a protocol-address pair for indirect binding. A location service is only the beginning of IceGrid's capabilities.

IceGrid:

- allows you to register servers for automatic start-up: instead of requiring a server to be running at the time a client issues a request, IceGrid starts servers on demand, when the first client request arrives.
- provides tools that make it easy to configure complex applications containing several servers.
- supports replication and load-balancing.
- automates the distribution and patching of server executables and dependent files.
- provides a simple query service that allows clients to obtain proxies for objects they are interested in.

IceBox Server

[IceBox](#) is a simple application server that can orchestrate the starting and stopping of a number of application components. Application components can be deployed as a dynamic library instead of as a process. This reduces overall system load, for example, by allowing you to run several application components in a single Java virtual machine instead of having multiple processes, each with its own virtual machine.

IceStorm

[IceStorm](#) is a publish-subscribe service that decouples clients and servers. Fundamentally, IceStorm acts as a distribution switch for events. Publishers send events to the service, which, in turn, passes the events to subscribers. In this way, a single event published by a publisher can be sent to multiple subscribers. Events are categorized by topic, and subscribers specify the topics they are interested in. Only events that match a subscriber's topic are sent to that subscriber. The service permits selection of a number of quality-of-service criteria to allow applications to choose the appropriate trade-off between reliability and performance.

IceStorm is particularly useful if you have a need to distribute information to large numbers of application components. (A typical example is a stock ticker application with a large number of subscribers.) IceStorm decouples the publishers of information from subscribers and takes care of the redistribution of the published events. In addition, IceStorm can be run as a *federated* service, that is, multiple instances of the service can be run on different machines to spread the processing load over a number of CPUs.

IcePatch2

[IcePatch2](#) is a software patching service. It allows you to easily distribute software updates to clients. Clients simply connect to the IcePatch2 server and request updates for a particular application. The service automatically checks the version of the client's software and downloads any updated application components in a compressed format to conserve bandwidth. Software patches can be secured using the Glacier2 service, so only authorized clients can download software updates.

IcePatch2 supersedes IcePatch, which was a previous version of this service.

Glacier2

[Glacier2](#) is the Ice firewall traversal service: it allows clients and servers to securely communicate through a firewall without compromising security. Client-server traffic is SSL-encrypted using public key certificates and is bidirectional. Glacier2 offers support for mutual authentication as well as secure session management.

Glacier2 supersedes Glacier, which was a previous version of this service

Architectural Benefits of Ice

The Ice architecture provides a number of benefits to application developers:

- **Object-oriented semantics**
Ice fully preserves the object-oriented paradigm "across the wire." All operation invocations use late binding, so the implementation of an operation is chosen depending on the actual run-time (not static) type of an object.
- **Support for synchronous and asynchronous messaging**
Ice provides both synchronous and asynchronous operation invocation and dispatch, as well as publish-subscribe messaging via IceStorm. This allows you to choose a communication model according to the needs of your application instead of having to shoe-horn the application to fit a single model.
- **Support for multiple interfaces**
With facets, objects can provide multiple, unrelated interfaces while retaining a single object identity across these interfaces. This provides great flexibility, particularly as an application evolves but needs to remain compatible with older, already deployed clients.
- **Machine independence**
Clients and servers are shielded from idiosyncrasies of the underlying machine architecture. Issues such as byte ordering and padding are hidden from application code.
- **Language independence**
Client and server can be developed independently and in different programming languages. The Slice definition used by both client and server establishes the interface contract between them and is the only thing they need to agree on.
- **Implementation independence**
Clients are unaware of how servers implement their objects. This means that the implementation of a server can be changed after clients are deployed, for example, to use a different persistence mechanism or even a different programming language.
- **Operating system independence**
The Ice APIs are fully portable, so the same source code compiles and runs under both Windows and Unix.
- **Threading support**
The Ice run time is fully threaded and APIs are thread-safe. No effort (beyond synchronizing access to shared data) is required on part of the application developer to develop threaded, high-performance clients and servers.
- **Transport independence**
Ice currently offers both TCP/IP and UDP as transport protocols. Neither client nor server code are aware of the underlying transport. (The desired transport can be chosen by a configuration parameter.)
- **Location and server transparency**
The Ice run time takes care of locating objects and managing the underlying transport mechanism, such as opening and closing connections. Interactions between client and server appear connection-less. Via IceGrid, you can arrange for servers to be started on demand if they are not running at the time a client invokes an operation. Servers can be migrated to different physical addresses without breaking proxies held by clients, and clients are completely unaware how object implementations are distributed over server processes.
- **Security**
Communications between client and server can be fully secured with strong encryption over SSL, so applications can use unsecured public networks to communicate securely. Via Glacier2, you can implement secure forwarding of requests through a firewall, with full support for callbacks.
- **Built-in persistence**
With Freeze, creating persistent object implementations becomes trivial. Ice comes with built-in support for [Berkeley DB](#), which is a high-performance database.
- **Source code availability**
The source code for Ice is available. While it is not necessary to have access to the source code to use the platform, it allows you to see how things are implemented or port the code to a new operating system.

Overall, Ice provides a state-of-the art development and deployment environment for distributed computing that is more complete than any other platform we are aware of.

Hello World Application

This section presents a very simple (but complete) client and server.

Writing an Ice application involves the following steps:

1. Write a Slice definition and compile it.
2. Write a server and compile it.
3. Write a client and compile it.

If someone else has written the server already and you are only writing a client, you do not need to write the Slice definition, only compile it (and, obviously, you do not need to write the server in that case).

The application described here enables remote printing: a client sends the text to be printed to a server, which in turn sends that text to a printer. For simplicity (and because we do not want to concern ourselves with the idiosyncrasies of print spoolers for various platforms), our printer will simply print to a terminal instead of a real printer. This is no great loss: the purpose of the exercise is to show how a client can communicate with a server; once the thread of control has reached the server application code, that code can of course do anything it likes (including sending the text to a real printer). How to do this is independent of Ice and therefore not relevant here.

Much of the detail of the source code will remain unexplained for now. The intent is to show you how to get started and give you a feel for what the development environment looks like; we will provide all the detail throughout the remainder of this manual.

Writing a Slice Definition

The first step in writing any Ice application is to write a [Slice](#) definition containing the interfaces that are used by the application. For our minimal printing application, we write the following Slice definition:

```

Slice

```
module Demo {
 interface Printer {
 void printString(string s);
 };
};
```

```

We save this text in a file called `Printer.ice`.

Our Slice definitions consist of the module `Demo` containing a single interface called `Printer`. For now, the interface is very simple and provides only a single operation, called `printString`. The `printString` operation accepts a string as its sole input parameter; the text of that string is what appears on the (possibly remote) printer.

Writing an Ice Application with C++

This page shows how to create an Ice application with C++.

On this page:

- [Compiling a Slice Definition for C++](#)
- [Writing and Compiling a Server in C++](#)
- [Writing and Compiling a Client in C++](#)
- [Running Client and Server in C++](#)

Compiling a Slice Definition for C++

The first step in creating our C++ application is to compile our [Slice definition](#) to generate C++ proxies and skeletons. You can compile the definition as follows:

```
$ slice2cpp Printer.ice
```

The `slice2cpp` compiler produces two C++ source files from this definition, `Printer.h` and `Printer.cpp`.

- `Printer.h`
The `Printer.h` header file contains C++ type definitions that correspond to the Slice definitions for our `Printer` interface. This header file must be included in both the client and the server source code.
- `Printer.cpp`
The `Printer.cpp` file contains the source code for our `Printer` interface. The generated source contains type-specific run-time support for both clients and servers. For example, it contains code that marshals parameter data (the string passed to the `printString` operation) on the client side and unmarshals that data on the server side. The `Printer.cpp` file must be compiled and linked into both client and server.

Writing and Compiling a Server in C++

The source code for the server takes only a few lines and is shown in full here:

C++

```

#include <Ice/Ice.h>
#include <Printer.h>

using namespace std;
using namespace Demo;

class PrinterI : public Printer {
public:
    virtual void printString(const string& s, const Ice::Current&);
};

void
PrinterI::
printString(const string& s, const Ice::Current&)
{
    cout << s << endl;
}

int
main(int argc, char* argv[])
{
    int status = 0;
    Ice::CommunicatorPtr ic;
    try {
        ic = Ice::initialize(argc, argv);
        Ice::ObjectAdapterPtr adapter =

ic->createObjectAdapterWithEndpoints("SimplePrinterAdapter", "default -
p 10000");
        Ice::ObjectPtr object = new PrinterI;
        adapter->add(object, ic->stringToIdentity("SimplePrinter"));
        adapter->activate();
        ic->waitForShutdown();
    } catch (const Ice::Exception& e) {
        cerr << e << endl;
        status = 1;
    } catch (const char* msg) {
        cerr << msg << endl;
        status = 1;
    }
    if (ic) {
        try {
            ic->destroy();
        } catch (const Ice::Exception& e) {
            cerr << e << endl;
            status = 1;
        }
    }
    return status;
}

```

There appears to be a lot of code here for something as simple as a server that just prints a string. Do not be concerned by this: most of the preceding code is boiler plate that never changes. For this very simple server, the code is dominated by this boiler plate.

Every Ice source file starts with an include directive for `Ice.h`, which contains the definitions for the Ice run time. We also include `Printer.h`, which was generated by the Slice compiler and contains the C++ definitions for our printer interface, and we import the contents of the `std` and `Demo` namespaces for brevity in the code that follows:

```

C++

#include <Ice/Ice.h>
#include <Printer.h>

using namespace std;
using namespace Demo;
```

Our server implements a single printer servant, of type `PrinterI`. Looking at the generated code in `Printer.h`, we find the following (tidied up a little to get rid of irrelevant detail):

```

C++

namespace Demo {
    class Printer : virtual public Ice::Object {
    public:
        virtual void printString(const std::string&, const Ice::Current&
= Ice::Current()) = 0;
    };
};
```

The `Printer` skeleton class definition is generated by the Slice compiler. (Note that the `printString` method is pure virtual so the skeleton class cannot be instantiated.) Our servant class inherits from the skeleton class to provide an implementation of the pure virtual `printString` method. (By convention, we use an `I`-suffix to indicate that the class implements an interface.)

```

C++

class PrinterI : public Printer {
public:
    virtual void printString(const string& s, const Ice::Current&);
};
```

The implementation of the `printString` method is trivial: it simply writes its string argument to `stdout`:

C++

```

void
PrinterI::
printString(const string& s, const Ice::Current&)
{
    cout << s << endl;
}

```

Note that `printString` has a second parameter of type `Ice::Current`. As you can see from the definition of `PrinterI::printString`, the Slice compiler generates a default argument for this parameter, so we can leave it unused in our implementation. (We will examine the purpose of the `Ice::Current` parameter later.)

What follows is the server main program. Note the general structure of the code:

C++

```

int
main(int argc, char* argv[])
{
    int status = 0;
    Ice::CommunicatorPtr ic;
    try {

        // Server implementation here...

    } catch (const Ice::Exception& e) {
        cerr << e << endl;
        status = 1;
    } catch (const char* msg) {
        cerr << msg << endl;
        status = 1;
    }
    if (ic) {
        try {
            ic->destroy();
        } catch (const Ice::Exception& e) {
            cerr << e << endl;
            status = 1;
        }
    }
    return status;
}

```

The body of `main` contains the declaration of two variables, `status` and `ic`. The `status` variable contains the exit status of the program and the `ic` variable, of type `Ice::CommunicatorPtr`, contains the main handle to the Ice run time.

Following these declarations is a `try` block in which we place all the server code, followed by two `catch` handlers. The first handler catches all exceptions that may be thrown by the Ice run time; the intent is that, if the code encounters an unexpected Ice run-time exception anywhere, the stack is unwound all the way back to `main`, which prints the exception and then returns failure to the operating system. The second handler catches string constants; the intent is that, if we encounter a fatal error condition somewhere in our code, we can simply

throw a string literal with an error message. Again, this unwinds the stack all the way back to `main`, which prints the error message and then returns failure to the operating system.

Following the `try` block, we see a bit of cleanup code that calls the `destroy` method on the communicator (provided that the communicator was initialized). The cleanup call is outside the first `try` block for a reason: we must ensure that the Ice run time is finalized whether the code terminates normally or terminates due to an exception.

Failure to call `destroy` on the communicator before the program exits results in undefined behavior.

The body of the first `try` block contains the actual server code:

C++

```

    ic = Ice::initialize(argc, argv);
    Ice::ObjectAdapterPtr adapter =

ic->createObjectAdapterWithEndpoints("SimplePrinterAdapter", "default -
p 10000");
    Ice::ObjectPtr object = new PrinterI;
    adapter->add(object, ic->stringToIdentity("SimplePrinter"));
    adapter->activate();
    ic->waitForShutdown();

```

The code goes through the following steps:

1. We initialize the Ice run time by calling `Ice::initialize`. (We pass `argc` and `argv` to this call because the server may have command-line arguments that are of interest to the run time; for this example, the server does not require any command-line arguments.) The call to `initialize` returns a smart pointer to an `Ice::Communicator` object, which is the main object in the Ice run time.
2. We create an object adapter by calling `createObjectAdapterWithEndpoints` on the `Communicator` instance. The arguments we pass are `"SimplePrinterAdapter"` (which is the name of the adapter) and `"default -p 10000"`, which instructs the adapter to listen for incoming requests using the default protocol (TCP/IP) at port number 10000.
3. At this point, the server-side run time is initialized and we create a servant for our `Printer` interface by instantiating a `PrinterI` object.
4. We inform the object adapter of the presence of a new servant by calling `add` on the adapter; the arguments to `add` are the servant we have just instantiated, plus an identifier. In this case, the string `"SimplePrinter"` is the name of the Ice object. (If we had multiple printers, each would have a different name or, more correctly, a different *object identity*.)
5. Next, we activate the adapter by calling its `activate` method. (The adapter is initially created in a holding state; this is useful if we have many servants that share the same adapter and do not want requests to be processed until after all the servants have been instantiated.) The server starts to process incoming requests from clients as soon as the adapter is activated.
6. Finally, we call `waitForShutdown`. This call suspends the calling thread until the server implementation terminates, either by making a call to shut down the run time, or in response to a signal. (For now, we will simply interrupt the server on the command line when we no longer need it.)

Note that, even though there is quite a bit of code here, that code is essentially the same for all servers. You can put that code into a helper class and, thereafter, will not have to bother with it again. (Ice provides such a helper class, called `Ice::Application`.) As far as actual application code is concerned, the server contains only a few lines: six lines for the definition of the `PrinterI` class, plus three lines to instantiate a `PrinterI` object and register it with the object adapter.

Assuming that we have the server code in a file called `Server.cpp`, we can compile it as follows:

```
$ g++ -I. -c Printer.cpp Server.cpp
```

This compiles both our application code and the code that was generated by the Slice compiler. Depending on your platform, you may have to add additional include directives or other options to the compiler; please see the demo programs that ship with Ice for the details.

Finally, we need to link the server into an executable:

```
$ c++ -o server Printer.o Server.o -lIce -lIceUtil
```

Again, depending on the platform, the actual list of libraries you need to link against may be longer. The demo programs that ship with Ice contain all the detail. The important point to note here is that the Ice run time is shipped in two libraries, `libIce` and `libIceUtil`.

Writing and Compiling a Client in C++

The client code looks very similar to the server. Here it is in full:

```
C++
```

```
#include <Ice/Ice.h>
#include <Printer.h>

using namespace std;
using namespace Demo;

int
main(int argc, char* argv[])
{
    int status = 0;
    Ice::CommunicatorPtr ic;
    try {
        ic = Ice::initialize(argc, argv);
        Ice::ObjectPrx base = ic->stringToProxy("SimplePrinter:default
-p 10000");
        PrinterPrx printer = PrinterPrx::checkedCast(base);
        if (!printer)
            throw "Invalid proxy";

        printer->printString("Hello World!");
    } catch (const Ice::Exception& ex) {
        cerr << ex << endl;
        status = 1;
    } catch (const char* msg) {
        cerr << msg << endl;
        status = 1;
    }
    if (ic)
        ic->destroy();
    return status;
}
```

Note that the overall code layout is the same as for the server: we include the headers for the Ice run time and the header generated by the Slice compiler, and we use the same `try` block and `catch` handlers to deal with errors.

The code in the `try` block does the following:

1. As for the server, we initialize the Ice run time by calling `Ice::initialize`.
2. The next step is to obtain a proxy for the remote printer. We create a proxy by calling `stringToProxy` on the communicator, with

the string `"SimplePrinter:default -p 10000"`. Note that the string contains the object identity and the port number that were used by the server. (Obviously, hard-coding object identities and port numbers into our applications is a bad idea, but it will do for now; we will see more architecturally sound ways of doing this when we discuss [IceGrid](#).)

3. The proxy returned by `stringToProxy` is of type `Ice::ObjectPrx`, which is at the root of the inheritance tree for interfaces and classes. But to actually talk to our printer, we need a proxy for a `Printer` interface, not an `Object` interface. To do this, we need to do a down-cast by calling `PrinterPrx::checkedCast`. A checked cast sends a message to the server, effectively asking "is this a proxy for a `Printer` interface?" If so, the call returns a proxy to a `Printer`; otherwise, if the proxy denotes an interface of some other type, the call returns a null proxy.
4. We test that the down-cast succeeded and, if not, throw an error message that terminates the client.
5. We now have a live proxy in our address space and can call the `printString` method, passing it the time-honored "Hello World!" string. The server prints that string on its terminal.

Compiling and linking the client looks much the same as for the server:

```
$ g++ -I. -I$ICE_HOME/include -c Printer.cpp Client.cpp
$ g++ -o client Printer.o Client.o -lIce -lIceUtil
```

Running Client and Server in C++

To run client and server, we first start the server in a separate window:

```
$ ./server
```

At this point, we won't see anything because the server simply waits for a client to connect to it. We run the client in a different window:

```
$ ./client
$
```

The client runs and exits without producing any output; however, in the server window, we see the "Hello World!" that is produced by the printer. To get rid of the server, we interrupt it on the command line for now. (We will see cleaner ways to terminate a server in our discussion of [Ice::Application](#).)

If anything goes wrong, the client will print an error message. For example, if we run the client without having first started the server, we get:

```
Network.cpp:471: Ice::ConnectFailedException:
connect failed: Connection refused
```

- [Writing and Compiling a Server in C#](#)
- [Writing and Compiling a Client in C#](#)
- [Running Client and Server in C#](#)

Compiling a Slice Definition for C#

The first step in creating our C# application is to compile our [Slice definition](#) to generate C# proxies and skeletons. You can compile the definition as follows:

```
> mkdir generated
> slice2cs --output-dir generated Printer.ice
```

The `--output-dir` option instructs the compiler to place the generated files into the `generated` directory. This avoids cluttering the working directory with the generated files. The `slice2cs` compiler produces a single source file, `Printer.cs`, from this definition. The exact contents of this file do not concern us for now — it contains the generated code that corresponds to the `Printer` interface we defined in `Printer.ice`.

Writing and Compiling a Server in C#

To implement our `Printer` interface, we must create a servant class. By convention, a servant class uses the name of its interface with an `I`-suffix, so our servant class is called `PrinterI` and placed into a source file `Server.cs`:

```
C#
```

```
using System;

public class PrinterI : Demo.PrinterDisp_
{
    public override void printString(string s, Ice.Current current)
    {
        Console.WriteLine(s);
    }
}
```

The `PrinterI` class inherits from a base class called `PrinterDisp_`, which is generated by the `slice2cs` compiler. The base class is abstract and contains a `printString` method that accepts a string for the printer to print and a parameter of type `Ice.Current`. (For now we will ignore the `Ice.Current` parameter.) Our implementation of the `printString` method simply writes its argument to the terminal.

The remainder of the server code follows in `Server.cs` and is shown in full here:

C#

```

public class Server
{
    public static void Main(string[] args)
    {
        int status = 0;
        Ice.Communicator ic = null;
        try {
            ic = Ice.Util.initialize(ref args);
            Ice.ObjectAdapter adapter =
                ic.createObjectAdapterWithEndpoints("SimplePrinterAdapt
er", "default -p 10000");
            Ice.Object obj = new PrinterI();
            adapter.add(obj, ic.stringToIdentity("SimplePrinter"));
            adapter.activate();
            ic.waitForShutdown();
        } catch (Exception e) {
            Console.Error.WriteLine(e);
            status = 1;
        }
        if (ic != null) {
            // Clean up
            //
            try {
                ic.destroy();
            } catch (Exception e) {
                Console.Error.WriteLine(e);
                status = 1;
            }
        }
        Environment.Exit(status);
    }
}

```

Note the general structure of the code:

C#

```

public class Server
{
    public static void Main(string[] args)
    {
        int status = 0;
        Ice.Communicator ic = null;
        try {

            // Server implementation here...

        } catch (Exception e) {
            Console.Error.WriteLine(e);
            status = 1;
        }
        if (ic != null) {
            // Clean up
            //
            try {
                ic.destroy();
            } catch (Exception e) {
                Console.Error.WriteLine(e);
                status = 1;
            }
        }
        Environment.Exit(status);
    }
}

```

The body of `Main` contains a `try` block in which we place all the server code, followed by a `catch` block. The `catch` block catches all exceptions that may be thrown by the code; the intent is that, if the code encounters an unexpected run-time exception anywhere, the stack is unwound all the way back to `Main`, which prints the exception and then returns failure to the operating system.

Before the code exits, it destroys the communicator (if one was created successfully). Doing this is essential in order to correctly finalize the Ice run time: the program *must* call `destroy` on any communicator it has created; otherwise, undefined behavior results.

The structure shown above closely resembles that of other Ice language mappings such as C++ and Java. We can simplify things a bit in C# by taking advantage of the fact that the `Ice.Communicator` object implements `IDisposable`, which allows us to write a `using` statement as follows:

```

C#
public class Server
{
    public static void Main(string[] args)
    {
        int status = 0;
        try {
            using(Ice.Communicator ic = Ice.Util.initialize(ref args)) {
                Ice.ObjectAdapter adapter =

                ic.createObjectAdapterWithEndpoints("SimplePrinterAdapter", "default
                -p 10000");

                Ice.Object obj = new PrinterI();
                adapter.add(obj, ic.stringToIdentity("SimplePrinter"));
                adapter.activate();
                ic.waitForShutdown();
            }
        } catch (Exception e) {
            Console.Error.WriteLine(e);
            status = 1;
        }
        Environment.Exit(status);
    }
}

```

We've eliminated the need for the clean-up code block because the `using` statement automatically calls `Dispose` on the communicator, which is equivalent to invoking its `destroy` method.

The body of our `try` block contains the actual server code:

```

C#
using(Ice.Communicator ic = Ice.Util.initialize(ref args)) {
    Ice.ObjectAdapter adapter =

    ic.createObjectAdapterWithEndpoints("SimplePrinterAdapter", "default -p
    10000");

    Ice.Object obj = new PrinterI();
    adapter.add(obj, ic.stringToIdentity("SimplePrinter"));
    adapter.activate();
    ic.waitForShutdown();
}

```

The code goes through the following steps:

1. We initialize the Ice run time by calling `Ice.Util.initialize`. (We pass `args` to this call because the server may have command-line arguments that are of interest to the run time; for this example, the server does not require any command-line arguments.) The call to `initialize` returns an `Ice.Communicator` reference, which is the main object in the Ice run time.
2. We create an object adapter by calling `createObjectAdapterWithEndpoints` on the `Communicator` instance. The arguments

we pass are "SimplePrinterAdapter" (which is the name of the adapter) and "default -p 10000", which instructs the adapter to listen for incoming requests using the default protocol (TCP/IP) at port number 10000.

3. At this point, the server-side run time is initialized and we create a servant for our `Printer` interface by instantiating a `PrinterI` object.
4. We inform the object adapter of the presence of a new servant by calling `add` on the adapter; the arguments to `add` are the servant we have just instantiated, plus an identifier. In this case, the string "SimplePrinter" is the name of the Ice object. (If we had multiple printers, each would have a different name or, more correctly, a different *object identity*.)
5. Next, we activate the adapter by calling its `activate` method. (The adapter is initially created in a holding state; this is useful if we have many servants that share the same adapter and do not want requests to be processed until after all the servants have been instantiated.)
6. Finally, we call `waitForShutdown`. This call suspends the calling thread until the server implementation terminates, either by making a call to shut down the run time, or in response to a signal. (For now, we will simply interrupt the server on the command line when we no longer need it.)

Note that, even though there is quite a bit of code here, that code is essentially the same for all servers. You can put that code into a helper class and, thereafter, will not have to bother with it again. (Ice provides such a helper class, called `Ice.Application`.) As far as actual application code is concerned, the server contains only a few lines: seven lines for the definition of the `PrinterI` class, plus three lines to instantiate a `PrinterI` object and register it with the object adapter.

We can compile the server code as follows:

```
$ csc /reference:Ice.dll /lib:%ICE_HOME%\Assemblies Server.cs
generated\Printer.cs
```

This compiles both our application code and the code that was generated by the Slice compiler. We assume that the `ICE_HOME` environment variable is set to the top-level directory containing the Ice run time. (For example, if you have installed Ice in `C:\Ice`, set `ICE_HOME` to that path.)

Writing and Compiling a Client in C#

The client code, in `Client.cs`, looks very similar to the server.

Here it is in full:

C#

```

using System;
using Demo;

public class Client
{
    public static void Main(string[] args)
    {
        int status = 0;
        try {
            using(Ice.Communicator ic = Ice.Util.initialize(ref args)) {

                Ice.ObjectPrx obj = ic.stringToProxy("SimplePrinter:default -p 10000");
                PrinterPrx printer = PrinterPrxHelper.checkedCast(obj);
                if (printer == null)
                    throw new ApplicationException("Invalid proxy");

                printer.printString("Hello World!");
            }
        } catch (Exception e) {
            Console.Error.WriteLine(e);
            status = 1;
        }
        Environment.Exit(status);
    }
}

```

Note that the overall code layout is the same as for the server: we use the same `try` and `catch` blocks to deal with errors. The code in the `try` block does the following:

1. As for the server, we initialize the Ice run time by calling `Ice.Util.initialize`.
2. The next step is to obtain a proxy for the remote printer. We create a proxy by calling `stringToProxy` on the communicator, with the string `"SimplePrinter:default -p 10000"`. Note that the string contains the object identity and the port number that were used by the server. (Obviously, hard-coding object identities and port numbers into our applications is a bad idea, but it will do for now; we will see more architecturally sound ways of doing this when we discuss [IceGrid](#).)
3. The proxy returned by `stringToProxy` is of type `Ice.ObjectPrx`, which is at the root of the inheritance tree for interfaces and classes. But to actually talk to our printer, we need a proxy for a `Printer` interface, not an `Object` interface. To do this, we need to do a down-cast by calling `PrinterPrxHelper.checkedCast`. A checked cast sends a message to the server, effectively asking "is this a proxy for a `Printer` interface?" If so, the call returns a proxy of type `Demo::Printer`; otherwise, if the proxy denotes an interface of some other type, the call returns null.
4. We test that the down-cast succeeded and, if not, throw an error message that terminates the client.
5. We now have a live proxy in our address space and can call the `printString` method, passing it the time-honored "Hello World!" string. The server prints that string on its terminal.

Compiling the client looks much the same as for the server:

```

$ csc /reference:Ice.dll /lib:%ICE_HOME%\Assemblies Client.cs
generated\Printer.cs

```

Running Client and Server in C#

To run client and server, we first start the server in a separate window:

```
$ server.exe
```

At this point, we won't see anything because the server simply waits for a client to connect to it. We run the client in a different window:

```
$ client.exe
$
```

The client runs and exits without producing any output; however, in the server window, we see the "Hello World!" that is produced by the printer. To get rid of the server, we interrupt it on the command line for now. (We will see cleaner ways to terminate a server in our discussion of [Ice.Application](#).)

If anything goes wrong, the client will print an error message. For example, if we run the client without having first started the server, we get something like the following:

```
Ice.ConnectionRefusedException
  error = 0
  at IceInternal.ProxyFactory.checkRetryAfterException(LocalException
ex, Reference ref, Int32 cnt)
  at Ice.ObjectPrxHelperBase.handleException__(ObjectDel_ delegate, Lo
calException ex, Int32 cnt)
  at Ice.ObjectPrxHelperBase.ice_isA(String id__, Dictionary`2 context
__, Boolean explicitContext__)
  at Ice.ObjectPrxHelperBase.ice_isA(String id__)
  at Demo.PrinterPrxHelper.checkedCast(ObjectPrx b)
  at Client.Main(String[] args)
Caused by: System.ComponentModel.Win32Exception: No connection could be
made because the target machine actively refused
it
```

Note that, to successfully run client and server, the C# run time must be able to locate the `Ice.dll` library. (Under Windows, one way to ensure this is to copy the library into the current directory. Please consult the documentation for your C# run time to see how it locates libraries.)

Writing an Ice Application with Java

This page shows how to create an Ice application with Java.

On this page:

- [Compiling a Slice Definition for Java](#)
- [Writing and Compiling a Server in Java](#)
- [Writing and Compiling a Client in Java](#)
- [Running Client and Server in Java](#)

Compiling a Slice Definition for Java

The first step in creating our Java application is to compile our [Slice definition](#) to generate Java proxies and skeletons. You can compile the definition as follows:

```
$ mkdir generated
$ slice2java --output-dir generated Printer.ice
```

The `--output-dir` option instructs the compiler to place the generated files into the `generated` directory. This avoids cluttering the working directory with the generated files. The `slice2java` compiler produces a number of Java source files from this definition. The exact contents of these files do not concern us for now — they contain the generated code that corresponds to the `Printer` interface we defined in `Printer.ice`.

Writing and Compiling a Server in Java

To implement our `Printer` interface, we must create a servant class. By convention, a servant class uses the name of its interface with an `I`-suffix, so our servant class is called `PrinterI` and placed into a source file `PrinterI.java`:

```
Java
```

```
public class PrinterI extends Demo._PrinterDisp {
    public void
    printString(String s, Ice.Current current)
    {
        System.out.println(s);
    }
}
```

The `PrinterI` class inherits from a base class called `_PrinterDisp`, which is generated by the `slice2java` compiler. The base class is abstract and contains a `printString` method that accepts a string for the printer to print and a parameter of type `Ice.Current`. (For now we will ignore the `Ice.Current` parameter.) Our implementation of the `printString` method simply writes its argument to the terminal.

The remainder of the server code is in a source file called `Server.java`, shown in full here:

Java

```

public class Server {
    public static void
    main(String[] args)
    {
        int status = 0;
        Ice.Communicator ic = null;
        try {
            ic = Ice.Util.initialize(args);
            Ice.ObjectAdapter adapter =
                ic.createObjectAdapterWithEndpoints("SimplePrinterAdapt
er", "default -p 10000");
            Ice.Object object = new PrinterI();
            adapter.add(object, ic.stringToIdentity("SimplePrinter"));
            adapter.activate();
            ic.waitForShutdown();
        } catch (Ice.LocalException e) {
            e.printStackTrace();
            status = 1;
        } catch (Exception e) {
            System.err.println(e.getMessage());
            status = 1;
        }
        if (ic != null) {
            // Clean up
            //
            try {
                ic.destroy();
            } catch (Exception e) {
                System.err.println(e.getMessage());
                status = 1;
            }
        }
        System.exit(status);
    }
}

```

Note the general structure of the code:

Java

```

public class Server {
    public static void
    main(String[] args)
    {
        int status = 0;
        Ice.Communicator ic = null;
        try {

            // Server implementation here...

        } catch (Ice.LocalException e) {
            e.printStackTrace();
            status = 1;
        } catch (Exception e) {
            System.err.println(e.getMessage());
            status = 1;
        }
        if (ic != null) {
            // Clean up
            //
            try {
                ic.destroy();
            } catch (Exception e) {
                System.err.println(e.getMessage());
                status = 1;
            }
        }
        System.exit(status);
    }
}

```

The body of `main` contains a `try` block in which we place all the server code, followed by two `catch` blocks. The first block catches all exceptions that may be thrown by the Ice run time; the intent is that, if the code encounters an unexpected Ice run-time exception anywhere, the stack is unwound all the way back to `main`, which prints the exception and then returns failure to the operating system. The second block catches `Exception` exceptions; the intent is that, if we encounter a fatal error condition somewhere in our code, we can simply throw an exception with an error message. Again, this unwinds the stack all the way back to `main`, which prints the error message and then returns failure to the operating system.

Before the code exits, it destroys the communicator (if one was created successfully). Doing this is essential in order to correctly finalize the Ice run time: the program *must* call `destroy` on any communicator it has created; otherwise, undefined behavior results.

The body of our `try` block contains the actual server code:

Java

```

ic = Ice.Util.initialize(args);
Ice.ObjectAdapter adapter =
    ic.createObjectAdapterWithEndpoints("SimplePrinterAdapter",
    "default -p 10000");
Ice.Object object = new PrinterI();
adapter.add(object, ic.stringToIdentity("SimplePrinter"));
adapter.activate();
ic.waitForShutdown();

```

The code goes through the following steps:

1. We initialize the Ice run time by calling `Ice.Util.initialize`. (We pass `args` to this call because the server may have command-line arguments that are of interest to the run time; for this example, the server does not require any command-line arguments.) The call to `initialize` returns an `Ice.Communicator` reference, which is the main object in the Ice run time.
2. We create an object adapter by calling `createObjectAdapterWithEndpoints` on the `Communicator` instance. The arguments we pass are `"SimplePrinterAdapter"` (which is the name of the adapter) and `"default -p 10000"`, which instructs the adapter to listen for incoming requests using the default protocol (TCP/IP) at port number 10000.
3. At this point, the server-side run time is initialized and we create a servant for our `Printer` interface by instantiating a `PrinterI` object.
4. We inform the object adapter of the presence of a new servant by calling `add` on the adapter; the arguments to `add` are the servant we have just instantiated, plus an identifier. In this case, the string `"SimplePrinter"` is the name of the Ice object. (If we had multiple printers, each would have a different name or, more correctly, a different *object identity*.)
5. Next, we activate the adapter by calling its `activate` method. (The adapter is initially created in a holding state; this is useful if we have many servants that share the same adapter and do not want requests to be processed until after all the servants have been instantiated.)
6. Finally, we call `waitForShutdown`. This call suspends the calling thread until the server implementation terminates, either by making a call to shut down the run time, or in response to a signal. (For now, we will simply interrupt the server on the command line when we no longer need it.)

Note that, even though there is quite a bit of code here, that code is essentially the same for all servers. You can put that code into a helper class and, thereafter, will not have to bother with it again. (Ice provides such a helper class, called `Ice.Application`.) As far as actual application code is concerned, the server contains only a few lines: seven lines for the definition of the `PrinterI` class, plus three lines to instantiate a `PrinterI` object and register it with the object adapter.

We can compile the server code as follows:

```

$ mkdir classes
$ javac -d classes -classpath classes:$ICE_HOME/lib/Ice.jar \
Server.java PrinterI.java generated/Demo/*.java

```

This compiles both our application code and the code that was generated by the Slice compiler. We assume that the `ICE_HOME` environment variable is set to the top-level directory containing the Ice run time. (For example, if you have installed Ice in `/opt/Ice`, set `ICE_HOME` to that path.) Note that Ice for Java uses the `ant` build environment to control building of source code. (`ant` is similar to `make`, but more flexible for Java applications.) You can have a look at the demo code that ships with Ice to see how to use this tool.

Writing and Compiling a Client in Java

The client code, in `Client.java`, looks very similar to the server. Here it is in full:

Java

```

public class Client {
    public static void
    main(String[] args)
    {
        int status = 0;
        Ice.Communicator ic = null;
        try {
            ic = Ice.Util.initialize(args);
            Ice.ObjectPrx base = ic.stringToProxy("SimplePrinter:default
t -p 10000");
            Demo.PrinterPrx printer
= Demo.PrinterPrxHelper.checkedCast(base);
            if (printer == null)
                throw new Error("Invalid proxy");

            printer.printString("Hello World!");
        } catch (Ice.LocalException e) {
            e.printStackTrace();
            status = 1;
        } catch (Exception e) {
            System.err.println(e.getMessage());
            status = 1;
        }
        if (ic != null) {
            // Clean up
            //
            try {
                ic.destroy();
            } catch (Exception e) {
                System.err.println(e.getMessage());
                status = 1;
            }
        }
        System.exit(status);
    }
}

```

Note that the overall code layout is the same as for the server: we use the same `try` and `catch` blocks to deal with errors. The code in the `try` block does the following:

1. As for the server, we initialize the Ice run time by calling `Ice.Util.initialize`.
2. The next step is to obtain a proxy for the remote printer. We create a proxy by calling `stringToProxy` on the communicator, with the string `"SimplePrinter:default -p 10000"`. Note that the string contains the object identity and the port number that were used by the server. (Obviously, hard-coding object identities and port numbers into our applications is a bad idea, but it will do for now; we will see more architecturally sound ways of doing this when we discuss `IceGrid`.)
3. The proxy returned by `stringToProxy` is of type `Ice.ObjectPrx`, which is at the root of the inheritance tree for interfaces and classes. But to actually talk to our printer, we need a proxy for a `Printer` interface, not an `Object` interface. To do this, we need to do a down-cast by calling `PrinterPrxHelper.checkedCast`. A checked cast sends a message to the server, effectively asking "is this a proxy for a `Printer` interface?" If so, the call returns a proxy of type `Demo::Printer`; otherwise, if the proxy denotes an interface of some other type, the call returns null.

4. We test that the down-cast succeeded and, if not, throw an error message that terminates the client.
5. We now have a live proxy in our address space and can call the `printString` method, passing it the time-honored "Hello World!" string. The server prints that string on its terminal.

Compiling the client looks much the same as for the server:

```
$ javac -d classes -classpath classes:$ICE_HOME/lib/Ice.jar \
Client.java PrinterI.java generated/Demo/*.java
```

Running Client and Server in Java

To run client and server, we first start the server in a separate window:

```
$ java Server
```

At this point, we won't see anything because the server simply waits for a client to connect to it. We run the client in a different window:

```
$ java Client
$
```

The client runs and exits without producing any output; however, in the server window, we see the "Hello World!" that is produced by the printer. To get rid of the server, we interrupt it on the command line for now. (We will see cleaner ways to terminate a server in our discussion of [Ice.Application](#).)

If anything goes wrong, the client will print an error message. For example, if we run the client without having first started the server, we get something like the following:

```
Ice.ConnectionRefusedException
    error = 0
    at
IceInternal.ConnectRequestHandler.getConnection(ConnectRequestHandler.java:240)
    at
IceInternal.ConnectRequestHandler.sendRequest(ConnectRequestHandler.java:138)
    at IceInternal.Outgoing.invoke(Outgoing.java:66)
    at Ice._ObjectDelM.ice_isA(_ObjectDelM.java:30)
    at Ice.ObjectPrxHelperBase.ice_isA(ObjectPrxHelperBase.java:111)
    at Ice.ObjectPrxHelperBase.ice_isA(ObjectPrxHelperBase.java:77)
    at Demo.HelloPrxHelper.checkedCast(HelloPrxHelper.java:228)
    at Client.run(Client.java:65)
Caused by: java.net.ConnectException: Connection refused
    ...
```

Note that, to successfully run client and server, your `CLASSPATH` must include the Ice library and the classes directory, for example:

```
$ export CLASSPATH=$CLASSPATH:./classes:$ICE_HOME/lib/Ice.jar
```

Please have a look at the demo applications that ship with Ice for the details for your platform.

Writing an Ice Application with JavaScript

This page shows how to create an Ice client application with JavaScript.

On this page:

- [Compiling a Slice Definition for JavaScript](#)
- [Writing a Client in JavaScript](#)
- [Running the Client in JavaScript](#)

Compiling a Slice Definition for JavaScript

The first step in creating our JavaScript application is to compile our [Slice definition](#) to generate JavaScript proxies. You can compile the definition as follows:

```
$ slice2js Printer.ice
```

The `slice2js` compiler produces a single source file, `Printer.js`, from this definition. The exact contents of the source file do not concern us for now — it contains the generated code that corresponds to the `Printer` interface we defined in `Printer.ice`.

Writing a Client in JavaScript

The client code, in `Client.js`, is shown below in full:

JavaScript

```

var Ice = require("ice").Ice;
var Demo = require("./Printer").Demo;

var ic;

Ice.Promise.try(
  function()
  {
    ic = Ice.initialize();
    var base = ic.stringToProxy("SimplePrinter:default -p 10000");
    return Demo.PrinterPrx.checkedCast(base).then(
      function(printer)
      {
        return printer.printString("Hello World!");
      }
    );
  }
).finally(
  function()
  {
    if(ic)
    {
      return ic.destroy();
    }
  }
).exception(
  function(ex)
  {
    console.log(ex.toString());
    process.exit(1);
  }
);

```

The program begins with `require` statements that assign modules from the Ice run time and the generated code to convenient local variables. (These statements are necessary for use with NodeJS. Browser applications would omit these statements and [load the modules](#) a different way.)

The program begins with a call to `Ice.Promise.try` to launch a chain of [promises](#) (or futures) that handles the asynchronous nature of Ice invocations with a structure that resembles synchronous code.

1. The function passed to `try` is executed immediately. The body of this function begins by calling `Ice.initialize` to initialize the Ice run time. The call to `initialize` returns an `Ice.Communicator` reference, which is the main object in the Ice run time.
2. The next step is to obtain a proxy for the remote printer. We create a proxy by calling `stringToProxy` on the communicator, with the string `"SimplePrinter:default -p 10000"`. Note that the string contains the object identity and the port number that were used by the server. (Obviously, hard-coding object identities and port numbers into our applications is a bad idea, but it will do for now; we will see more architecturally sound ways of doing this when we discuss [IceGrid](#).)
3. The proxy returned by `stringToProxy` is of type `Ice.ObjectPrx`, which is at the root of the inheritance tree for interfaces and classes. But to actually talk to our printer, we need a proxy for a `Demo:Printer` interface, not an `Object` interface. To do this, we need to do a down-cast by calling `Demo.PrinterPrx.checkedCast`. A checked cast sends a message to the server, effectively asking "is this a proxy for a `Demo:Printer` interface?" If so, the call returns a proxy of type `Demo:PrinterPrx`; otherwise, if the proxy denotes an interface of some other type, the call returns `null`.
4. The `checkedCast` function involves a remote invocation to the server, which means this function has asynchronous semantics and therefore it returns a new promise object.

5. We call `then` on the promise returned by `checkedCast` and supply a "success" function, meaning the code that's executed when `checkedCast` succeeds. This inner function accepts one argument, `printer`, representing a proxy to the newly-downcasted object, or `null` if the remote object doesn't support the `Printer` interface.
6. Inside the success function, we now have a live proxy in our address space and can call the `printString` method, passing it the time-honored "Hello World!" string. The server prints that string on its terminal. Again, `printString` is a remote invocation, and it returns a promise that the success function passes along as its own return value.
7. The `then` function also returns a new promise which our outer function passes back to `try`. This outer promise is chained to the promise associated with the `printString` invocation; the outer promise completes successfully if and when the `printString` invocation completes successfully.
8. The function passed to `finally` is executed after the `try` block has completed, whether or not it completes successfully. If we created a communicator in the `try` block, we destroy it here. Doing this is essential in order to correctly finalize the Ice run time: the program *must* call `destroy` on any communicator it has created; otherwise, undefined behavior results. The `destroy` function has asynchronous semantics, so we return its promise to ensure no subsequent code is executed until `destroy` completes.
9. Lastly, the function passed to `exception` is the default exception handler for this entire promise chain.

Running the Client in JavaScript

The server must be started before the client. Since Ice for JavaScript does not currently include a complete server-side implementation, we need to use a server from another language mapping. In this case, we will use the C++ server:

```
$ server
```

At this point, we won't see anything because the server simply waits for a client to connect to it. We run the client in a different window:

```
$ node Client.js
$
```

The client runs and exits without producing any output; however, in the server window, we see the "Hello World!" that is produced by the printer. To get rid of the server, we interrupt it on the command line.

If anything goes wrong, the client will print an error message. For example, if we run the client without having first started the server, we get something like the following:

```
Ice::ConnectionRefusedException
  ice_cause: "Error: connect ECONNREFUSED"
  error: "ECONNREFUSED"
```

Note that, to successfully run the client, NodeJS must be able to locate the Ice for JavaScript modules. See the Ice for JavaScript installation instructions for more information.

Writing an Ice Application with Objective-C

This page shows how to create an Ice application with Objective-C.

On this page:

- [Compiling a Slice Definition for Objective-C](#)
- [Writing and Compiling a Server in Objective-C](#)
- [Writing and Compiling a Client in Objective-C](#)
- [Running Client and Server in Objective-C](#)

Compiling a Slice Definition for Objective-C

The first step in creating our Objective-C application is to compile our [Slice definition](#) to generate Objective-C proxies and skeletons. You can compile the definition as follows:

```
$ slice2objc Printer.ice
```

The `slice2objc` compiler produces two Objective-C source files from this definition, `Printer.h` and `Printer.m`.

- `Printer.h`
The `Printer.h` header file contains Objective-C type definitions that correspond to the Slice definitions for our `Printer` interface. This header file must be included in both the client and the server source code.
- `Printer.m`
The `Printer.m` file contains the source code for our `Printer` interface. The generated source contains type-specific run-time support for both clients and servers. For example, it contains code that marshals parameter data (the string passed to the `printString` operation) on the client side and unmarshals that data on the server side. The `Printer.m` file must be compiled and linked into both client and server.

Writing and Compiling a Server in Objective-C

The source code for the server takes only a few lines and is shown in full here:

```

Objective-C

#import <Ice/Ice.h>
#import <Printer.h>

#import <Foundation/NSAutoreleasePool.h>
#import <stdio.h>

@interface PrinterI : DemoPrinter <DemoPrinter>
@end

@implementation PrinterI
-(void) printString:(NSMutableString *)s
                current:(ICECurrent *)current
{
    printf("%s\n", [s UTF8String]);
}
@end

int
main(int argc, char* argv[])

```

```

{
    NSAutoreleasePool * pool = [[NSAutoreleasePool alloc] init];

    int status = 1;
    id<ICECommunicator> communicator = nil;
    @try {
        communicator = [ICEUtil createCommunicator:&argc argv:argv];

        id<ICEObjectAdapter> adapter =
            [communicator createObjectAdapterWithEndpoints:
             @"SimplePrinterAdapter"
             endpoints:@"default -p 10000"];

        ICEObject *object = [[[PrinterI alloc] init] autorelease];
        [adapter add:object identity:[communicator
stringToIdentity:@"SimplePrinter"]];
        [adapter activate];

        [communicator waitForShutdown];

        status = 0;
    } @catch (NSEException* ex) {
        NSLog(@"%@", ex);
    }

    @try {
        [communicator destroy];
    } @catch (NSEException* ex) {
        NSLog(@"%@", ex);
    }

    [pool release];
}

```

```

    return status;
}

```

There appears to be a lot of code here for something as simple as a server that just prints a string. Do not be concerned by this: most of the preceding code is boiler plate that never changes. For this very simple server, the code is dominated by this boiler plate.

Every Ice source file starts with an include directive for `Ice.h`, which contains the definitions for the Ice run time. We also include `Printer.h`, which was generated by the Slice compiler and contains the Objective-C definitions for our printer interface. In addition, we import headers to allow us to use an autorelease pool and to produce output:

Objective-C

```

#import <Ice/Ice.h>
#import <Printer.h>

#import <Foundation/NSAutoreleasePool.h>
#import <stdio.h>

```

Our server implements a single printer servant, of type `PrinterI`. Looking at the generated code in `Printer.h`, we find the following (tidied up a little to get rid of irrelevant detail):

Objective-C

```

@protocol DemoPrinter <ICEObject>
-(void) printString:(NSMutableString *)s
                current:(ICECurrent *)current;

@end

@interface DemoPrinter : ICEObject
// ...
@end

```

The `DemoPrinter` protocol and class definitions are generated by the Slice compiler. The protocol defines the `printString` method, which we must implement in our servant. The `DemoPrinter` class contains methods that are internal to the mapping, so we are not concerned with these. However, our servant must derive from this skeleton class:

Objective-C

```

@interface PrinterI : DemoPrinter <DemoPrinter>
@end

@implementation PrinterI
-(void) printString:(NSMutableString *)s
                current:(ICECurrent *)current
{
    printf("%s\n", [s UTF8String]);
}
@end

```

As you can see, the implementation of the `printString` method is trivial: it simply writes its string argument to `stdout`.

Note that `printString` has a second parameter of type `ICECurrent`. The Ice run time passes additional information about an incoming request to the servant in this parameter. For now, we will ignore it.

What follows is the server main program. Note the general structure of the code:

Objective-C

```
int
main(int argc, char* argv[])
{
    NSAutoreleasePool * pool = [[NSAutoreleasePool alloc] init];

    int status = 1;
    id<ICECommunicator> communicator = nil;
    @try {
        communicator = [ICEUtil createCommunicator:&argc argv:argv];

        // Server implementation here...

        status = 0;
    } @catch (NSEException* ex) {
        NSLog(@"%@", ex);
    }

    @try {
        [communicator destroy];
    } @catch (NSEException* ex) {
        NSLog(@"%@", ex);
    }

    [pool release];
    return status;
}
```

The body of `main` instantiates an autorelease pool, which it releases before returning to ensure that the program does not leak memory. `main` contains the declaration of two variables, `status` and `communicator`. The `status` variable contains the exit status of the program and the `communicator` variable, of type `id<ICECommunicator>`, contains the main handle to the Ice run time.

Following these declarations is a `try` block in which we place all the server code, followed by a `catch` handler that logs any unhandled exceptions.

Before returning, `main` executes a bit of cleanup code that calls the `destroy` method on the communicator. The cleanup call is outside the first `try` block for a reason: we must ensure that the Ice run time is finalized whether the code terminates normally or terminates due to an exception.

Failure to call `destroy` on the communicator before the program exits results in undefined behavior.

The body of the first `try` block contains the actual server code:

Objective-C

```

communicator = [ICEUtil createCommunicator:&argc argv:argv];

id<ICEObjectAdapter> adapter =
    [communicator createObjectAdapterWithEndpoints:
        @"SimplePrinterAdapter"
        endpoints:@"default -p 10000"];

ICEObject *object = [[[PrinterI alloc] init] autorelease];
[adapter add:object identity:[communicator
stringToIdentity:@"SimplePrinter"]];
[adapter activate];

[communicator waitForShutdown];

```

The code goes through the following steps:

1. We initialize the Ice run time by calling `createCommunicator`. (We pass `argc` and `argv` to this call because the server may have command-line arguments that are of interest to the run time; for this example, the server does not require any command-line arguments.) The call to `createCommunicator` returns a value of type `id<ICECommunicator>`, which is the main object in the Ice run time.
2. We create an object adapter by calling `createObjectAdapterWithEndpoints` on the `Communicator` instance. The arguments we pass are `"SimplePrinterAdapter"` (which is the name of the adapter) and `"default -p 10000"`, which instructs the adapter to listen for incoming requests using the default protocol (TCP/IP) at port number 10000.
3. At this point, the server-side run time is initialized and we create a servant for our `Printer` interface by instantiating a `PrinterI` object.
4. We inform the object adapter of the presence of a new servant by calling `add` on the adapter; the arguments to `add` are the servant we have just instantiated, plus an identifier. In this case, the string `"SimplePrinter"` is the name of the Ice object. (If we had multiple printers, each would have a different name or, more correctly, a different *object identity*.)
5. Next, we activate the adapter by calling its `activate` method. (The adapter is initially created in a holding state; this is useful if we have many servants that share the same adapter and do not want requests to be processed until after all the servants have been instantiated.) The server starts to process incoming requests from clients as soon as the adapter is activated.
6. Finally, we call `waitForShutdown`. This call suspends the calling thread until the server implementation terminates, either by making a call to shut down the run time, or in response to a signal. (For now, we will simply interrupt the server on the command line when we no longer need it.)

Note that, even though there is quite a bit of code here, that code is essentially the same for all servers. You can put that code into a helper class and, thereafter, will not have to bother with it again. As far as actual application code is concerned, the server contains only a few lines: nine lines for the definition of the `PrinterI` class, plus three lines to instantiate a `PrinterI` object and register it with the object adapter.

Assuming that we have the server code in a file called `Server.m`, we can compile it as follows:

```
$ cc -c -I. -I$ICE_HOME/include Printer.m Server.m
```

This compiles both our application code and the code that was generated by the Slice compiler. We assume that the `ICE_HOME` environment variable is set to the top-level directory containing the Ice run time. (For example, if you have installed Ice in `/opt/Ice`, set `ICE_HOME` to that path.) Depending on your platform, you may have to add additional include directives or other options to the compiler; please see the demo programs that ship with Ice for the details.

Finally, we need to link the server into an executable:

```
$ c++ Printer.o Server.o -o server -L$ICE_HOME/lib -lIceObjC -framework
Foundation
```

Again, depending on the platform, the actual list of libraries you need to link against may be longer. The demo programs that ship with Ice contain all the detail.

Writing and Compiling a Client in Objective-C

The client code looks very similar to the server. Here it is in full:

```

Objective-C

#import <Ice/Ice.h>
#import <Printer.h>

#import <Foundation/NSAutoreleasePool.h>
#import <stdio.h>

int
main(int argc, char* argv[])
{
    NSAutoreleasePool * pool = [[NSAutoreleasePool alloc] init];

    int status = 1;
    id<ICECommunicator> communicator = nil;
    @try {
        communicator = [ICEUtil createCommunicator:&argc argv:argv];
        id<ICEObjectPrx> base = [communicator
stringToProxy:@"SimplePrinter:default -p 10000"];
        id<DemoPrinterPrx> printer = [DemoPrinterPrx checkedCast:base];
        if(!printer)
            [NSException raise:@"Invalid proxy" format:nil];

        [printer printString:@"Hello World!"];

        status = 0;
    } @catch (NSException* ex) {
        NSLog(@"%@", ex);
    }

    @try {
        [communicator destroy];
    } @catch (NSException* ex) {
        NSLog(@"%@", ex);
    }

    [pool release];
    return status;
}

```

Note that the overall code layout is the same as for the server: we include the headers for the Ice run time and the header generated by the Slice compiler, and we use the same `try` block and `catch` handlers to deal with errors.

The code in the `try` block does the following:

1. As for the server, we initialize the Ice run time by calling `createCommunicator`.
2. The next step is to obtain a proxy for the remote printer. We create a proxy by calling `stringToProxy` on the communicator, with the string `"SimplePrinter:default -p 10000"`. Note that the string contains the object identity and the port number that were used by the server. (Obviously, hard-coding object identities and port numbers into our applications is a bad idea, but it will do for now; we will see more architecturally sound ways of doing this when we discuss `IceGrid`.)
3. The proxy returned by `stringToProxy` is of type `id<ICEObjectPrx>`, which is at the root of the inheritance tree for interfaces and classes. But to actually talk to our printer, we need a proxy for a `Printer` interface, not an `Object` interface. To do this, we need to do a down-cast by calling the `checkedCast` class method on the `DemoPrinterPrx` class. A checked cast sends a message to the server, effectively asking "is this a proxy for a `Printer` interface?" If so, the call returns a proxy to a `Printer`; otherwise, if the proxy denotes an interface of some other type, the call returns a null proxy.
4. We test that the down-cast succeeded and, if not, throw an error message that terminates the client.
5. We now have a live proxy in our address space and can call the `printString` method, passing it the time-honored "Hello World!" string. The server prints that string on its terminal.

Compiling and linking the client looks much the same as for the server:

```
$ cc -c -I. -I$ICE_HOME/include Printer.m Client.m
$ c++ Printer.o Client.o -o client -L$ICE_HOME/lib -lIceObjC -framework
Foundation
```

Running Client and Server in Objective-C

To run client and server, we first start the server in a separate window:

```
$ ./server
```

At this point, we won't see anything because the server simply waits for a client to connect to it. We run the client in a different window:

```
$ ./client
$
```

The client runs and exits without producing any output; however, in the server window, we see the "Hello World!" that is produced by the printer. To get rid of the server, we interrupt it on the command line for now.

If anything goes wrong, the client will print an error message. For example, if we run the client without having first started the server, we get:

```
Network.cpp:1218: Ice::ConnectionRefusedException:
connection refused: Connection refused
```

Note that, to successfully run client and server, you may have to set `DYLD_LIBRARY_PATH` to include the Ice library directory. Please see the installation instructions and the demo applications that ship with Ice Touch for details.

Writing an Ice Application with PHP

This page shows how to create an Ice client application with PHP.

On this page:

- [Compiling a Slice Definition for PHP](#)
- [Writing a Client in PHP](#)
- [Running the Client in PHP](#)

Compiling a Slice Definition for PHP

The first step in creating our PHP application is to compile our [Slice definition](#) to generate PHP code. You can compile the definition as follows:

```
$ slice2php Printer.ice
```

The `slice2php` compiler produces a single source file, `Printer.php`, from this definition. The exact contents of the source file do not concern us for now — it contains the generated code that corresponds to the `Printer` interface we defined in `Printer.ice`.

Writing a Client in PHP

The client code, in `Client.php`, is shown below in full:

PHP

```

<?php
require 'Ice.php';
require 'Printer.php';

$ic = null;
try
{
    $ic = Ice_initialize();
    $base = $ic->stringToProxy("SimplePrinter:default -p 10000");
    $printer = Demo_PrinterPrxHelper::checkedCast($base);
    if(!$printer)
        throw new RuntimeException("Invalid proxy");

    $printer->printString("Hello World!");
}
catch(Exception $ex)
{
    echo $ex;
}

if($ic)
{
    // Clean up
    try
    {
        $ic->destroy();
    }
    catch(Exception $ex)
    {
        echo $ex;
    }
}
?>

```

The program begins with `require` statements to load the Ice run-time definitions (`Ice.php`) and the code we generated from our Slice definition in the previous section (`Printer.php`).

The body of the main program contains a `try` block in which we place all the client code, followed by a `catch` block. The `catch` block catches all exceptions that may be thrown by the code; the intent is that, if the code encounters an unexpected run-time exception anywhere, the stack is unwound all the way back to the main program, which prints the exception and then returns failure to the operating system.

The body of our `try` block goes through the following steps:

1. We initialize the Ice run time by calling `Ice_initialize`. The call to `initialize` returns an `Ice_Communicator` reference, which is the main object in the Ice run time.
2. The next step is to obtain a proxy for the remote printer. We create a proxy by calling `stringToProxy` on the communicator, with the string `"SimplePrinter:default -p 10000"`. Note that the string contains the object identity and the port number that were used by the server. (Obviously, hard-coding object identities and port numbers into our applications is a bad idea, but it will do for now; we will see more architecturally sound ways of doing this when we discuss [IceGrid](#).)
3. The proxy returned by `stringToProxy` is of type `Ice_ObjectPrx`, which is at the root of the inheritance tree for interfaces and classes. But to actually talk to our printer, we need a proxy for a `Demo::Printer` interface, not an `Object` interface. To do this, we

need to do a down-cast by calling `Demo_PrinterPrxHelper::checkedCast`. A checked cast sends a message to the server, effectively asking "is this a proxy for a `Demo::Printer` interface?" If so, the call returns a proxy narrowed to the `Printer` interface; otherwise, if the proxy denotes an interface of some other type, the call returns `null`.

4. We test that the down-cast succeeded and, if not, throw an exception that terminates the client.
5. We now have a live proxy in our address space and can call the `printString` method, passing it the time-honored "Hello World!" string. The server prints that string on its terminal.

Before the code exits, it destroys the communicator (if one was created successfully). Doing this is essential in order to correctly finalize the Ice run time. If a script neglects to destroy the communicator, Ice destroys it automatically.

Running the Client in PHP

The server must be started before the client. Since Ice for PHP does not support server-side behavior, we need to use a server from another language mapping. In this case, we will use the [C++ server](#):

```
$ server
```

At this point, we won't see anything because the server simply waits for a client to connect to it. We run the client in a different window using PHP's command-line interpreter:

```
$ php -f Client.php
$
```

The client runs and exits without producing any output; however, in the server window, we see the "Hello World!" that is produced by the printer. To get rid of the server, we interrupt it on the command line.

If anything goes wrong, the client will print an error message. For example, if we run the client without having first started the server, we get something like the following:

```
exception ::Ice::ConnectionRefusedException
{
    error = 111
}
```

Note that, to successfully run the client, the PHP interpreter must be able to locate the Ice extension for PHP. See the [Ice for PHP installation instructions](#) for more information.

Writing an Ice Application with Python

This page shows how to create an Ice application with Python.

On this page:

- [Compiling a Slice Definition for Python](#)
- [Writing a Server in Python](#)
- [Writing a Client in Python](#)
- [Running Client and Server in Python](#)

Compiling a Slice Definition for Python

The first step in creating our Python application is to compile our [Slice definition](#) to generate Python proxies and skeletons. You can compile the definition as follows:

```
$ slice2py Printer.ice
```

The `slice2py` compiler produces a single source file, `Printer_ice.py`, from this definition. The compiler also creates a Python package for the `Demo` module, resulting in a subdirectory named `Demo`. The exact contents of the source file do not concern us for now — it contains the generated code that corresponds to the `Printer` interface we defined in `Printer.ice`.

Writing a Server in Python

To implement our `Printer` interface, we must create a servant class. By convention, a servant class uses the name of its interface with an `I`-suffix, so our servant class is called `PrinterI`:

```

Python
class PrinterI(Demo.Printer):
    def printString(self, s, current=None):
        print s

```

The `PrinterI` class inherits from a base class called `Demo.Printer`, which is generated by the `slice2py` compiler. The base class is abstract and contains a `printString` method that accepts a string for the printer to print and a parameter of type `Ice.Current`. (For now we will ignore the `Ice.Current` parameter.) Our implementation of the `printString` method simply writes its argument to the terminal.

The remainder of the server code, in `Server.py`, follows our servant class and is shown in full here:

Python

```

import sys, traceback, Ice
import Demo

class PrinterI(Demo.Printer):
    def printString(self, s, current=None):
        print s

status = 0
ic = None
try:
    ic = Ice.initialize(sys.argv)
    adapter = ic.createObjectAdapterWithEndpoints("SimplePrinterAdapter", "default -p 10000")
    object = PrinterI()
    adapter.add(object, ic.stringToIdentity("SimplePrinter"))
    adapter.activate()
    ic.waitForShutdown()
except:
    traceback.print_exc()
    status = 1

if ic:
    # Clean up
    try:
        ic.destroy()
    except:
        traceback.print_exc()
        status = 1

sys.exit(status)

```

Note the general structure of the code:

Python

```

status = 0
ic = None
try:

    # Server implementation here...

except:
    traceback.print_exc()
    status = 1

if ic:
    # Clean up
    try:
        ic.destroy()
    except:
        traceback.print_exc()
        status = 1

sys.exit(status)

```

The body of the main program contains a `try` block in which we place all the server code, followed by an `except` block. The `except` block catches all exceptions that may be thrown by the code; the intent is that, if the code encounters an unexpected run-time exception anywhere, the stack is unwound all the way back to the main program, which prints the exception and then returns failure to the operating system.

Before the code exits, it destroys the communicator (if one was created successfully). Doing this is essential in order to correctly finalize the Ice run time: the program *must* call `destroy` on any communicator it has created; otherwise, undefined behavior results.

The body of our `try` block contains the actual server code:

Python

```

ic = Ice.initialize(sys.argv)
adapter = ic.createObjectAdapterWithEndpoints("SimplePrinterAdapter", "
default -p 10000")
object = PrinterI()
adapter.add(object, ic.stringToIdentity("SimplePrinter"))
adapter.activate()
ic.waitForShutdown()

```

The code goes through the following steps:

1. We initialize the Ice run time by calling `Ice.initialize`. (We pass `sys.argv` to this call because the server may have command-line arguments that are of interest to the run time; for this example, the server does not require any command-line arguments.) The call to `initialize` returns an `Ice.Communicator` reference, which is the main object in the Ice run time.
2. We create an object adapter by calling `createObjectAdapterWithEndpoints` on the `Communicator` instance. The arguments we pass are `"SimplePrinterAdapter"` (which is the name of the adapter) and `"default -p 10000"`, which instructs the adapter to listen for incoming requests using the default protocol (TCP/IP) at port number 10000.
3. At this point, the server-side run time is initialized and we create a servant for our `Printer` interface by instantiating a `PrinterI` object.
4. We inform the object adapter of the presence of a new servant by calling `add` on the adapter; the arguments to `add` are the servant we have just instantiated, plus an identifier. In this case, the string `"SimplePrinter"` is the name of the Ice object. (If we had

- multiple printers, each would have a different name or, more correctly, a different *object identity*.)
- Next, we activate the adapter by calling its `activate` method. (The adapter is initially created in a holding state; this is useful if we have many servants that share the same adapter and do not want requests to be processed until after all the servants have been instantiated.)
 - Finally, we call `waitForShutdown`. This call suspends the calling thread until the server implementation terminates, either by making a call to shut down the run time, or in response to a signal. (For now, we will simply interrupt the server on the command line when we no longer need it.)

Note that, even though there is quite a bit of code here, that code is essentially the same for all servers. You can put that code into a helper class and, thereafter, will not have to bother with it again. (Ice provides such a helper class, called `Ice.Application`.) As far as actual application code is concerned, the server contains only a few lines: three lines for the definition of the `PrinterI` class, plus two lines to instantiate a `PrinterI` object and register it with the object adapter.

Writing a Client in Python

The client code, in `Client.py`, looks very similar to the server. Here it is in full:

```

Python

import sys, traceback, Ice
import Demo

status = 0
ic = None
try:
    ic = Ice.initialize(sys.argv)
    base = ic.stringToProxy("SimplePrinter:default -p 10000")
    printer = Demo.PrinterPrx.checkedCast(base)
    if not printer:
        raise RuntimeError("Invalid proxy")

    printer.printString("Hello World!")
except:
    traceback.print_exc()
    status = 1

if ic:
    # Clean up
    try:
        ic.destroy()
    except:
        traceback.print_exc()
        status = 1

sys.exit(status)
```

Note that the overall code layout is the same as for the server: we use the same `try` and `except` blocks to deal with errors. The code in the `try` block does the following:

- As for the server, we initialize the Ice run time by calling `Ice.initialize`.
- The next step is to obtain a proxy for the remote printer. We create a proxy by calling `stringToProxy` on the communicator, with the string `"SimplePrinter:default -p 10000"`. Note that the string contains the object identity and the port number that were used by the server. (Obviously, hard-coding object identities and port numbers into our applications is a bad idea, but it will do for now; we will see more architecturally sound ways of doing this when we discuss `IceGrid`.)
- The proxy returned by `stringToProxy` is of type `Ice.ObjectPrx`, which is at the root of the inheritance tree for interfaces and

classes. But to actually talk to our printer, we need a proxy for a `Demo::Printer` interface, not an `Object` interface. To do this, we need to do a down-cast by calling `Demo.PrinterPrx.checkedCast`. A checked cast sends a message to the server, effectively asking "is this a proxy for a `Demo::Printer` interface?" If so, the call returns a proxy of type `Demo.PrinterPrx`; otherwise, if the proxy denotes an interface of some other type, the call returns `None`.

4. We test that the down-cast succeeded and, if not, throw an error message that terminates the client.
5. We now have a live proxy in our address space and can call the `printString` method, passing it the time-honored "Hello World!" string. The server prints that string on its terminal.

Running Client and Server in Python

To run client and server, we first start the server in a separate window:

```
$ python Server.py
```

At this point, we won't see anything because the server simply waits for a client to connect to it. We run the client in a different window:

```
$ python Client.py
$
```

The client runs and exits without producing any output; however, in the server window, we see the "Hello World!" that is produced by the printer. To get rid of the server, we interrupt it on the command line for now. (We will see cleaner ways to terminate a server in our discussion of [Ice.Application](#).)

If anything goes wrong, the client will print an error message. For example, if we run the client without having first started the server, we get something like the following:

```
Traceback (most recent call last):
  File "Client.py", line 10, in ?
    printer = Demo.PrinterPrx.checkedCast(base)
  File "Printer_ice.py", line 43, in checkedCast
    return Demo.PrinterPrx.ice_checkedCast(proxy, '::Demo::Printer', fa
cet)
ConnectionRefusedException: Ice.ConnectionRefusedException:
Connection refused
```

Note that, to successfully run the client and server, the Python interpreter must be able to locate the Ice extension for Python. See the Ice for Python installation instructions for more information.

Writing an Ice Application with Ruby

This page shows how to create an Ice client application with Ruby.

On this page:

- [Compiling a Slice Definition for Ruby](#)
- [Writing a Client in Ruby](#)
- [Running the Client in Ruby](#)

Compiling a Slice Definition for Ruby

The first step in creating our Ruby application is to compile our [Slice definition](#) to generate Ruby proxies. You can compile the definition as follows:

```
$ slice2rb Printer.ice
```

The `slice2rb` compiler produces a single source file, `Printer.rb`, from this definition. The exact contents of the source file do not concern us for now — it contains the generated code that corresponds to the `Printer` interface we defined in `Printer.ice`.

Writing a Client in Ruby

The client code, in `Client.rb`, is shown below in full:

Ruby

```

require 'Printer.rb'

status = 0
ic = nil
begin
  ic = Ice::initialize(ARGV)
  base = ic.stringToProxy("SimplePrinter:default -p 10000")
  printer = Demo::PrinterPrx::checkedCast(base)
  if not printer
    raise "Invalid proxy"
  end

  printer.printString("Hello World!")
rescue
  puts $!
  puts $!.backtrace.join("\n")
  status = 1
end

if ic
  # Clean up
  begin
    ic.destroy()
  rescue
    puts $!
    puts $!.backtrace.join("\n")
    status = 1
  end
end

exit(status)

```

The program begins with a `require` statement, which loads the Ruby code we generated from our Slice definition in the previous section. It is not necessary for the client to explicitly load the `Ice` module because `Printer.rb` does that for you.

The body of the main program contains a `begin` block in which we place all the client code, followed by a `rescue` block. The `rescue` block catches all exceptions that may be thrown by the code; the intent is that, if the code encounters an unexpected run-time exception anywhere, the stack is unwound all the way back to the main program, which prints the exception and then returns failure to the operating system.

The body of our `begin` block goes through the following steps:

1. We initialize the Ice run time by calling `Ice::initialize`. (We pass `ARGV` to this call because the client may have command-line arguments that are of interest to the run time; for this example, the client does not require any command-line arguments.) The call to `initialize` returns an `Ice::Communicator` reference, which is the main object in the Ice run time.
2. The next step is to obtain a proxy for the remote printer. We create a proxy by calling `stringToProxy` on the communicator, with the string `"SimplePrinter:default -p 10000"`. Note that the string contains the object identity and the port number that were used by the server. (Obviously, hard-coding object identities and port numbers into our applications is a bad idea, but it will do for now; we will see more architecturally sound ways of doing this when we discuss `IceGrid`.)
3. The proxy returned by `stringToProxy` is of type `Ice::ObjectPrx`, which is at the root of the inheritance tree for interfaces and classes. But to actually talk to our printer, we need a proxy for a `Demo::Printer` interface, not an `Object` interface. To do this, we

need to do a down-cast by calling `Demo::PrinterPrx::checkedCast`. A checked cast sends a message to the server, effectively asking "is this a proxy for a `Demo::Printer` interface?" If so, the call returns a proxy of type `Demo::PrinterPrx`; otherwise, if the proxy denotes an interface of some other type, the call returns `nil`.

4. We test that the down-cast succeeded and, if not, throw an error message that terminates the client.
5. We now have a live proxy in our address space and can call the `printString` method, passing it the time-honored "Hello World!" string. The server prints that string on its terminal.

Before the code exits, it destroys the communicator (if one was created successfully). Doing this is essential in order to correctly finalize the Ice run time: the program *must* call `destroy` on any communicator it has created; otherwise, undefined behavior results.

Running the Client in Ruby

The server must be started before the client. Since Ice for Ruby does not support server-side behavior, we need to use a server from another language mapping. In this case, we will use the [C++ server](#):

```
$ server
```

At this point, we won't see anything because the server simply waits for a client to connect to it. We run the client in a different window:

```
$ ruby Client.rb
$
```

The client runs and exits without producing any output; however, in the server window, we see the "Hello World!" that is produced by the printer. To get rid of the server, we interrupt it on the command line.

If anything goes wrong, the client will print an error message. For example, if we run the client without having first started the server, we get something like the following:

```
exception ::Ice::ConnectionRefusedException
{
  error = 111
}
```

Note that, to successfully run the client, the Ruby interpreter must be able to locate the Ice extension for Ruby. See the [Ice for Ruby installation instructions](#) for more information.

Writing an Ice Application with Visual Basic

This page shows how to create an Ice application with Visual Basic.

On this page:

- [Visual Basic Development Process](#)
- [Compiling a Slice Definition for Visual Basic](#)
- [Writing and Compiling a Server in Visual Basic](#)
- [Writing and Compiling a Client in Visual Basic](#)
- [Running Client and Server in Visual Basic](#)

Visual Basic Development Process

As of version 3.3, Ice no longer includes a separate compiler to create Visual Basic source code from Slice definitions. Instead, you need to use the Slice-to-C# compiler `slice2cs` to create C# source code and compile the generated C# source code with a C# compiler into a DLL that contains the compiled generated code for your Slice definitions. Your Visual Basic application then links with this DLL and the Ice for .NET DLL (`Ice.dll`).

This approach works not only with Visual Basic, but with any language that targets the .NET run time. However, ZeroC does not provide support for languages other than C# and Visual Basic.

The following illustration demonstrates this development process:

Developing a Visual Basic application with Ice.

Compiling a Slice Definition for Visual Basic

The first step in creating our VB application is to compile our [Slice definition](#) to generate proxies and skeletons. You can compile the definition as follows:

```
> mkdir generated
> slice2cs --output-dir generated Printer.ice
```

The `--output-dir` option instructs the compiler to place the generated files into the `generated` directory. This avoids cluttering the working directory with the generated files. The `slice2cs` compiler produces a single source file, `Printer.cs`, from this definition. The exact contents of this file do not concern us for now — it contains the generated code that corresponds to the `Printer` interface we defined in `Printer.ice`.

We now need to compile this generated code into a DLL:

```
> csc /reference:Ice.dll /lib:%ICE_HOME%\bin /t:library /out:Printer.dll
generated\Printer.cs
```

This creates a DLL called `Printer.dll` that contains the code we generated from the Slice definitions.

Writing and Compiling a Server in Visual Basic

To implement our `Printer` interface, we must create a servant class. By convention, a servant class uses the name of its interface with an `I`-suffix, so our servant class is called `PrinterI` and placed into a source file `Server.vb`:

```

                                Visual Basic
Imports System
Imports Demo

Public Class PrinterI
    Inherits PrinterDisp_

    Public Overloads Overrides Sub printString( _
                                   ByVal s As String, _
                                   ByVal current As Ice.Current)
        Console.WriteLine(s)
    End Sub

End Class
```

The `PrinterI` class inherits from a base class called `PrinterDisp_`, which is generated by the `slice2cs` compiler. The base class is abstract and contains a `printString` method that accepts a string for the printer to print and a parameter of type `Ice.Current`. (For now we will ignore the `Ice.Current` parameter.) Our implementation of the `printString` method simply writes its argument to the terminal.

The remainder of the server code follows in `Server.vb` and is shown in full here:

Visual Basic

Module Server

```

Public Sub Main(ByVal args() As String)

    Dim status As Integer = 0
    Dim ic As Ice.Communicator = Nothing
    Try
        ic = Ice.Util.initialize(args)
        Dim adapter As Ice.ObjectAdapter = _
            ic.createObjectAdapterWithEndpoints("SimplePrinterAdapt
er", "default -p 10000")
        Dim obj As Ice.Object = New PrinterI
        adapter.add(obj, ic.stringToIdentity("SimplePrinter"))
        adapter.activate()
        ic.waitForShutdown()
    Catch e As Exception
        Console.Error.WriteLine(e)
        status = 1
    End Try
    If Not ic Is Nothing Then
        ' Clean up
        ,
        Try
            ic.destroy()
        Catch e As Exception
            Console.Error.WriteLine(e)
            status = 1
        End Try
    End If
    Environment.Exit(status)
End Sub

End module

```

Note the general structure of the code:

Visual Basic

Module Server

```

Public Sub Main(ByVal args() As String)

    Dim status As Integer = 0
    Dim ic As Ice.Communicator = Nothing
    Try

        ' Server implementation here...

    Catch e As Exception
        Console.Error.WriteLine(e)
        status = 1
    End Try
    If Not ic Is Nothing Then
        ' Clean up
        '
        Try
            ic.destroy()
        Catch e As Exception
            Console.Error.WriteLine(e)
            status = 1
        End Try
    End If
    Environment.Exit(status)
End Sub

End module

```

The body of `Main` contains a `Try` block in which we place all the server code, followed by a `Catch` block. The catch block catches all exceptions that may be thrown by the code; the intent is that, if the code encounters an unexpected run-time exception anywhere, the stack is unwound all the way back to `Main`, which prints the exception and then returns failure to the operating system.

Before the code exits, it destroys the communicator (if one was created successfully). Doing this is essential in order to correctly finalize the Ice run time: the program *must* call `destroy` on any communicator it has created; otherwise, undefined behavior results.

The body of our `Try` block contains the actual server code:

Visual Basic

```

ic = Ice.Util.initialize(args)
Dim adapter As Ice.ObjectAdapter = _
    ic.createObjectAdapterWithEndpoints("SimplePrinterAdapter", "default -p 10000")
Dim obj As Ice.Object = New PrinterI
adapter.add(obj, ic.stringToIdentity("SimplePrinter"))
adapter.activate()
ic.waitForShutdown()

```

The code goes through the following steps:

1. We initialize the Ice run time by calling `Ice.Util.initialize`. (We pass `args` to this call because the server may have command-line arguments that are of interest to the run time; for this example, the server does not require any command-line arguments.) The call to `initialize` returns an `Ice::Communicator` reference, which is the main object in the Ice run time.
2. We create an object adapter by calling `createObjectAdapterWithEndpoints` on the `Communicator` instance. The arguments we pass are `"SimplePrinterAdapter"` (which is the name of the adapter) and `"default -p 10000"`, which instructs the adapter to listen for incoming requests using the default protocol (TCP/IP) at port number 10000.
3. At this point, the server-side run time is initialized and we create a servant for our `Printer` interface by instantiating a `PrinterI` object.
4. We inform the object adapter of the presence of a new servant by calling `add` on the adapter; the arguments to `add` are the servant we have just instantiated, plus an identifier. In this case, the string `"SimplePrinter"` is the name of the servant. (If we had multiple printers, each would have a different name or, more correctly, a different *object identity*.)
5. Next, we activate the adapter by calling its `activate` method. (The adapter is initially created in a holding state; this is useful if we have many servants that share the same adapter and do not want requests to be processed until after all the servants have been instantiated.)
6. Finally, we call `waitForShutdown`. This call suspends the calling thread until the server implementation terminates, either by making a call to shut down the run time, or in response to a signal. (For now, we will simply interrupt the server on the command line when we no longer need it.)

Note that, even though there is quite a bit of code here, that code is essentially the same for all servers. You can put that code into a helper class and, thereafter, will not have to bother with it again. (Ice provides such a helper class, called `Ice.Application`.) As far as actual application code is concerned, the server contains only a few lines: ten lines for the definition of the `PrinterI` class, plus three lines to instantiate a `PrinterI` object and register it with the object adapter.

We can compile the server code as follows:

```

> vbc /reference:Ice.dll /libpath:%ICE_HOME%\bin /reference:Printer.dll
/out:server.exe Server.vb

```

This compiles our application code and links it with the Ice run time and the DLL we generated earlier. We assume that the `ICE_HOME` environment variable is set to the top-level directory containing the Ice run time. (For example, if you have installed Ice in `C:\Ice`, set `ICE_HOME` to that path.)

Writing and Compiling a Client in Visual Basic

The client code, in `Client.vb`, looks very similar to the server. Here it is in full:

Visual Basic

```
Imports System
Imports Demo

Module Client

    Public Sub Main(ByVal args() As String)
        Dim status As Integer = 0
        Dim ic As Ice.Communicator = Nothing
        Try
            ic = Ice.Util.initialize(args)
            Dim obj As Ice.ObjectPrx = ic.stringToProxy("SimplePrinter:
default -p 10000")
            Dim printer As PrinterPrx = PrinterPrxHelper.checkedCast(obj)

            If printer Is Nothing Then
                Throw New ApplicationException("Invalid proxy")
            End If

            printer.printString("Hello World!")
        Catch e As Exception
            Console.Error.WriteLine(e)
            status = 1
        End Try
        If Not ic Is Nothing Then
            ' Clean up
            '
            Try
                ic.destroy()
            Catch e As Exception
                Console.Error.WriteLine(e)
                status = 1
            End Try
        End If
        Environment.Exit(status)
    End Sub

End Module
```

Note that the overall code layout is the same as for the server: we use the same `Try` and `Catch` blocks to deal with errors. The code in the `Try` block does the following:

1. As for the server, we initialize the Ice run time by calling `Ice.Util.initialize`.
2. The next step is to obtain a proxy for the remote printer. We create a proxy by calling `stringToProxy` on the communicator, with the string `"SimplePrinter:default -p 10000"`. Note that the string contains the object identity and the port number that were used by the server. (Obviously, hard-coding object identities and port numbers into our applications is a bad idea, but it will do for now; we will see more architecturally sound ways of doing this when we discuss [IceGrid](#).)
3. The proxy returned by `stringToProxy` is of type `Ice.ObjectPrx`, which is at the root of the inheritance tree for interfaces and classes. But to actually talk to our printer, we need a proxy for a `Printer` interface, not an `Object` interface. To do this, we need to do a down-cast by calling `PrinterPrxHelper.checkedCast`. A checked cast sends a message to the server, effectively asking

"is this a proxy for a `Printer` interface?" If so, the call returns a proxy of type `Demo::Printer`; otherwise, if the proxy denotes an interface of some other type, the call returns null.

4. We test that the down-cast succeeded and, if not, throw an error message that terminates the client.
5. We now have a live proxy in our address space and can call the `printString` method, passing it the time-honored "Hello World!" string. The server prints that string on its terminal.

Compiling the client looks much the same as for the server:

```
> vbc /reference:Ice.dll /libpath:%ICE_HOME%\bin /reference:Printer.dll
/out:client.exe Client.vb
```

Running Client and Server in Visual Basic

To run client and server, we first start the server in a separate window:

```
> server.exe
```

At this point, we won't see anything because the server simply waits for a client to connect to it. We run the client in a different window:

```
> client.exe
>
```

The client runs and exits without producing any output; however, in the server window, we see the "Hello World!" that is produced by the printer. To get rid of the server, we interrupt it on the command line for now. (We will see cleaner ways to terminate a server in our discussion of [Ice.Application](#).)

If anything goes wrong, the client will print an error message. For example, if we run the client without having first started the server, we get something like the following:

```
Ice.ConnectionRefusedException
  error = 0
  at IceInternal.ProxyFactory.checkRetryAfterException(LocalException
ex, Reference ref, Int32 cnt)
  at Ice.ObjectPrxHelperBase.handleException__(ObjectDel_ delegate, Lo
calException ex, Int32 cnt)
  at Ice.ObjectPrxHelperBase.ice_isA(String id__, Dictionary`2 context
__, Boolean explicitContext__)
  at Ice.ObjectPrxHelperBase.ice_isA(String id__)
  at Demo.PrinterPrxHelper.checkedCast(ObjectPrx b)
  at Client.Main(String[] args)
Caused by: System.ComponentModel.Win32Exception: No connection could be
made because the target machine actively refused
it
```

Note that, to successfully run client and server, the VB run time must be able to locate the `Ice.dll` library. (Under Windows, one way to ensure this is to copy the library into the current directory. Please consult the documentation for your VB run time to see how it locates libraries.)

The Slice Language

Here, we present the Slice language. Slice (Specification Language for Ice) is the fundamental abstraction mechanism for separating object interfaces from their implementations. Slice establishes a contract between client and server that describes the types and object interfaces used by an application. This description is independent of the implementation language, so it does not matter whether the client is written in the same language as the server.

Even though Slice is an acronym, it is pronounced as a single syllable, like a slice of bread.

Slice definitions are compiled for a particular implementation language by a compiler. The compiler translates the language-independent definitions into language-specific type definitions and APIs. These types and APIs are used by the developer to provide application functionality and to interact with Ice. The translation algorithms for various implementation languages are known as *language mappings*. Currently, Ice defines language mappings for C++, Java, C#, Python, Objective-C, Ruby, and PHP.

Because Slice describes interfaces and types (but not implementations), it is a purely declarative language; there is no way to write executable statements in Slice.

Slice definitions focus on object interfaces, the operations supported by those interfaces, and exceptions that may be raised by operations. In addition, Slice offers features for [object persistence](#). This requires quite a bit of supporting machinery; in particular, much of Slice is concerned with the definition of data types. This is because data can be exchanged between client and server only if their types are defined in Slice. You cannot exchange arbitrary C++ data between client and server because it would destroy the language independence of Ice. However, you can always create a Slice type definition that corresponds to the C++ data you want to send, and then you can transmit the Slice type.

We present the full syntax and semantics of Slice here. Because much of Slice is based on C++ and Java, we focus on those areas where Slice differs from C++ or Java or constrains the equivalent C++ or Java feature in some way. Slice features that are identical to C++ and Java are mentioned mostly by example.

Slice Compilation

On this page:

- [Compilation](#)
- [Single Development Environment for Client and Server](#)
- [Different Development Environments for Client and Server](#)

Compilation

A Slice compiler produces source files that must be combined with application code to produce client and server executables.

The outcome of the development process is a client executable and a server executable. These executables can be deployed anywhere, whether the target environments use the same or different operating systems and whether the executables are implemented using the same or different languages. The only constraint is that the host machines must provide the necessary run-time environment, such as any required dynamic libraries, and that connectivity can be established between them.

Single Development Environment for Client and Server

The figure below shows the situation when both client and server are developed in C++. The Slice compiler generates two files from a Slice definition in a source file `Printer.ice`: a header file (`Printer.h`) and a source file (`Printer.cpp`)

Development process if client and server share the same development environment.

- The `Printer.h` header file contains definitions that correspond to the types used in the Slice definition. It is included in the source code of both client and server to ensure that client and server agree about the types and interfaces used by the application.
- The `Printer.cpp` source file provides an API to the client for sending messages to remote objects. The client source code (`Client`

`t.cpp`, written by the client developer) contains the client-side application logic. The generated source code and the client code are compiled and linked into the client executable.

The `Printer.cpp` source file also contains source code that provides an up-call interface from the Ice run time into the server code written by the developer and provides the connection between the networking layer of Ice and the application code. The server implementation file (`Server.cpp`, written by the server developer) contains the server-side application logic (the object implementations, properly termed *servants*). The generated source code and the implementation source code are compiled and linked into the server executable.

Both client and server also link with an Ice library that provides the necessary run-time support.

You are not limited to a single implementation of a client or server. For example, you can build multiple servers, each of which implements the same interfaces but uses different implementations (for example, with different performance characteristics). Multiple such server implementations can coexist in the same system. This arrangement provides one fundamental scalability mechanism in Ice: if you find that a server process starts to bog down as the number of objects increases, you can run an additional server for the same interfaces on a different machine. Such *federated* servers provide a single logical service that is distributed over a number of processes on different machines. Each server in the federation implements the same interfaces but hosts different object instances. (Of course, federated servers must somehow ensure consistency of any databases they share across the federation.)

Ice also provides support for *replicated* servers. Replication permits multiple servers to each implement the same set of object instances. This improves performance and scalability (because client load can be shared over a number of servers) as well as redundancy (because each object is implemented in more than one server).

Different Development Environments for Client and Server

Client and server cannot share any source or binary components if they are developed in different languages. For example, a client written in Java cannot include a C++ header file.

This figure shows the situation when a client written in Java and the corresponding server is written in C++. In this case, the client and server developers are completely independent, and each uses his or her own development environment and language mapping. The only link between client and server developers is the Slice definition each one uses.

Development process for different development environments.

For Java, the slice compiler creates a number of files whose names depend on the names of various Slice constructs. (These files are collectively referred to as `*.java` in the above figure.)

Slice Source Files

Slice defines a number of rules for the naming and contents of Slice source files.

On this page:

- [File Naming](#)
- [File Format](#)
- [Preprocessing](#)
 - [Detecting Ice Versions](#)
 - [Detecting Slice Compilers](#)
- [Definition Order](#)

File Naming

Files containing Slice definitions must end in a `.ice` file extension, for example, `Clock.ice` is a valid file name. Other file extensions are rejected by the compilers.

For case-insensitive file systems (such as DOS), the file extension may be written as uppercase or lowercase, so `Clock.ICE` is legal. For case-sensitive file systems (such as Unix), `Clock.ICE` is illegal. (The extension must be in lowercase.)

File Format

Slice is a free-form language so you can use spaces, horizontal and vertical tab stops, form feeds, and newline characters to lay out your code in any way you wish. (White space characters are token separators). Slice does not attach semantics to the layout of a definition. You may wish to follow the style we have used for the Slice examples throughout this book.

Slice files can be ASCII text files or use the UTF-8 character encoding with a byte order marker (BOM) at the beginning of each file. However, Slice identifiers are limited to ASCII letters and digits; non-ASCII letters can appear only in comments and string literals.

Preprocessing

Slice supports the same preprocessor directives as C++, so you can use directives such as `#include` and macro definitions. However, Slice permits `#include` directives only at the beginning of a file, before any Slice definitions.

If you use `#include` directives, it is a good idea to protect them with guards to prevent double inclusion of a file:

Slice
<pre>// File Clock.ice #ifndef _CLOCK_ICE #define _CLOCK_ICE // #include directives here... // Definitions here... #endif _CLOCK_ICE</pre>

The following `#pragma` directive offers a simpler way to achieve the same result:

Slice

```
// File Clock.ice
#pragma once

// #include directives here...
// Definitions here...
```

`#include` directives permit a Slice definition to use types defined in a different source file. The Slice compilers parse all of the code in a source file, including the code in subordinate `#include` files. However, the compilers generate code only for the top-level file(s) nominated on the command line. You must separately compile subordinate `#include` files to obtain generated code for all the files that make up your Slice definition.

Note that you should avoid `#include` with double quotes:

Slice

```
#include "Clock.ice" // Not recommended!
```

While double quotes will work, the directory in which the preprocessor tries to locate the file can vary depending on the operating system, so the included file may not always be found where you expect it. Instead, use angle brackets (<>); you can control which directories are searched for the file with the `-I` option of the Slice compiler.

Also note that, if you include a path separator in a `#include` directive, you must use a forward slash:

Slice

```
#include <SliceDefs/Clock.ice> // OK
```

You cannot use a backslash in `#include` directives:

Slice

```
#include <SliceDefs\Clock.ice> // Illegal
```

Detecting Ice Versions

As of Ice 3.5, the Slice compilers define the preprocessor macro `__ICE_VERSION__` with a numeric representation of the Ice version. The value of this macro is the same as the C++ macro `ICE_INT_VERSION`. You can use this macro to make your Slice definitions backward-compatible with older Ice releases, while still taking advantage of newer Ice features when possible. For example, the Slice definition shown below makes use of custom enumerator values:

Slice

```

#if defined(__ICE_VERSION__) && __ICE_VERSION__ >= 030500
enum Fruit { Apple, Pear = 3, Orange };
#else
enum Fruit { Apple, Pear, Orange };
#endif

```

Although this example is intended to show how to use the `ICE_VERSION` macro, it also highlights a potential pitfall that you must be aware of when trying to maintain backward compatibility: the two definitions of `Fruit` are not wire-compatible.

Detecting Slice Compilers

As of Ice 3.5, each Slice compiler defines its own macro so that you can customize your Slice code for certain language mappings. The following macros are defined by their respective compilers:

```

__SLICE2JAVA__
__SLICE2JS__
__SLICE2CPP__
__SLICE2CS__
__SLICE2PY__
__SLICE2PHP__
__SLICE2RB__
__SLICE2FREEZE__
__SLICE2FREEZEJ__
__SLICE2HTML__
__TRANSFORMDB__
__DUMPDB__

```

For example, .NET developers may elect to avoid the use of default values for structure members because the presence of default values changes the C# mapping of the structure from `struct` to `class`:

Slice

```

struct Record {
    // ...
#if __SLICE2CS__
    bool active;
#else
    bool active = true;
#endif
};

```

Definition Order

Slice constructs, such as modules, interfaces, or type definitions, can appear in any order you prefer. However, identifiers must be declared before they can be used.

- [Using the Slice Compilers](#)

Lexical Rules

Slice's lexical rules are very similar to those of C++ and Java, except for some differences for identifiers.

On this page:

- [Comments](#)
- [Keywords](#)
- [Identifiers](#)
 - [Case Sensitivity](#)
 - [Identifiers That Are Keywords](#)
 - [Escaped Identifiers](#)
 - [Reserved Identifiers](#)

Comments

Slice definitions permit both the C and the C++ style of writing comments:

Slice
<pre> /* * C-style comment. */ // C++-style comment extending to the end of this line.</pre>

Keywords

Slice uses a number of [keywords](#), which must be spelled in lowercase. For example, `class` and `dictionary` are keywords and must be spelled as shown. There are two exceptions to this lowercase rule: `Object` and `LocalObject` are keywords and must be capitalized as shown.

Identifiers

Identifiers begin with an alphabetic character followed by any number of alphabetic characters or digits. Underscores are also permitted in identifiers with the following limitations:

- an identifier cannot begin or end with an underscore
- an identifier cannot contain multiple consecutive underscores

Given these rules, the identifier `get_account_name` is legal but not `_account`, `account_`, or `get__account`.

Slice identifiers are restricted to the ASCII range of alphabetic characters and cannot contain non-English letters, such as Å. (Supporting non-ASCII identifiers would make it very difficult to map Slice to target languages that lack support for this feature.)

Case Sensitivity

Identifiers are case-insensitive but must be capitalized consistently. For example, `TimeOfDay` and `TIMEOFDAY` are considered the same identifier within a naming scope. However, Slice enforces consistent capitalization. After you have introduced an identifier, you must capitalize it consistently throughout; otherwise, the compiler will reject it as illegal. This rule exists to permit mappings of Slice to languages that ignore case in identifiers as well as to languages that treat differently capitalized identifiers as distinct.

Identifiers That Are Keywords

You can define Slice identifiers that are keywords in one or more implementation languages. For example, `switch` is a perfectly good Slice

identifier but is a C++ and Java keyword. Each language mapping defines rules for dealing with such identifiers. The solution typically involves using a prefix to map away from the keyword. For example, the Slice identifier `switch` is mapped to `_cpp_switch` in C++ and `_switch` in Java.

The rules for dealing with keywords can result in hard-to-read source code. Identifiers such as `native`, `throw`, or `export` will clash with C++ or Java keywords (or both). To make life easier for yourself and others, try to avoid Slice identifiers that are implementation language keywords. Keep in mind that mappings for new languages may be added to Ice in the future. While it is not reasonable to expect you to compile a list of all keywords in all popular programming languages, you should make an attempt to avoid at least common keywords. Slice identifiers such as `self`, `import`, and `while` are definitely not a good idea.

Escaped Identifiers

It is possible to use a Slice keyword as an identifier by prefixing the keyword with a backslash, for example:

Slice	
<code>struct dictionary {</code>	<code>// Error!</code>
<code> // ...</code>	
<code>};</code>	
<code>struct \dictionary {</code>	<code>// OK</code>
<code> // ...</code>	
<code>};</code>	
<code>struct \foo {</code>	<code>// Legal, same as "struct foo"</code>
<code> // ...</code>	
<code>};</code>	

The backslash escapes the usual meaning of a keyword; in the preceding example, `\dictionary` is treated as the identifier `dictionary`. The escape mechanism exists to permit keywords to be added to the Slice language over time with minimal disruption to existing specifications: if a pre-existing specification happens to use a newly-introduced keyword, that specification can be fixed by simply prepending a backslash to the new keyword. Note that, as a matter of style, you should avoid using Slice keywords as identifiers (even though the backslash escapes allow you to do this).

It is legal (though redundant) to precede an identifier that is not a keyword with a backslash — the backslash is ignored in that case.

Reserved Identifiers

Slice reserves the identifier `Ice` and all identifiers beginning with `Ice` (in any capitalization) for the Ice implementation. For example, if you try to define a type named `Icecream`, the Slice compiler will issue an error message.

You can suppress this behavior by using the `--ice` compiler option, which enables definition of identifiers beginning with `Ice`. However, do not use this option unless you are compiling the Slice definitions for the Ice run time itself.

Slice identifiers ending in any of the suffixes `Helper`, `Holder`, `Prx`, and `Ptr` are also reserved. These endings are used by the various language mappings and are reserved to prevent name clashes in the generated code.

Modules

On this page:

- [Modules Reduce Clutter](#)
- [Modules are Mandatory](#)
- [Reopening Modules](#)
- [Module Mapping](#)
- [The Ice Module](#)

Modules Reduce Clutter

A common problem in large systems is pollution of the global namespace: over time, as isolated systems are integrated, name clashes become quite likely. Slice provides the `module` construct to alleviate this problem:

Slice

```

module ZeroC {
  module Client {
    // Definitions here...
  };
  module Server {
    // Definitions here...
  };
};

```

A module can contain any legal Slice construct, including other module definitions. Using modules to group related definitions together avoids polluting the global namespace and makes accidental name clashes quite unlikely. (You can use a well-known name, such as a company or product name, as the name of the outermost module.)

Modules are Mandatory

Slice requires all definitions to be nested inside a module, that is, you cannot define anything other than a module at global scope. For example, the following is illegal:

Slice

```

interface I { // Error: only modules can appear at global scope
  // ...
};

```

Definitions at global scope are prohibited because they cause problems with some implementation languages (such as Python, which does not have a true global scope).

Throughout the Ice manual, you will occasionally see Slice definitions that are not nested inside a module. This is to keep the examples short and free of clutter. Whenever you see such a definition, assume that it is nested in a module.

Reopening Modules

Modules can be reopened:

Slice

```

module ZeroC {
    // Definitions here...
};

// Possibly in a different source file:

module ZeroC { // OK, reopened module
    // More definitions here...
};

```

Reopened modules are useful for larger projects: they allow you to split the contents of a module over several different [source files](#). The advantage of doing this is that, when a developer makes a change to one part of the module, only files dependent on the changed part need be recompiled (instead of having to recompile all files that use the module).

Module Mapping

Modules map to a corresponding scoping construct in each programming language. (For example, for C++ and C#, Slice modules map to namespaces whereas, for Java, they map to packages.) This allows you to use an appropriate C++ `using` or Java `import` declaration to avoid excessively long identifiers in your source code.

The Ice Module

APIs for the Ice run time, apart from a small number of language-specific calls that cannot be expressed in Ice, are defined in the `Ice` module. In other words, most of the Ice API is actually expressed as Slice definitions. The advantage of doing this is that a single Slice definition is sufficient to define the API for the Ice run time for all supported languages. The respective language mapping rules then determine the exact shape of each Ice API for each implementation language.

We will incrementally explore the contents of the `Ice` module throughout this manual.

Basic Types

On this page:

- [Built-In Basic Types](#)
- [Integer Types](#)
- [Floating-Point Types](#)
- [Strings](#)
- [Booleans](#)
- [Bytes](#)

Built-In Basic Types

Slice provides a number of built-in basic types, as shown in this table:

Type	Range of Mapped Type	Size of Mapped Type
<code>bool</code>	false or true	1bit
<code>byte</code>	-128-127 or 0-255 ^a	8 bits
<code>short</code>	-2^{15} to $2^{15}-1$	16 bits
<code>int</code>	-2^{31} to $2^{31}-1$	32 bits
<code>long</code>	-2^{63} to $2^{63}-1$	64 bits
<code>float</code>	IEEE single-precision	32 bits
<code>double</code>	IEEE double-precision	64 bits
<code>string</code>	All Unicode characters, excluding the character with all bits zero.	Variable-length

^a The range depends on whether `byte` maps to a signed or an unsigned type.

All the basic types (except `byte`) are subject to changes in representation as they are transmitted between clients and servers. For example, a `long` value is byte-swapped when sent from a little-endian to a big-endian machine. Similarly, strings undergo translation in representation if they are sent, for example, from an EBCDIC to an ASCII implementation, and the characters of a string may also change in size. (Not all architectures use 8-bit characters). However, these changes are transparent to the programmer and do exactly what is required.

Integer Types

Slice provides integer types `short`, `int`, and `long`, with 16-bit, 32-bit, and 64-bit ranges, respectively. Note that, on some architectures, any of these types may be mapped to a native type that is wider. Also note that no unsigned types are provided. (This choice was made because unsigned types are difficult to map into languages without native unsigned types, such as Java. In addition, the unsigned integers add little value to a language. (See [1] for a good treatment of the topic.)

Floating-Point Types

These types follow the IEEE specification for single- and double-precision floating-point representation [2]. If an implementation cannot support IEEE format floating-point values, the Ice run time converts values into the native floating-point representation (possibly at a loss of precision or even magnitude, depending on the capabilities of the native floating-point format).

Strings

Slice strings use the Unicode character set. The only character that cannot appear inside a string is the zero character.

This decision was made as a concession to C++, with which it becomes impossibly difficult to manipulate strings with embedded zero characters using standard library routines, such as `strlen` or `strcat`.

The Slice data model does not have the concept of a null string (in the sense of a C++ null pointer). This decision was made because null strings are difficult to map to languages without direct support for this concept (such as Python). Do not design interfaces that depend on a

null string to indicate "not there" semantics. If you need the notion of an optional string, use a [class](#), a [sequence](#) of strings, or use an empty string to represent the idea of a null string. (Of course, the latter assumes that the empty string is not otherwise used as a legitimate string value by your application.)

Booleans

Boolean values can have only the values `false` and `true`. Language mappings use the corresponding native boolean type if one is available.

Bytes

The Slice type `byte` is an (at least) 8-bit type that is guaranteed not to undergo any changes in representation as it is transmitted between address spaces. This guarantee permits exchange of binary data such that it is not tampered with in transit. All other Slice types are subject to changes in representation during transmission.

User-Defined Types

In addition to providing the built-in basic types, Slice allows you to define complex types: enumerations, structures, sequences, and dictionaries.

Topics

- [Enumerations](#)
- [Structures](#)
- [Sequences](#)
- [Dictionaries](#)

Enumerations

Enumeration Syntax and Semantics

A Slice enumerated type definition looks identical to C++:

```
enum Fruit { Apple, Pear, Orange };
```

This definition introduces a type named `Fruit` that becomes a new type in its own right. Slice guarantees that the values of enumerators increase from left to right, so `Apple` compares less than `Pear` in every language mapping. By default, the first enumerator has a value of zero, with sequentially increasing values for subsequent enumerators.

Slice enumerator symbols enter the enclosing namespace scope, so the following is illegal:

```
enum Fruit { Apple, Pear, Orange };
enum ComputerBrands { Apple, IBM, Sun, HP }; // Apple redefined
```

The example below shows how to refer to an enumerator from a different scope:

```
module M {
    enum Color { red, green, blue };
};
module N {
    struct Pixel {
        M::Color c = M::blue;
    };
};
```

Slice does not permit empty enumerations.

Custom Enumerator Values

Slice also permits you to assign custom values to enumerators:

```
const int PearValue = 7;
enum Fruit { Apple = 0, Pear = PearValue, Orange };
```

Custom values must be unique and non-negative, and may refer to Slice constants of integer types. If no custom value is specified for an enumerator, its value is one greater than the enumerator that immediately precedes it. In the example above, `Orange` has the value 8.

The maximum value for an enumerator value is the same as the maximum value for `int`, $2^{31} - 1$.

Slice does not require custom enumerator values to be declared in increasing order:

```
Slice  
enum Fruit { Apple = 5, Pear = 3, Orange = 1 }; // Legal
```

Note however that when there is an inconsistency between the declaration order and the numerical order of the enumerators, the behavior of comparison operations may vary between language mappings.

For an application that is still using version 1.0 of the [Ice encoding](#), changing the definition of an enumerated type may break backward compatibility with existing applications. For more information, please refer to the encoding rules for enumerated types.

Structures

Slice supports structures containing one or more named members of arbitrary type, including user-defined complex types. For example:

```

Slice

struct TimeOfDay {
    short hour;           // 0 - 23
    short minute;        // 0 - 59
    short second;        // 0 - 59
};
```

As in C++, this definition introduces a new type called `TimeOfDay`. Structure definitions form a namespace, so the names of the structure members need to be unique only within their enclosing structure.

Data member definitions using a named type are the only construct that can appear inside a structure. It is impossible to, for example, define a structure inside a structure:

```

Slice

struct TwoPoints {
    struct Point {      // Illegal!
        short x;
        short y;
    };
    Point coord1;
    Point coord2;
};
```

This rule applies to Slice in general: type definitions cannot be nested (except for [modules](#), which do support nesting). The reason for this rule is that nested type definitions can be difficult to implement for some target languages and, even if implementable, greatly complicate the scope resolution rules. For a specification language, such as Slice, nested type definitions are unnecessary – you can always write the above definitions as follows (which is stylistically cleaner as well):

```

Slice

struct Point {
    short x;
    short y;
};

struct TwoPoints {      // Legal (and cleaner!)
    Point coord1;
    Point coord2;
};
```

You can specify a default value for a data member that has one of the following types:

- An **integral** type (byte, short, int, long)
- A **floating point** type (float or double)
- `string`
- `bool`
- `enum`

For example:

Slice

```
struct Location {
    string name;
    Point pt;
    bool display = true;
    string source = "GPS";
};
```

The legal syntax for literal values is the same as for Slice [constants](#), and you may also use a constant as a default value. The language mapping guarantees that data members are initialized to their declared default values using a language-specific mechanism.

Sequences

On this page:

- [Sequence Syntax and Semantics](#)
- [Using Sequences for Optional Values](#)

Sequence Syntax and Semantics

Sequences are variable-length collections of elements:

Slice

```
sequence<Fruit> FruitPlatter;
```

A sequence can be empty—that is, it can contain no elements, or it can hold any number of elements up to the memory limits of your platform.

Sequences can contain elements that are themselves sequences. This arrangement allows you to create lists of lists:

Slice

```
sequence<FruitPlatter> FruitBanquet;
```

Sequences are used to model a variety of collections, such as vectors, lists, queues, sets, bags, or trees. (It is up to the application to decide whether or not order is important; by discarding order, a sequence serves as a set or bag.)

Using Sequences for Optional Values

Using a sequence to model an optional value is unnecessary with the introduction of [optional data members](#) and [optional parameters](#) in Ice 3.5.

One particular use of sequences has become idiomatic, namely, the use of a sequence to indicate an optional value. For example, we might have a `Part` structure that records the details of the parts that go into a car. The structure could record things such as the name of the part, a description, weight, price, and other details. Spare parts commonly have a serial number, which we can model as a `long` value. However, some parts, such as simple screws, often do not have a serial number, so what are we supposed to put into the serial number field of a screw? There are a number of options for dealing with this situation:

- **Use a sentinel value, such as zero, to indicate the "no serial number" condition.**
This approach is workable, provided that a sentinel value is actually available. While it may seem unlikely that anyone would use a serial number of zero for a part, it is not impossible. And, for other values, such as a temperature value, all values in the range of their type can be legal, so no sentinel value is available.
- **Change the type of the serial number from `long` to `string`.**
Strings come with their own built-in sentinel value, namely the empty string, so we can use an empty string to indicate the "no serial number" case. This is workable but not ideal: we should not have to change the natural data type of something to `string` just so we get a sentinel value.
- **Add an indicator as to whether the contents of the serial number are valid:**

Slice

```
struct Part {
    string name;
    string description;
    // ...
    bool   serialIsValid; // true if part has serial number
    long   serialNumber;
};
```

This is guaranteed to get you into trouble eventually: sooner or later, some programmer will forget to check whether the serial number is valid before using it and create havoc.

- **Use a sequence to model the optional field.**

This technique uses the following convention:

Slice

```
sequence<long> SerialOpt;

struct Part {
    string   name;
    string   description;
    // ...
    SerialOpt serialNumber; // optional: zero or one element
};
```

By convention, the `Opt` suffix is used to indicate that the sequence is used to model an optional value. If the sequence is empty, the value is obviously not there; if it contains a single element, that element is the value. The obvious drawback of this scheme is that someone could put more than one element into the sequence. This could be rectified by adding a special-purpose Slice construct for optional values. However, optional values are not used frequently enough to justify the complexity of adding a dedicated language feature. (As we will see in [Classes](#), you can also use class hierarchies to model optional fields.)

- [Classes](#)

Dictionaries

On this page:

- [Dictionary Syntax and Semantics](#)
- [Allowable Types for Dictionary Keys and Values](#)

Dictionary Syntax and Semantics

A dictionary is a mapping from a key type to a value type.

For example:

Slice
<pre>struct Employee { long number; string firstName; string lastName; }; dictionary<long, Employee> EmployeeMap;</pre>

This definition creates a dictionary named `EmployeeMap` that maps from an employee number to a structure containing the details for an employee. Whether or not the key type (the employee number, of type `long` in this example) is also part of the value type (the `Employee` structure in this example) is up to you — as far as Slice is concerned, there is no need to include the key as part of the value.

Dictionaries can be used to implement sparse arrays, or any lookup data structure with non-integral key type. Even though a sequence of structures containing key-value pairs could be used to model the same thing, a dictionary is more appropriate:

- A dictionary clearly signals the intent of the designer, namely, to provide a mapping from a domain of values to a range of values. (A sequence of structures of key-value pairs does not signal that same intent as clearly.)
- At the programming language level, sequences are implemented as vectors (or possibly lists), that is, they are not well suited to model sparsely populated domains and require a linear search to locate an element with a particular value. On the other hand, dictionaries are implemented as a data structure (typically a hash table or red-black tree) that supports efficient searching in $O(\log n)$ average time or better.

Allowable Types for Dictionary Keys and Values

The key type of a dictionary need not be an integral type. For example, we could use the following definition to translate the names of the days of the week:

Slice
<pre>dictionary<string, string> WeekdaysEnglishToGerman;</pre>

The server implementation would take care of initializing this map with the key-value pairs `Monday-Montag`, `Tuesday-Dienstag`, and so on.

The value type of a dictionary can be any Slice type. However, the key type of a dictionary is limited to one of the following types:

- [Integral types](#) (`byte`, `short`, `int`, `long`, `bool`)
- [string](#)

- [enum](#)
- [Structures](#) containing only data members of legal key types

Other complex types, such as dictionaries, and floating-point types (`float` and `double`) cannot be used as the key type. Complex types are disallowed because they complicate the language mappings for dictionaries, and floating-point types are disallowed because representational changes of values as they cross machine boundaries can lead to ill-defined semantics for equality.

Constants and Literals

On this page:

- [Allowable Types for Constants](#)
- [Boolean constants](#)
- [Integer literals](#)
- [Floating-point literals](#)
- [String literals](#)
- [Constant Expressions](#)

Allowable Types for Constants

Slice allows you to define constants for the following types:

- An **integral** type (`bool`, `byte`, `short`, `int`, `long`)
- A **floating point** type (`float` or `double`)
- `string`
- `enum`

Here are a few examples:

Slice	
<code>const bool</code>	<code>AppendByDefault = true;</code>
<code>const byte</code>	<code>LowerNibble = 0x0f;</code>
<code>const string</code>	<code>Advice = "Don't Panic!";</code>
<code>const short</code>	<code>TheAnswer = 42;</code>
<code>const double</code>	<code>PI = 3.1416;</code>
<code>enum Fruit {</code>	<code>Apple, Pear, Orange };</code>
<code>const Fruit</code>	<code>FavoriteFruit = Pear;</code>

The syntax for literals is the same as for C++ and Java (with a few minor exceptions).

Boolean constants

Boolean constants can only be initialized with the keywords `false` and `true`. (You cannot use `0` and `1` to represent `false` and `true`.)

Integer literals

Integer literals can be specified in decimal, octal, or hexadecimal notation.

For example:

Slice	
<code>const byte</code>	<code>TheAnswer = 42;</code>
<code>const byte</code>	<code>TheAnswerInOctal = 052;</code>
<code>const byte</code>	<code>TheAnswerInHex = 0x2A; // or 0x2a</code>

Be aware that, if you interpret `byte` as a number instead of a bit pattern, you may get different results in different languages. For example, for C++, `byte` maps to `unsigned char` whereas, for Java, `byte` maps to `byte`, which is a signed type.

Note that suffixes to indicate long and unsigned constants (l, L, u, U, used by C++) are illegal:

Slice	
<code>const long Wrong = 0u;</code>	<code>// Syntax error</code>
<code>const long WrongToo = 1000000L;</code>	<code>// Syntax error</code>

The value of an integer literal must be within the range of its constant type, as shown in the [Built-In Basic Types](#) table; otherwise the compiler will issue a diagnostic.

Floating-point literals

Floating-point literals use C++ syntax, except that you cannot use an l or L suffix to indicate an extended floating-point constant; however, f and F are legal (but are ignored).

Here are a few examples:

Slice	
<code>const float P1 = -3.14f;</code>	<code>// Integer & fraction, with suffix</code>
<code>const float P2 = +3.1e-3;</code>	<code>// Integer, fraction, and exponent</code>
<code>const float P3 = .1;</code>	<code>// Fraction part only</code>
<code>const float P4 = 1.;</code>	<code>// Integer part only</code>
<code>const float P5 = .9E5;</code>	<code>// Fraction part and exponent</code>
<code>const float P6 = 5e2;</code>	<code>// Integer part and exponent</code>

Floating-point literals must be within the range of the constant type (float or double); otherwise, the compiler will issue a diagnostic.

String literals

String literals support the same escape sequences as C++.

Here are some examples:

Slice

```

const string AnOrdinaryString = "Hello World!";

const string DoubleQuote =    "\"";
const string TwoSingleQuotes = "'\''";    // ' and \' are OK
const string Newline =       "\n";
const string CarriageReturn = "\r";
const string HorizontalTab = "\t";
const string VerticalTab =   "\v";
const string FormFeed =     "\f";
const string Alert =        "\a";
const string Backspace =    "\b";
const string QuestionMark = "\?";
const string Backslash =    "\\";

const string OctalEscape =   "\007";    // Same as \a
const string HexEscape =    "\x07";    // Ditto
const string Universal1 =   "\u0041";   // Same as A
const string Universal2 =   "\U00000041"; // Ditto

```

Note that Slice has no concept of a null string:

Slice

```
const string NullString = 0;    // Illegal!
```

Null strings simply do not exist in Slice and, therefore, do not exist as a legal value for a string anywhere in the Ice platform. The reason for this decision is that null strings do not exist in many programming languages.

Many languages other than C and C++ use a byte array as the internal string representation. Null strings do not exist (and would be very difficult to map) in such languages.

Constant Expressions

A constant definition may also refer to another constant. It is not necessary for both constants to have the same Slice type, but the value of the existing constant must be compatible with the type of the constant being defined.

Consider the examples below:

Slice

```

const int SIZE = 500;

const int DEFAULT_SIZE = SIZE; // OK
const short SHORT_SIZE = SIZE; // OK
const byte BYTE_SIZE = SIZE;   // ERROR

```

The `DEFAULT_SIZE` constant is legal because it has the same type as `SIZE`, and `SHORT_SIZE` is legal because the value of `SIZE` (500) is

within the range of the `Slice short` type. However, `BYTE_SIZE` is illegal because the value of `SIZE` is outside the range of the `byte` type.

Interfaces, Operations, and Exceptions

The central focus of Slice is on defining interfaces, for example:

```

Slice

```

struct TimeOfDay {
 short hour; // 0 - 23
 short minute; // 0 - 59
 short second; // 0 - 59
};

interface Clock {
 TimeOfDay getTime();
 void setTime(TimeOfDay time);
};

```

```

This definition defines an interface type called `clock`. The interface supports two operations: `getTime` and `setTime`. Clients access an object supporting the `clock` interface by invoking an operation on the proxy for the object: to read the current time, the client invokes the `getTime` operation; to set the current time, the client invokes the `setTime` operation, passing an argument of type `TimeOfDay`.

Invoking an operation on a proxy instructs the Ice run time to send a message to the target object. The target object can be in another address space or can be collocated (in the same process) as the caller — the location of the target object is transparent to the client. If the target object is in another (possibly remote) address space, the Ice run time invokes the operation via a remote procedure call; if the target is collocated with the client, the Ice run time bypasses the network stack altogether to deliver the request more efficiently.

You can think of an interface definition as the equivalent of the public part of a C++ class definition or as the equivalent of a Java interface, and of operation definitions as (virtual) member functions. Note that nothing but operation definitions are allowed to appear inside an interface definition. In particular, you cannot define a type, an exception, or a data member inside an interface. This does not mean that your object implementation cannot contain state — it can, but how that state is implemented (in the form of data members or otherwise) is hidden from the client and, therefore, need not appear in the object's interface definition.

An Ice object has exactly one (most derived) Slice interface type (or *class type*). Of course, you can create multiple Ice objects that have the same type; to draw the analogy with C++, a Slice interface corresponds to a C++ class definition, whereas an Ice object corresponds to a C++ class instance (but Ice objects can be implemented in multiple different address spaces).

Ice also provides multiple interfaces via a feature called *facets*.

A Slice interface defines the smallest grain of distribution in Ice: each Ice object has a unique identity (encapsulated in its proxy) that distinguishes it from all other Ice objects; for communication to take place, you must invoke operations on an object's proxy. There is no other notion of an addressable entity in Ice. You cannot, for example, instantiate a Slice structure and have clients manipulate that structure remotely. To make the structure accessible, you must create an interface that allows clients to access the structure.

The partition of an application into interfaces therefore has profound influence on the overall architecture. Distribution boundaries must follow interface (or class) boundaries; you can spread the implementation of interfaces over multiple address spaces (and you can implement multiple interfaces in the same address space), but you cannot implement parts of interfaces in different address spaces.

Operations

On this page:

- [Parameters and Return Values](#)
- [Optional Parameters and Return Values](#)
- [Style of Operation Definition](#)
- [Overloading Operations](#)
- [Idempotent Operations](#)

Parameters and Return Values

An operation definition must contain a return type and zero or more parameter definitions. For example, in the `clock` interface, the `getTime` operation has a return type of `TimeOfDay` and the `setTime` operation has a return type of `void`. You must use `void` to indicate that an operation returns no value — there is no default return type for Slice operations.

An operation can have one or more input parameters. For example, `setTime` accepts a single input parameter of type `TimeOfDay` called `time`. Of course, you can use multiple input parameters:

Slice

```
interface CircadianRhythm {
    void setSleepPeriod(TimeOfDay startTime, TimeOfDay stopTime);
    // ...
};
```

Note that the parameter name (as for Java) is mandatory. You cannot omit the parameter name, so the following is in error:

Slice

```
interface CircadianRhythm {
    void setSleepPeriod(TimeOfDay, TimeOfDay); // Error!
    // ...
};
```

By default, parameters are sent from the client to the server, that is, they are input parameters. To pass a value from the server to the client, you can use an output parameter, indicated by the `out` keyword. For example, an alternative way to define the `getTime` operation in the `clock` interface would be:

Slice

```
void getTime(out TimeOfDay time);
```

This achieves the same thing but uses an output parameter instead of the return value. As with input parameters, you can use multiple output parameters:

Slice

```
interface CircadianRhythm {
    void setSleepPeriod(TimeOfDay startTime, TimeOfDay stopTime);
    void getSleepPeriod(out TimeOfDay startTime,
out TimeOfDay stopTime);
    // ...
};
```

If you have both input and output parameters for an operation, the output parameters must follow the input parameters:

Slice

```
void changeSleepPeriod(    TimeOfDay startTime,
TimeOfDay stopTime,      // OK
                        out TimeOfDay prevStartTime,
out TimeOfDay prevStopTime);

void changeSleepPeriod(out TimeOfDay prevStartTime, out TimeOfDay prevS
topTime, // Error
                        TimeOfDay startTime,
TimeOfDay stopTime);
```

Slice does not support parameters that are both input and output parameters (call by reference). The reason is that, for remote calls, reference parameters do not result in the same savings that one can obtain for call by reference in programming languages. (Data still needs to be copied in both directions and any gains in marshaling efficiency are negligible.) Also, reference (or input-output) parameters result in more complex language mappings, with concomitant increases in code size.

Optional Parameters and Return Values

As of Ice 3.5, an operation's return value and parameters may be declared as *optional* to indicate that a program can leave their values unset. Parameters not declared as optional are known as *required* parameters; a program must supply legal values for all required parameters. In the discussion below, we use *parameter* to refer to input parameters, output parameters, and return values.

A unique, non-negative integer *tag* must be assigned to each optional parameter:

Slice

```
optional(3) bool example(optional(2) string name, out optional(1) int
value);
```

The scope of a tag is limited to its operation and has no effect on other operations.

An operation's signature can include any combination of required and optional parameters, but output parameters still must follow input parameters:

Slice

```
bool example(string name, optional(3) string referrer, out optional(1)
string promo, out int id);
```

Language mappings specify an API for passing optional parameters and testing whether a parameter is present. Refer to the language mapping sections for more details on the optional parameter API.

A well-behaved program must test for the presence of an optional parameter and not assume that it is always set. Dereferencing an unset optional parameter causes a run-time error.

Style of Operation Definition

As you would expect, language mappings follow the style of operation definition you use in Slice: Slice return types map to programming language return types, and Slice parameters map to programming language parameters.

For operations that return only a single value, it is common to return the value from the operation instead of using an out-parameter. This style maps naturally into all programming languages. Note that, if you use an out-parameter instead, you impose a different API style on the client: most programming languages permit the return value of a function to be ignored whereas it is typically not possible to ignore an output parameter.

For operations that return multiple values, it is common to return all values as out-parameters and to use a return type of `void`. However, the rule is not all that clear-cut because operations with multiple output values can have one particular value that is considered more "important" than the remainder. A common example of this is an iterator operation that returns items from a collection one-by-one:

Slice

```
bool next(out RecordType r);
```

The `next` operation returns two values: the record that was retrieved and a Boolean to indicate the end-of-collection condition. (If the return value is `false`, the end of the collection has been reached and the parameter `r` has an undefined value.) This style of definition can be useful because it naturally fits into the way programmers write control structures. For example:

```
while (next(record))
    // Process record...

if (next(record))
    // Got a valid record...
```

Overloading Operations

Slice does not support any form of overloading of operations. For example:

Slice

```
interface CircadianRhythm {
    void modify(TimeOfDay startTime, TimeOfDay endTime);
    void modify(    TimeOfDay startTime,          // Error
                 TimeOfDay endTime,
                 out timeOfDay prevStartTime,
                 out TimeOfDay prevEndTime);
};
```

Operations in the same interface must have different names, regardless of what type and number of parameters they have. This restriction exists because overloaded functions cannot sensibly be mapped to languages without built-in support for overloading.

Name mangling is not an option in this case: while it works fine for compilers, it is unacceptable to humans.

Idempotent Operations

Some operations, such as `getTime` in the `Clock` interface, do not modify the state of the object they operate on. They are the conceptual equivalent of C++ `const` member functions. Similarly, `setTime` does modify the state of the object, but is idempotent. You can indicate this in Slice as follows:

Slice

```
interface Clock {
    idempotent TimeOfDay getTime();
    idempotent void setTime(TimeOfDay time);
};
```

This marks the `getTime` and `setTime` operations as idempotent. An operation is idempotent if two successive invocations of the operation have the same effect as a single invocation. For example, `x = 1;` is an idempotent operation because it does not matter whether it is executed once or twice — either way, `x` ends up with the value 1. On the other hand, `x += 1;` is not an idempotent operation because executing it twice results in a different value for `x` than executing it once. Obviously, any read-only operation is idempotent.

The `idempotent` keyword is useful because it allows the Ice run time to be more aggressive when performing [automatic retries](#) to recover from errors. Specifically, Ice guarantees *at-most-once* semantics for operation invocations:

- For normal (not idempotent) operations, the Ice run time has to be conservative about how it deals with errors. For example, if a client sends an operation invocation to a server and then loses connectivity, there is no way for the client-side run time to find out whether the request it sent actually made it to the server. This means that the run time cannot attempt to recover from the error by re-establishing a connection and sending the request a second time because that could cause the operation to be invoked a second time and violate *at-most-once* semantics; the run time has no option but to report the error to the application.
- For `idempotent` operations, on the other hand, the client-side run time can attempt to re-establish a connection to the server and safely send the failed request a second time. If the server can be reached on the second attempt, everything is fine and the application never notices the (temporary) failure. Only if the second attempt fails need the run time report the error back to the application. (The number of retries can be increased with an Ice configuration parameter.)

- [User Exception Inheritance](#)

User Exception Syntax and Semantics

Looking at the `setTime` operation in the `clock` interface, we find a potential problem: given that the `TimeOfDay` structure uses `short` as the type of each field, what will happen if a client invokes the `setTime` operation and passes a `TimeOfDay` value with meaningless field values, such as `-199` for the minute field, or `42` for the hour? Obviously, it would be nice to provide some indication to the caller that this is meaningless. Slice allows you to define user exceptions to indicate error conditions to the client. For example:

```

Slice

exception Error {}; // Empty exceptions are legal

exception RangeError {
    TimeOfDay errorTime;
    TimeOfDay minTime;
    TimeOfDay maxTime;
};

```

A user exception is much like a structure in that it contains a number of data members. However, unlike structures, exceptions can have zero data members, that is, be empty. Like classes, user exceptions support inheritance and may include [optional data members](#).

Default Values for User Exception Members

You can specify a default value for an exception data member that has one of the following types:

- An [integral type](#) (`byte`, `short`, `int`, `long`)
- A [floating point type](#) (`float` or `double`)
- `string`
- `bool`
- `enum`

For example:

```

Slice

exception RangeError {
    TimeOfDay errorTime;
    TimeOfDay minTime;
    TimeOfDay maxTime;
    string reason = "out of range";
};

```

The legal syntax for literal values is the same as for [Slice constants](#), and you may also use a constant as a default value. The language mapping guarantees that data members are initialized to their declared default values using a language-specific mechanism.

Declaring User Exceptions in Operations

Exceptions allow you to return an arbitrary amount of error information to the client if an error condition arises in the implementation of an operation. Operations use an exception specification to indicate the exceptions that may be returned to the client:

Slice

```
interface Clock {
    idempotent TimeOfDay getTime();
    idempotent void setTime(TimeOfDay time)
        throws RangeError, Error;
};
```

This definition indicates that the `setTime` operation may throw either a `RangeError` or an `Error` user exception (and no other type of exception). If the client receives a `RangeError` exception, the exception contains the `TimeOfDay` value that was passed to `setTime` and caused the error (in the `errorTime` member), as well as the minimum and maximum time values that can be used (in the `minTime` and `maxTime` members). If `setTime` failed because of an error not caused by an illegal parameter value, it throws `Error`. Obviously, because `Error` does not have data members, the client will have no idea what exactly it was that went wrong — it simply knows that the operation did not work.

An operation can throw only those user exceptions that are listed in its exception specification. If, at run time, the implementation of an operation throws an exception that is not listed in its exception specification, the client receives a [run-time exception](#) to indicate that the operation did something illegal. To indicate that an operation does not throw any user exception, simply omit the exception specification. (There is no empty exception specification in `Slice`.)

Restrictions for User Exceptions

Exceptions are not first-class data types and first-class data types are not exceptions:

- You cannot pass an exception as a parameter value.
- You cannot use an exception as the type of a data member.
- You cannot use an exception as the element type of a sequence.
- You cannot use an exception as the key or value type of a dictionary.
- You cannot throw a value of non-exception type (such as a value of type `int` or `string`).

The reason for these restrictions is that some implementation languages use a specific and separate type for exceptions (in the same way as `Slice` does). For such languages, it would be difficult to map exceptions if they could be used as an ordinary data type. (C++ is somewhat unusual among programming languages by allowing arbitrary types to be used as exceptions.)

User Exception Inheritance

Exceptions support inheritance. For example:

Slice

```

exception ErrorBase {
    string reason;
};

enum RLError {
    DivideByZero, NegativeRoot, IllegalNull /* ... */
};

exception RuntimeError extends ErrorBase {
    RLError err;
};

enum LError { ValueOutOfRange, ValuesInconsistent, /* ... */ };

exception LogicError extends ErrorBase {
    LError err;
};

exception RangeError extends LogicError {
    TimeOfDay errorTime;
    TimeOfDay minTime;
    TimeOfDay maxTime;
};

```

These definitions set up a simple exception hierarchy:

- `ErrorBase` is at the root of the tree and contains a string explaining the cause of the error.
- Derived from `ErrorBase` are `RuntimeError` and `LogicError`. Each of these exceptions contains an enumerated value that further categorizes the error.
- Finally, `RangeError` is derived from `LogicError` and reports the details of the specific error.

Setting up exception hierarchies such as this not only helps to create a more readable specification because errors are categorized, but also can be used at the language level to good advantage. For example, the Slice C++ mapping preserves the exception hierarchy so you can catch exceptions generically as a base exception, or set up exception handlers to deal with specific exceptions.

Looking at the exception hierarchy, it is not clear whether, at run time, the application will only throw most derived exceptions, such as `RangeError`, or if it will also throw base exceptions, such as `LogicError`, `RuntimeError`, and `ErrorBase`. If you want to indicate that a base exception, interface, or class is abstract (will not be instantiated), you can add a comment to that effect.

Note that, if the exception specification of an operation indicates a specific exception type, at run time, the implementation of the operation may also throw more derived exceptions. For example:

Slice

```

exception Base {
    // ...
};

exception Derived extends Base {
    // ...
};

interface Example {
    void op() throws Base;    // May throw Base or Derived
};

```

In this example, `op` may throw a `Base` or a `Derived` exception, that is, any exception that is compatible with the exception types listed in the exception specification can be thrown at run time.

As a system evolves, it is quite common for new, derived exceptions to be added to an existing hierarchy. Assume that we initially construct clients and server with the following definitions:

Slice

```

exception Error {
    // ...
};

interface Application {
    void doSomething() throws Error;
};

```

Also assume that a large number of clients are deployed in field, that is, when you upgrade the system, you cannot easily upgrade all the clients. As the application evolves, a new exception is added to the system and the server is redeployed with the new definition:

Slice

```

exception Error {
    // ...
};

exception FatalApplicationError extends Error {
    // ...
};

interface Application {
    void doSomething() throws Error;
};

```

This raises the question of what should happen if the server throws a `FatalApplicationError` from `doSomething`. The answer depends whether the client was built using the old or the updated definition:

- If the client was built using the same definition as the server, it simply receives a `FatalApplicationError`.
- If the client was built with the original definition, that client has no knowledge that `FatalApplicationError` even exists. In this case, the Ice run time automatically slices the exception to the most-derived type that is understood by the receiver (`Error`, in this case) and discards the information that is specific to the derived part of the exception. (This is exactly analogous to catching C++ exceptions by value — the exception is sliced to the type used in the `catch`-clause.)

Exceptions support single inheritance only. (Multiple inheritance would be difficult to map into many programming languages.)

Run-Time Exceptions

In addition to any [user exceptions](#) that are listed in an operation's exception specification, an operation can also throw Ice *run-time exceptions*. Run-time exceptions are predefined exceptions that indicate platform-related run-time errors. For example, if a networking error interrupts communication between client and server, the client is informed of this by a run-time exception, such as `ConnectTimeoutException` or `SocketException`.

The exception specification of an operation must not list any run-time exceptions. (It is understood that all operations can raise run-time exceptions and you are not allowed to restate that.)

 - [UnknownException](#)

Inheritance Hierarchy for Exceptions

All the Ice run-time and user exceptions are arranged in an inheritance hierarchy, as shown below:

Inheritance structure for exceptions.

`Ice::Exception` is at the root of the inheritance hierarchy. Derived from that are the (abstract) types `Ice::LocalException` and `Ice::UserException`. In turn, all run-time exceptions are derived from `Ice::LocalException`, and all user exceptions are derived from `Ice::UserException`.

Ice run-time exceptions are all defined in Slice as `local` exceptions. *Local exception* is a synonym for Ice run-time exception.

This figure shows the complete hierarchy of the Ice run-time exceptions:

Many of the run-time exceptions have self-explanatory names, such as `MemoryLimitException`. Others indicate problems in the Ice run time, such as `EncapsulationException`. Still others can arise only through application programming errors, such as `TwowayOnlyException`. In practice, you will likely never see most of these exceptions. However, there are a few run-time exceptions you will encounter and whose meaning you should know.

Local Versus Remote Exceptions

Most error conditions are detected on the client side and raised locally in the client. For example, if an attempt to contact a server fails, the client-side run time raises a `ConnectTimeoutException`.

However, there are a few specific error conditions (shown as shaded in the [Ice run-time exception hierarchy](#) diagram) that are detected by the server and transmitted to the client via the Ice protocol: `ObjectNotExistException`, `FacetNotExistException` and `OperationNotExistException` (collectively the Request Failed exceptions) plus `UnknownException`, `UnknownLocalException` and `UnknownUserException` (collectively the Unknown exceptions).

All other run-time exceptions (not shaded in the [Ice run-time exception hierarchy](#)) are detected by the client-side run time and are raised locally.

It is possible for the implementation of an operation to throw Ice run-time exceptions (as well as user exceptions). For example, if a client holds a proxy to an object that no longer exists in the server, your server application code is required to throw an `ObjectNotExistException`. If you do throw run-time exceptions from your application code, you should take care to throw a run-time exception only if appropriate, that is, do not use run-time exceptions to indicate something that really should be a user exception. Doing so can be very confusing to the client: if the application "hijacks" some run-time exceptions for its own purposes, the client can no longer decide whether the exception was thrown by the Ice run time or by the server application code. This can make debugging very difficult.

Request Failed Exceptions

ObjectNotExistException

This exception indicates that a request was delivered to the server but the server could not locate a servant with the identity that is embedded in the proxy. In other words, the server could not find an object to dispatch the request to.

The Ice run time raises `ObjectNotExistException` only if there are no facets in existence with a matching identity; otherwise, it raises `FacetNotExistException`.

Most likely, this is the case because the object existed some time in the past and has since been destroyed, but the same exception is also raised if a client uses a proxy with the identity of an object that has never been created.

FacetNotExistException

The client attempted to contact a non-existent facet of an object, that is, the server has at least one servant with the given identity, but no servant with a matching facet name.

OperationNotExistException

This exception is raised if the server could locate an object with the correct identity but, on attempting to dispatch the client's operation invocation, the server found that the target object does not have such an operation. You will see this exception in only two cases:

- Client and server have been built with Slice definitions for an interface that disagree with each other, that is, the client was built with an interface definition for the object that indicates that an operation exists, but the server was built with a different version of the interface definition in which the operation is absent.
- You have used an unchecked down-cast on a proxy of the incorrect type.

`ObjectNotExistException`, `FacetNotExistException` and `OperationNotExistException` derive from `RequestFailedException`, and don't add any data member for this exception:

Slice

```

module Ice
{
    local slice RequestFailException
    {
        Identity id;
        string facet;
        string operation;
    }
}

```

`RequestFailedException` itself is not transmissible as a response from a server to client—only the three derived exceptions are.

If you throw one of these three exceptions from the implementation of an operation, and you leave `id`, `facet` or `operation` empty, Ice will automatically fill-in the missing data members using values from `Current`.

Unknown Exceptions

Any error condition on the server side that is not described by one of the three preceding exceptions is made known to the client as one of three generic exceptions: `UnknownUserException`, `UnknownLocalException`, or `UnknownException`. Furthermore if a servant implementation throws one of these `Unknown` exceptions, the Ice run time transmits it as is—it does not wrap it a new `UnknownLocalException`.

```

module Ice
{
    local exception UnknownException
    {
        string unknown;
    }

    local exception UnknownLocalException extends UnknownException
    {
    }

    local exception UnknownUserException extends UnknownException
    {
    }
}

```

UnknownUserException

This exception indicates that an operation implementation has thrown a Slice exception that is not declared in the operation's exception specification (and is not derived from one of the exceptions in the operation's exception specification). Ice itself never throws this exception, as all user-exception checking for a given operation is performed only in the client's generated code and Ice run-time. It is nevertheless permissible for a servant to throw this exception.

UnknownLocalException

If an operation implementation raises a run-time exception other than `ObjectNotExistException`, `FacetNotExistException`, `Opera`

tionNotExistException or UnknownException (such as a NotRegisteredException), the client receives an UnknownLocalException. In other words, the Ice protocol does not transmit the exact exception that was encountered in the server, but simply returns a bit to the client in the reply to indicate that the server encountered a run-time exception.

A common cause for a client receiving an UnknownLocalException is failure to catch and handle all exceptions in the server. For example, if the implementation of an operation encounters an exception it does not handle, the exception propagates all the way up the call stack until the stack is unwound to the point where the Ice run time invoked the operation. The Ice run time catches all Ice exceptions that "escape" from an operation invocation and returns them to the client as an UnknownLocalException.

UnknownException

An operation has thrown a non-Ice exception. For example, if the operation in the server throws a C++ exception, such as a `std::bad_alloc`, or a Java exception, such as a `ClassCastException`, the client receives an `UnknownException`.

Proxies for Ice Objects

Building on the [Clock](#) example, we can create definitions for a world-time server:

```

Slice

exception GenericError {
    string reason;
};

struct TimeOfDay {
    short hour;           // 0 - 23
    short minute;        // 0 - 59
    short second;        // 0 - 59
};

exception BadTimeVal extends GenericError {};

interface Clock {
    idempotent TimeOfDay getTime();
    idempotent void setTime(TimeOfDay time) throws BadTimeVal;
};

dictionary<string, Clock*> TimeMap; // Time zone name to clock map

exception BadZoneName extends GenericError {};

interface WorldTime {
    idempotent void addZone(string zoneName, Clock* zoneClock);
    void removeZone(string zoneName) throws BadZoneName;
    idempotent Clock* findZone(string zoneName) throws BadZoneName;
    idempotent TimeMap listZones();
    idempotent void setZones(TimeMap zones);
};

```

The `WorldTime` interface acts as a collection manager for clocks, one for each time zone. In other words, the `WorldTime` interface manages a collection of pairs. The first member of each pair is a time zone name; the second member of the pair is the clock that provides the time for that zone. The interface contains operations that permit you to add or remove a clock from the map (`addZone` and `removeZone`), to search for a particular time zone by name (`findZone`), and to read or write the entire map (`listZones` and `setZones`).

The `WorldTime` example illustrates an important Slice concept: note that `addZone` accepts a parameter of type `Clock*` and `findZone` returns a parameter of type `Clock*`. In other words, interfaces are types in their own right and can be passed as parameters. The `*` operator is known as the *proxy operator*. Its left-hand argument must be an interface (or `class`) and its return type is a proxy. A proxy is like a pointer that can denote an object. The semantics of proxies are very much like those of C++ class instance pointers:

- A proxy can be `null`.
- A proxy can dangle (point at an object that is no longer there).
- Operations dispatched via a proxy use late binding: if the actual run-time type of the object denoted by the proxy is more derived than the proxy's type, the implementation of the most-derived interface will be invoked.

When a client passes a `Clock` proxy to the `addZone` operation, the proxy denotes an actual `Clock` object in a server. The `Clock` *Ice object* denoted by that proxy may be implemented in the same server process as the `WorldTime` interface, or in a different server process. Where the `Clock` object is physically implemented matters neither to the client nor to the server implementing the `WorldTime` interface; if either invokes an operation on a particular clock, such as `getTime`, an RPC call is sent to whatever server implements that particular clock. In other words, a proxy acts as a local "ambassador" for the remote object; invoking an operation on the proxy forwards the invocation to the

actual object implementation. If the object implementation is in a different address space, this results in a remote procedure call; if the object implementation is collocated in the same address space, the Ice run time may optimize the invocation.

Note that proxies also act very much like pointers in their sharing semantics: if two clients have a proxy to the same object, a state change made by one client (such as setting the time) will be visible to the other client.

Proxies are strongly typed (at least for statically typed languages, such as C++ and Java). This means that you cannot pass something other than a `clock` proxy to the `addZone` operation; attempts to do so are rejected at compile time.

Interface Inheritance

On this page:

- [Interface Inheritance](#)
- [Interface Inheritance Limitations](#)
- [Implicit Inheritance from Object](#)
- [Null Proxies](#)
- [Self-Referential Interfaces](#)
- [Empty Interfaces](#)
- [Interface Versus Implementation Inheritance](#)

Interface Inheritance

Interfaces support inheritance. For example, we could extend our [world-time server](#) to support the concept of an alarm clock:

```

Slice

interface AlarmClock extends Clock {
    idempotent TimeOfDay getAlarmTime();
    idempotent void setAlarmTime(TimeOfDay alarmTime)
        throws BadTimeVal;
};

```

The semantics of this are the same as for C++ or Java: `AlarmClock` is a subtype of `Clock` and an `AlarmClock` proxy can be substituted wherever a `Clock` proxy is expected. Obviously, an `AlarmClock` supports the same `getTime` and `setTime` operations as a `Clock` but also supports the `getAlarmTime` and `setAlarmTime` operations.

Multiple interface inheritance is also possible. For example, we can construct a radio alarm clock as follows:

```

Slice

interface Radio {
    void setFrequency(long hertz) throws GenericError;
    void setVolume(long dB) throws GenericError;
};

enum AlarmMode { RadioAlarm, BeepAlarm };

interface RadioClock extends Radio, AlarmClock {
    void setMode(AlarmMode mode);
    AlarmMode getMode();
};

```

`RadioClock` extends both `Radio` and `AlarmClock` and can therefore be passed where a `Radio`, an `AlarmClock`, or a `Clock` is expected. The inheritance diagram for this definition looks as follows:

Inheritance diagram for RadioClock.

Interfaces that inherit from more than one base interface may share a common base interface. For example, the following definition is legal:

Slice

```

interface B { /* ... */ };
interface I1 extends B { /* ... */ };
interface I2 extends B { /* ... */ };
interface D extends I1, I2 { /* ... */ };
  
```

This definition results in the familiar diamond shape:

Diamond-shaped inheritance.

Interface Inheritance Limitations

If an interface uses multiple inheritance, it must not inherit the same operation name from more than one base interface. For example, the following definition is illegal:

Slice

```

interface Clock {
    void set(TimeOfDay time);           // set time
};

interface Radio {
    void set(long hertz);              // set frequency
};

interface RadioClock extends Radio, Clock { // Illegal!
    // ...
};

```

This definition is illegal because `RadioClock` inherits two `set` operations, `Radio::set` and `Clock::set`. The Slice compiler makes this illegal because (unlike C++) many programming languages do not have a built-in facility for disambiguating the different operations. In Slice, the simple rule is that all inherited operations must have unique names. (In practice, this is rarely a problem because inheritance is rarely added to an interface hierarchy "after the fact". To avoid accidental clashes, we suggest that you use descriptive operation names, such as `setTime` and `setFrequency`. This makes accidental name clashes less likely.)

Implicit Inheritance from Object

All Slice interfaces are ultimately derived from `Object`. For example, the [inheritance hierarchy](#) would be shown more correctly as:

Implicit inheritance from Object.

Because all interfaces have a common base interface, we can pass any type of interface as that type. For example:

Slice

```
interface ProxyStore {
    idempotent void putProxy(string name, Object* o);
    idempotent Object* getProxy(string name);
};
```

`Object` is a Slice keyword (note the capitalization) that denotes the root type of the inheritance hierarchy. The `ProxyStore` interface is a generic proxy storage facility: the client can call `putProxy` to add a proxy of any type under a given name and later retrieve that proxy again by calling `getProxy` and supplying that name. The ability to generically store proxies in this fashion allows us to build general-purpose facilities, such as a [naming service](#) that can store proxies and deliver them to clients. Such a service, in turn, allows us to avoid hard-coding proxy details into clients and servers.

Inheritance from type `Object` is always implicit. For example, the following Slice definition is illegal:

Slice

```
interface MyInterface extends Object { /* ... */ }; // Error!
```

It is understood that all interfaces inherit from type `Object`; you are not allowed to restate that.

Type `Object` is mapped to an abstract type by the various language mappings, so you cannot instantiate an Ice object of that type.

Null Proxies

Looking at the `ProxyStore` interface once more, we notice that `getProxy` does not have an exception specification. The question then is what should happen if a client calls `getProxy` with a name under which no proxy is stored? Obviously, we could add an exception to indicate this condition to `getProxy`. However, another option is to return a *null proxy*. Ice has the built-in notion of a null proxy, which is a proxy that "points nowhere". When such a proxy is returned to the client, the client can test the value of the returned proxy to check whether it is null or denotes a valid object.

A more interesting question is: "which approach is more appropriate, throwing an exception or returning a null proxy?" The answer depends on the expected usage pattern of an interface. For example, if, in normal operation, you do not expect clients to call `getProxy` with a non-existent name, it is better to throw an exception. (This is probably the case for our `ProxyStore` interface: the fact that there is no `list` operation makes it clear that clients are expected to know which names are in use.)

On the other hand, if you expect that clients will occasionally try to look up something that is not there, it is better to return a null proxy. The reason is that throwing an exception breaks the normal flow of control in the client and requires special handling code. This means that you should throw exceptions only in exceptional circumstances. For example, throwing an exception if a database lookup returns an empty result set is wrong; it is expected and normal that a result set is occasionally empty.

It is worth paying attention to such design issues: well-designed interfaces that get these details right are easier to use and easier to understand. Not only do such interfaces make life easier for client developers, they also make it less likely that latent bugs cause problems later.

Self-Referential Interfaces

Proxies have pointer semantics, so we can define self-referential interfaces. For example:

Slice

```
interface Link {
    idempotent SomeType getValue();
    idempotent Link* next();
};
```

The `Link` interface contains a `next` operation that returns a proxy to a `Link` interface. Obviously, this can be used to create a chain of interfaces; the final link in the chain returns a null proxy from its `next` operation.

Empty Interfaces

The following Slice definition is legal:

Slice

```
interface Empty {};
```

The Slice compiler will compile this definition without complaint. An interesting question is: "why would I need an empty interface?" In most cases, empty interfaces are an indication of design errors. Here is one example:

Slice

```
interface ThingBase {};
```

```
interface Thing1 extends ThingBase {
    // Operations here...
};
```

```
interface Thing2 extends ThingBase {
    // Operations here...
};
```

Looking at this definition, we can make two observations:

- `Thing1` and `Thing2` have a common base and are therefore related.
- Whatever is common to `Thing1` and `Thing2` can be found in interface `ThingBase`.

Of course, looking at `ThingBase`, we find that `Thing1` and `Thing2` do not share any operations at all because `ThingBase` is empty. Given that we are using an object-oriented paradigm, this is definitely strange: in the object-oriented model, the *only* way to communicate with an object is to send a message to the object. But, to send a message, we need an operation. Given that `ThingBase` has no operations, we cannot send a message to it, and it follows that `Thing1` and `Thing2` are *not* related because they have no common operations. But of course, seeing that `Thing1` and `Thing2` have a common base, we conclude that they *are* related, otherwise the common base would not exist. At this point, most programmers begin to scratch their head and wonder what is going on here.

One common use of the above design is a desire to treat `Thing1` and `Thing2` polymorphically. For example, we might continue the previous definition as follows:

Slice

```
interface ThingUser {
    void putThing(ThingBase* thing);
};
```

Now the purpose of having the common base becomes clear: we want to be able to pass both `Thing1` and `Thing2` proxies to `putThing`. Does this justify the empty base interface? To answer this question, we need to think about what happens in the implementation of `putThing`. Obviously, `putThing` cannot possibly invoke an operation on a `ThingBase` because there are no operations. This means that `putThing` can do one of two things:

1. `putThing` can simply remember the value of `thing`.
2. `putThing` can try to down-cast to either `Thing1` or `Thing2` and then invoke an operation. The pseudo-code for the implementation of `putThing` would look something like this:

```
void putThing(ThingBase thing)
{
    if (is_a(Thing1, thing)) {
        // Do something with Thing1...
    } else if (is_a(Thing2, thing)) {
        // Do something with Thing2...
    } else {
        // Might be a ThingBase?
        // ...
    }
}
```

The implementation tries to down-cast its argument to each possible type in turn until it has found the actual run-time type of the argument. Of course, any object-oriented text book worth its price will tell you that this is an abuse of inheritance and leads to maintenance problems.

If you find yourself writing operations such as `putThing` that rely on artificial base interfaces, ask yourself whether you really need to do things this way. For example, a more appropriate design might be:

Slice

```
interface Thing1 {
    // Operations here...
};

interface Thing2 {
    // Operations here...
};

interface ThingUser {
    void putThing1(Thing1* thing);
    void putThing2(Thing2* thing);
};
```

With this design, `Thing1` and `Thing2` are not related, and `ThingUser` offers a separate operation for each type of proxy. The implementation of these operations does not need to use any down-casts, and all is well in our object-oriented world.

Another common use of empty base interfaces is the following:

Slice

```
interface PersistentObject {}

interface Thing1 extends PersistentObject {
    // Operations here...
};

interface Thing2 extends PersistentObject {
    // Operations here...
};
```

Clearly, the intent of this design is to place persistence functionality into the `PersistentObject` base *implementation* and require objects that want to have persistent state to inherit from `PersistentObject`. On the face of things, this is reasonable: after all, using inheritance in this way is a well-established design pattern, so what can possibly be wrong with it? As it turns out, there are a number of things that are wrong with this design:

- The above inheritance hierarchy is used to add *behavior* to `Thing1` and `Thing2`. However, in a strict OO model, behavior can be invoked only by sending messages. But, because `PersistentObject` has no operations, no messages can be sent. This raises the question of how the implementation of `PersistentObject` actually goes about doing its job; presumably, it knows something about the implementation (that is, the internal state) of `Thing1` and `Thing2`, so it can write that state into a database. But, if so, `PersistentObject`, `Thing1`, and `Thing2` can no longer be implemented in different address spaces because, in that case, `PersistentObject` can no longer get at the state of `Thing1` and `Thing2`. Alternatively, `Thing1` and `Thing2` use some functionality provided by `PersistentObject` in order to make their internal state persistent. But `PersistentObject` does not have any operations, so how would `Thing1` and `Thing2` actually go about achieving this? Again, the only way that can work is if `PersistentObject`, `Thing1`, and `Thing2` are implemented in a single address space and share implementation state behind the scenes, meaning that they cannot be implemented in different address spaces.
- The above inheritance hierarchy splits the world into two halves, one containing persistent objects and one containing non-persistent ones. This has far-reaching ramifications:
 - Suppose you have an existing application with already implemented, non-persistent objects. Requirements change over time and you find that you now would like to make some of your objects persistent. With the above design, you cannot do

this unless you change the type of your objects because they now must inherit from `PersistentObject`. Of course, this is extremely bad news: not only do you have to change the implementation of your objects in the server, you also need to locate and update all the clients that are currently using your objects because they suddenly have a completely new type. What is worse, there is no way to keep things backward compatible: either all clients change with the server, or none of them do. It is impossible for some clients to remain "unupgraded".

- The design does not scale to multiple features. Imagine that we have a number of additional behaviors that objects can inherit, such as serialization, fault-tolerance, persistence, and the ability to be searched by a search engine. We quickly end up in a mess of multiple inheritance. What is worse, each possible combination of features creates a completely separate type hierarchy. This means that you can no longer write operations that generically operate on a number of object types. For example, you cannot pass a persistent object to something that expects a non-persistent object, *even if the receiver of the object does not care about the persistence aspects of the object*. This quickly leads to fragmented and hard-to-maintain type systems. Before long, you will either find yourself rewriting your application or end up with something that is both difficult to use and difficult to maintain.

The foregoing discussion will hopefully serve as a warning: Slice is an *interface* definition language that has nothing to do with *implementation* (but empty interfaces almost always indicate that implementation state is shared via mechanisms other than defined interfaces). If you find yourself writing an empty interface definition, at least step back and think about the problem at hand; there may be a more appropriate design that expresses your intent more cleanly. If you do decide to go ahead with an empty interface regardless, be aware that, almost certainly, you will lose the ability to later change the distribution of the object model over physical server processes because you cannot place an address space boundary between interfaces that share hidden state.

Interface Versus Implementation Inheritance

Keep in mind that Slice interface inheritance applies only to *interfaces*. In particular, if two interfaces are in an inheritance relationship, this in no way implies that the implementations of those interfaces must also inherit from each other. You can choose to use implementation inheritance when you implement your interfaces, but you can also make the implementations independent of each other. (To C++ programmers, this often comes as a surprise because C++ uses implementation inheritance by default, and interface inheritance requires extra effort to implement.)

In summary, Slice inheritance simply establishes type compatibility. It says nothing about how interfaces are implemented and, therefore, keeps implementation choices open to whatever is most appropriate for your application.

Classes

In addition to [interfaces](#), Slice permits the definition of classes. Classes are like interfaces in that they can have operations and are like structures in that they can have data members. This leads to hybrid objects that can be treated as interfaces and passed by reference, or can be treated as values and passed by value.

Classes support inheritance and are therefore polymorphic: at run time, you can pass a class instance to an operation as long as the actual class type is derived from the formal parameter type in the operation's signature. This also permits classes to be used as type-safe unions, similarly to Pascal's discriminated variant records.

Simple Classes

A Slice class definition is similar to a structure definition, but uses the `class` keyword. For example:

```

class TimeOfDay {
    short hour;           // 0 - 23
    short minute;        // 0 - 59
    short second;        // 0 - 59
};

```

Apart from the keyword `class`, this definition is identical to the [structure](#) example. You can use a Slice class wherever you can use a Slice structure (but, as we will see shortly, for performance reasons, you should not use a class where a structure is sufficient). Unlike structures, classes can be empty:

```

class EmptyClass {}; // OK
struct EmptyStruct {}; // Error

```

Much the same design considerations as for [empty interfaces](#) apply to empty classes: you should at least stop and rethink your approach before committing yourself to an empty class.

A class can define any number of data members, including [optional data members](#). You can also specify a default value for a data member if its type is one of the following:

- An [integral](#) type (byte, short, int, long)
- A [floating point](#) type (float or double)
- `string`
- `bool`
- `enum`

For example:

```

class Location {
    string name;
    Point pt;
    bool display = true;
    string source = "GPS";
};

```

The legal syntax for literal values is the same as for [Slice constants](#), and you may also use a constant as a default value. The language mapping guarantees that data members are initialized to their declared default values using a language-specific mechanism.

See Also

- [Structures](#)
- [Constants and Literals](#)

- [Optional Data Members](#)

Class Inheritance

Unlike `structures`, classes support inheritance. For example:

Slice
<pre> class TimeOfDay { short hour; // 0 - 23 short minute; // 0 - 59 short second; // 0 - 59 }; class DateTime extends TimeOfDay { short day; // 1 - 31 short month; // 1 - 12 short year; // 1753 onwards }; </pre>

This example illustrates one major reason for using a class: a class can be extended by inheritance, whereas a structure is not extensible. The previous example defines `DateTime` to extend the `TimeOfDay` class with a date.

If you are puzzled by the comment about the year 1753, search the Web for "1752 date change". The intricacies of calendars for various countries prior to that year can keep you occupied for months...

Classes only support single inheritance. The following is illegal:

Slice
<pre> class TimeOfDay { short hour; // 0 - 23 short minute; // 0 - 59 short second; // 0 - 59 }; class Date { short day; short month; short year; }; class DateTime extends TimeOfDay, Date { // Error! // ... }; </pre>

A derived class also cannot redefine a data member of its base class:

Slice

```
class Base {
    int integer;
};

class Derived extends Base {
    int integer;           // Error, integer redefined
};
```

See Also

- [Structures](#)

Class Inheritance Semantics

Classes use the same pass-by-value semantics as [structures](#). If you pass a class instance to an operation, the class and all its members are passed. The usual type compatibility rules apply: you can pass a derived instance where a base instance is expected. If the receiver has static type knowledge of the actual derived run-time type, it receives the derived instance; otherwise, if the receiver does not have static type knowledge of the derived type, depending on the format used to encode the class, it will either fail to read the instance or slice the instance to the base type.

For an example, suppose we have the following definitions:

Slice
<pre> // In file Clock.ice: class TimeOfDay { short hour; // 0 - 23 short minute; // 0 - 59 short second; // 0 - 59 }; interface Clock { TimeOfDay getTime(); void setTime(TimeOfDay time); }; // In file DateTime.ice: #include <Clock.ice> class DateTime extends TimeOfDay { short day; // 1 - 31 short month; // 1 - 12 short year; // 1753 onwards }; </pre>

Because `DateTime` is a sub-class of `TimeOfDay`, the server can return a `DateTime` instance from `getTime`, and the client can pass a `DateTime` instance to `setTime`. In this case, if both client and server are linked to include the code generated for both `Clock.ice` and `DateTime.ice`, they each receive the actual derived `DateTime` instance, that is, the actual run-time type of the instance is preserved.

Contrast this with the case where the server is linked to include the code generated for both `Clock.ice` and `DateTime.ice`, but the client is linked only with the code generated for `Clock.ice`. In other words, the server understands the type `DateTime` and can return a `DateTime` instance from `getTime`, but the client only understands `TimeOfDay`. In this case, there are two possible outcomes depending on the format used by the server to encode the instance:

- with the sliced format, the derived `DateTime` instance returned by the server is sliced to its `TimeOfDay` base type in the client
- with the compact format, `getTime` fails with the `Ice::NoObjectFactoryException` exception

See [Design Considerations for Objects](#) for additional information on the sliced and compact formats.

Class hierarchies are useful if you need polymorphic *values* (instead of polymorphic *interfaces*). For example:

Slice

```

class Shape {
    // Definitions for shapes, such as size, center, etc.
};

class Circle extends Shape {
    // Definitions for circles, such as radius...
};

class Rectangle extends Shape {
    // Definitions for rectangles, such as width and length...
};

sequence<Shape> ShapeSeq;

interface ShapeProcessor {
    void processShapes(ShapeSeq ss);
};

```

Note the definition of `ShapeSeq` and its use as a parameter to the `processShapes` operation: the class hierarchy allows us to pass a polymorphic sequence of shapes (instead of having to define a separate operation for each type of shape).

The receiver of a `ShapeSeq` can iterate over the elements of the sequence and down-cast each element to its actual run-time type. (The receiver can also ask each element for its `type ID` to determine its type.)

See Also

- [Structures](#)
- [Type IDs](#)

Classes as Unions

Slice does not offer a dedicated union construct because it is redundant. By deriving classes from a common base class, you can create the same effect as with a union:

Slice
<pre>interface ShapeShifter { Shape translate(Shape s, long xDistance, long yDistance); };</pre>

The parameter `s` of the `translate` operation can be viewed as a union of two members: a `Circle` and a `Rectangle`. The receiver of a `Shape` instance can use the `type ID` of the instance to decide whether it received a `Circle` or a `Rectangle`. Alternatively, if you want something more along the lines of a conventional discriminated union, you can use the following approach:

Slice
<pre>class UnionDiscriminator { int d; }; class Member1 extends UnionDiscriminator { // d == 1 string s; float f; }; class Member2 extends UnionDiscriminator { // d == 2 byte b; int i; };</pre>

With this approach, the `UnionDiscriminator` class provides a discriminator value. The "members" of the union are the classes that are derived from `UnionDiscriminator`. For each derived class, the discriminator takes on a distinct value. The receiver of such a union uses the discriminator value in a `switch` statement to select the active union member.

- [Type IDs](#)

Self-Referential Classes

Classes can be self-referential.

For example:

Slice
<pre>class Link { SomeType value; Link next; };</pre>

This looks very similar to the [self-referential interface example](#), but the semantics are very different. Note that `value` and `next` are data members, not operations, and that the type of `next` is `Link` (*not* `Link*`). As you would expect, this forms the same linked list arrangement as the `Link` interface in [Self-Referential Interfaces](#): each instance of a `Link` class contains a `next` member that points at the next link in the chain; the final link's `next` member contains a null value. So, what looks like a class including itself really expresses pointer semantics: the `next` data member contains a pointer to the next link in the chain.

You may be wondering at this point what the difference is then between the `Link` interface in [Self-Referential Interfaces](#) and the `Link` class shown above. The difference is that classes have *value* semantics, whereas proxies have *reference* semantics. To illustrate this, consider the `Link` interface from [Self-Referential Interfaces](#) once more:

Slice
<pre>interface Link { idempotent SomeType getValue(); idempotent Link* next(); };</pre>

Here, `getValue` and `next` are both operations and the return value of `next` is `Link*`, that is, `next` returns a *proxy*. A proxy has *reference* semantics, that is, it denotes an object somewhere. If you invoke the `getValue` operation on a `Link` proxy, a message is sent to the (possibly remote) servant for that proxy. In other words, for proxies, the object stays put in its server process and we access the state of the object via remote procedure calls. Compare this with the definition of our `Link` class:

Slice
<pre>class Link { SomeType value; Link next; };</pre>

Here, `value` and `next` are data members and the type of `next` is `Link`, which has *value* semantics. In particular, while `next` looks and feels like a pointer, *it cannot denote an instance in a different address space*. This means that if we have a chain of `Link` instances, all of the instances are in our local address space and, when we read or write a value data member, we are performing local address space operations. This means that an operation that returns a `Link` instance, such as `getHead`, does not just return the head of the chain, *but the entire chain*, as shown:

Class version of `Link` before and after calling `getHead`.

On the other hand, for the interface version of `Link`, we do not know where all the links are physically implemented. For example, a chain of four links could have each object instance in its own physical server process; those server processes could be each in a different continent. If you have a proxy to the head of this four-link chain and traverse the chain by invoking the `next` operation on each link, you will be sending four remote procedure calls, one to each object.

Self-referential classes are particularly useful to model graphs. For example, we can create a simple expression tree along the following lines:

```

Slice

enum UnaryOp { UnaryPlus, UnaryMinus, Not };
enum BinaryOp { Plus, Minus, Multiply, Divide, And, Or };

class Node {};

class UnaryOperator extends Node {
    UnaryOp operator;
    Node operand;
};

class BinaryOperator extends Node {
    BinaryOp op;
    Node operand1;
    Node operand2;
};

class Operand extends Node {
    long val;
};

```

The expression tree consists of leaf nodes of type `Operand`, and interior nodes of type `UnaryOperator` and `BinaryOperator`, with one or two descendants, respectively. All three of these classes are derived from a common base class `Node`. Note that `Node` is an empty class. This is one of the few cases where an empty base class is justified. (See the discussion on [empty interfaces](#); once we add [operations](#) to this class hierarchy, the base class is no longer empty.)

If we write an operation that, for example, accepts a `Node` parameter, passing that parameter results in transmission of the entire tree to the server:

Slice

```
interface Evaluator {  
    long eval(Node expression); // Send entire tree for evaluation  
};
```

Self-referential classes are not limited to acyclic graphs; the Ice run time permits loops: it ensures that no resources are leaked and that infinite loops are avoided during marshaling.

- [Classes with Operations](#)
- [Self-Referential Interfaces](#)

Classes Versus Structures

One obvious question to ask is: why does Ice provide [structures](#) as well as classes, when classes obviously can be used to model structures? The answer has to do with the cost of implementation: classes provide a number of features that are absent for structures:

- Classes support inheritance.
- Classes can be self-referential.
- Classes can have optional data members.
- Classes can have [operations](#).
- Classes can [implement interfaces](#).

Obviously, an implementation cost is associated with the additional features of classes, both in terms of the size of the generated code and the amount of memory and CPU cycles consumed at run time. On the other hand, structures are simple collections of values ("plain old structs") and are implemented using very efficient mechanisms. This means that, if you use structures, you can expect better performance and smaller memory footprint than if you would use classes (especially for languages with direct support for "plain old structures", such as C++ and C#). Use a class only if you need at least one of its more powerful features.

See Also

- [Structures](#)
- [Classes with Operations](#)
- [Classes Implementing Interfaces](#)

Classes with Operations

Classes, in addition to data members, can have operations. The syntax for operation definitions in classes is identical to the syntax for operations in interfaces. For example, we can modify the expression tree from [Self-Referential Classes](#) as follows:

```

Slice

enum UnaryOp { UnaryPlus, UnaryMinus, Not };
enum BinaryOp { Plus, Minus, Multiply, Divide, And, Or };

class Node {
    idempotent long eval();
};

class UnaryOperator extends Node {
    UnaryOp operator;
    Node operand;
};

class BinaryOperator extends Node {
    BinaryOp op;
    Node operand1;
    Node operand2;
};

class Operand {
    long val;
};
```

The only change compared to the version in [Self-Referential Classes](#) is that the `Node` class now has an `eval` operation. The semantics of this are as for a virtual member function in C++: each derived class inherits the operation from its base class and can choose to override the operation's definition. For our expression tree, the `Operand` class provides an implementation that simply returns the value of its `val` member, and the `UnaryOperator` and `BinaryOperator` classes provide implementations that compute the value of their respective subtrees. If we call `eval` on the root node of an expression tree, it returns the value of that tree, regardless of whether we have a complex expression or a tree that consists of only a single `Operand` node.

Operations on classes are normally executed in the caller's address space, that is, operations on classes are *local* operations that do not result in a remote procedure call.

It is also possible to invoke an operation on a [remote class instance](#).

Of course, this immediately raises an interesting question: what happens if a client receives a class instance with operations from a server, but client and server are implemented in different languages? Classes with operations require the receiver to supply a factory for instances of the class. The Ice run time only marshals the data members of the class. If a class has operations, the receiver of the class must provide a class factory that can instantiate the class in the receiver's address space, and the receiver is responsible for providing an implementation of the class's operations.

Therefore, if you use classes with operations, it is understood that client and server each have access to an implementation of the class's operations. No code is shipped over the wire (which, in an environment of heterogeneous nodes using different operating systems and languages is infeasible).

Architectural Implications of Classes

Classes have a number of architectural implications that are worth exploring in some detail.

On this page:

- [Classes without Operations](#)
- [Classes with Operations](#)
- [Classes for Persistence](#)

Classes without Operations

Classes that do not use inheritance and only have data members (whether self-referential or not) pose no architectural problems: they simply are values that are marshaled like any other value, such as a sequence, structure, or dictionary. Classes using derivation also pose no problems: if the receiver of a derived instance has knowledge of the derived type, it simply receives the derived type; otherwise, the instance is sliced to the most-derived type that is understood by the receiver. This makes class inheritance useful as a system is extended over time: you can create derived class without having to upgrade all parts of the system at once.

Classes with Operations

Classes with operations require additional thought. Here is an example: suppose that you are creating an Ice application. Also assume that the Slice definitions use quite a few classes with operations. You sell your clients and servers (both written in Java) and end up with thousands of deployed systems.

As time passes and requirements change, you notice a demand for clients written in C++.

For commercial reasons, you would like to leave the development of C++ clients to customers or a third party but, at this point, you discover a glitch: your application has lots of classes with operations along the following lines:

Slice

```

class ComplexThingForExpertsOnly {
    // Lots of arcane data members here...
    MysteriousThing mysteriousOperation(/* parameters */);
    ArcaneThing arcaneOperation(/* parameters */);
    ComplexThing complexOperation(/* parameters */);
    // etc...
};

```

It does not matter what exactly these operations do. (Presumably, you decided to off-load some of the processing for your application onto the client side for performance reasons.) Now that you would like other developers to write C++ clients, it turns out that your application will work only if these developers provide implementations of all the client-side operations and, moreover, if the semantics of these operations exactly match the semantics of your Java implementations. Depending on what these operations do, providing exact semantic equivalents in a different language may not be trivial, so you decide to supply the C++ implementations yourself.

But now, you discover another problem: the C++ clients need to be supported for a variety of operating systems that use a variety of different C++ compilers. Suddenly, your task has become quite daunting: you really need to supply implementations for all the combinations of operating systems and compiler versions that are used by clients. Given the different state of compliance with the ISO C++ standard of the various compilers, and the idiosyncrasies of different operating systems, you may find yourself facing a development task that is much larger than anticipated. And, of course, the same scenario will arise again should you need client implementations in yet another language.

The moral of this story is not that classes with operations should be avoided; they can provide significant performance gains and are not necessarily bad. But, keep in mind that, once you use classes with operations, you are, in effect, using client-side native code and, therefore, you can no longer enjoy the implementation transparencies that are provided by interfaces. This means that classes with operations should be used only if you can tightly control the deployment environment of clients. If not, you are better off using interfaces and classes without operations. That way, all the processing stays on the server and the contract between client and server is provided solely by the Slice definitions, not by the semantics of the additional client-side code that is required for classes with operations.

Classes for Persistence

Ice also provides a built-in [persistence mechanism](#) that allows you to store the state of a class in a database with very little implementation effort. To get access to these persistence features, you must define a Slice class whose members store the state of the class.

See Also

- [Freeze](#)

Classes Implementing Interfaces

A Slice class can also be used as a servant in a server, that is, an instance of a class can be used to provide the behavior for an interface, for example:

Slice
<pre> interface Time { idempotent TimeOfDay getTime(); idempotent void setTime(TimeOfDay time); }; class Clock implements Time { TimeOfDay time; }; </pre>

The `implements` keyword indicates that the class `Clock` provides an *implementation* of the `Time` interface. The class can provide data members and operations of its own; in the preceding example, the `Clock` class stores the current time that is accessed via the `Time` interface. A class can implement several interfaces, for example:

Slice
<pre> interface Time { idempotent TimeOfDay getTime(); idempotent void setTime(TimeOfDay time); }; interface Radio { idempotent void setFrequency(long hertz); idempotent void setVolume(long dB); }; class RadioClock implements Time, Radio { TimeOfDay time; long hertz; }; </pre>

The class `RadioClock` implements both `Time` and `Radio` interfaces.

A class, in addition to implementing an interface, can also extend another class:

Slice

```

interface Time {
    idempotent TimeOfDay getTime();
    idempotent void setTime(TimeOfDay time);
};

class Clock implements Time {
    TimeOfDay time;
};

interface AlarmClock extends Time {
    idempotent TimeOfDay getAlarmTime();
    idempotent void setAlarmTime(TimeOfDay alarmTime);
};

interface Radio {
    idempotent void setFrequency(long hertz);
    idempotent void setVolume(long dB);
};

class RadioAlarmClock extends Clock
    implements AlarmClock, Radio {
    TimeOfDay alarmTime;
    long hertz;
};

```

These definitions result in the following inheritance graph:

A Class using implementation and interface inheritance.

For this definition, `Radio` and `AlarmClock` are abstract interfaces, and `Clock` and `RadioAlarmClock` are concrete classes. As for Java, a class can implement multiple interfaces, but can extend at most one class.

See Also

- [Architectural Implications of Classes](#)
- [Class Inheritance Limitations](#)

Class Inheritance Limitations

As for [interface inheritance](#), a class cannot redefine an operation or data member that it inherits from a base interface or class. For example:

```

Slice

```
interface BaseInterface {
 void op();
};

class BaseClass {
 int member;
};

class DerivedClass extends BaseClass implements BaseInterface {
 void someOperation(); // OK
 int op(); // Error!
 int someMember; // OK
 long member; // Error!
};
```

```

See Also

- [Interface Inheritance](#)

Pass-by-Value Versus Pass-by-Reference

As we saw in [Self-Referential Classes](#), classes naturally support pass-by-value semantics: passing a class transmits the data members of the class to the receiver. Any changes made to these data members by the receiver affect only the receiver's copy of the class; the data members of the sender's class are not affected by the changes made by the receiver.

In addition to passing a class by value, you can pass a class by reference. For example:

Slice
<pre> class TimeOfDay { short hour; short minute; short second; string format(); }; interface Example { TimeOfDay* get(); // Note: returns a proxy! }; </pre>

Note that the `get` operation returns a *proxy* to a `TimeOfDay` class and not a `TimeOfDay` instance itself. The semantics of this are as follows:

- When the client receives a `TimeOfDay` proxy from the `get` call, it holds a proxy that differs in no way from an ordinary proxy for an interface.
- The client can invoke operations via the proxy, but *cannot* access the data members. This is because proxies do not have the concept of data members, but represent interfaces: even though the `TimeOfDay` class has data members, only its *operations* can be accessed via a the proxy.

The net effect is that, in the preceding example, the server holds an instance of the `TimeOfDay` class. A proxy for that instance was passed to the client. The only thing the client can do with this proxy is to invoke the `format` operation. The implementation of that operation is provided by the server and, when the client invokes `format`, it sends an RPC message to the server just as it does when it invokes an operation on an interface. The implementation of the `format` operation is entirely up to the server. (Presumably, the server will use the data members of the `TimeOfDay` instance it holds to return a string containing the time to the client.)

The preceding example looks somewhat contrived for classes only. However, it makes perfect sense if classes implement interfaces: parts of your application can exchange class instances (and, therefore, state) by value, whereas other parts of the system can treat these instances as remote interfaces.

For example:

Slice

```

interface Time {
    string format();
    // ...
};

class TimeOfDay implements Time {
    short hour;
    short minute;
    short second;
};

interface I1 {
    TimeOfDay get();           // Pass by value
    void put(TimeOfDay time); // Pass by value
};

interface I2 {
    Time* get();              // Pass by reference
};

```

In this example, clients dealing with interface `I1` are aware of the `TimeOfDay` class and pass it by value whereas clients dealing with interface `I2` deal only with the `Time` interface. However, the actual implementation of the `Time` interface in the server uses `TimeOfDay` instances.

Be careful when designing systems that use such mixed pass-by-value and pass-by-reference semantics. Unless you are clear about what parts of the system deal with the interface (pass by reference) aspects and the class (pass by value) aspects, you can end up with something that is more confusing than helpful.

A good example of putting this feature to use can be found in [Freeze](#), which allows you to add classes to an existing interface to implement persistence.

See Also

- [Self-Referential Classes](#)
- [Freeze](#)

Passing Interfaces by Value

Consider the following definitions:

```

Slice

```
interface Time {
 idempotent TimeOfDay getTime();
 // ...
};

interface Record {
 void addTimeStamp(Time t); // Note: Time t, not Time* t
 // ...
};
```

```

Note that `addTimeStamp` accepts a parameter of type `Time`, not of type `Time*`. The question is, what does it mean to pass an interface *by value*? Obviously, at run time, we cannot pass an actual interface to this operation because interfaces are abstract and cannot be instantiated. Neither can we pass a proxy to a `Time` object to `addTimeStamp` because a proxy cannot be passed where an interface is expected.

However, what we *can* pass to `addTimeStamp` is something that is not abstract and derives from the `Time` interface. For example, at run time, we could pass an instance of the `TimeOfDay` class we saw [earlier](#). Because the `TimeOfDay` class derives from the `Time` interface, the class type is compatible with the formal parameter type `Time` and, at run time, what is sent over the wire to the server is the `TimeOfDay` class instance.

See Also

- [Pass-by-Value Versus Pass-by-Reference](#)

Classes with Compact Type IDs

As of Ice 3.5, you can optionally associate a numeric identifier with a class. The Ice run time substitutes this value, known as a *compact type ID*, in place of its equivalent *string type ID* during marshaling to conserve space. The compact type ID follows immediately after the class name, enclosed in parentheses:

```

Slice

```
module MyModule {
 class CompactExample(4) {
 // ...
 };
};
```

```

In this example, the Ice run time marshals the value 4 instead of its string equivalent "`::MyModule::CompactExample`". The specified value must be a non-negative integer that is unique within the translation unit.

Using values less than 255 produces the most efficient encoding.

See Also

- [Classes](#)
- [Type IDs](#)
- [Data Encoding for Class Type IDs](#)

Forward Declarations

Both [interfaces](#) and [classes](#) can be forward declared. Forward declarations permit the creation of mutually dependent objects, for example:

Slice
<pre> module Family { interface Child; // Forward declaration sequence<Child*> Children; // OK interface Parent { Children getChildren(); // OK }; interface Child { // Definition Parent* getMother(); Parent* getFather(); }; }; </pre>

Without the forward declaration of `Child`, the definition obviously could not compile because `Child` and `Parent` are mutually dependent interfaces. You can use forward-declared interfaces and classes to define types (such as the `Children` sequence in the previous example). Forward-declared interfaces and classes are also legal as the type of a structure, exception, or class member, as the value type of a dictionary, and as the parameter and return type of an operation. However, you cannot inherit from a forward-declared interface or class until after its definition has been seen by the compiler:

Slice
<pre> interface Base; // Forward declaration interface Derived1 extends Base {}; // Error! interface Base {}; // Definition interface Derived2 extends Base {}; // OK, definition was seen </pre>

Not inheriting from a forward-declared base interface or class until its definition is seen is necessary because, otherwise, the compiler could not enforce that derived interfaces must not redefine operations that appear in base interfaces.

A multi-pass compiler could be used, but the added complexity is not worth it.

- [Interfaces, Operations, and Exceptions](#)
- [Classes](#)

Optional Data Members

On this page:

- [Overview of Optional Data Members](#)
- [Declaring Optional Data Members](#)
- [Optional Data Members with Default Values](#)

Overview of Optional Data Members

As of Ice 3.5, a data member of a Slice [class](#) or [exception](#) may be declared as [optional](#) to indicate that a program can leave its value unset. Data members not declared as optional are known as *required* members; a program must supply legal values for all required members.

Declaring Optional Data Members

Each optional data member in a type must be assigned a unique, non-negative integer *tag*:

Slice
<pre>class C { string name; bool active; optional(2) string alternateName; optional(5) int overrideCode; };</pre>

It is legal for a base type's tag to be reused by a derived type:

Slice
<pre>exception Base { optional(1) int systemCode; }; exception Derived extends Base { optional(1) string diagnostic; // OK };</pre>

The scope of a tag is limited to its enclosing type and has no effect on base or derived types.

Language mappings specify an API for setting an optional member and testing whether a member is set. Here is an example in C++:

C++

```

CPtr c = new C;
c->name = "xyz";           // required
c->active = true;         // required
c->alternateName = "abc"; // optional
c->overrideCode = 42;    // optional

if(c->alternateName)
    cout << "alt name = " << c->alternateName << endl;

```

As you can see, the C++ language mapping makes setting an optional member as simple as assigning it a value. Refer to the language mapping sections for more details on the optional data member API.

A well-behaved program must test for the presence of an optional member and not assume that it is always set. Dereferencing an unset optional member causes a run-time error.

In all supported language mappings, an optional data member's initial condition is unset if not otherwise assigned during construction. Again using C++ as an example:

C++

```

CPtr c = new C;           // default constructor
assert(!c->alternateName); // not set

c = new C("xyz", true, "abc", 42); // one-shot constructor
assert(c->alternateName);           // set by constructor

```

Optional Data Members with Default Values

You can declare a default value for optional members just as you can for required members:

Slice

```

class C
{
    string name;
    bool active = true;
    optional(2) string alternateName;
    optional(5) int overrideCode = -1;
};

```

An optional data member with a default value is considered to be set by default:

C++

```
CPtr c = new C;           // default constructor
assert(!c->alternateName); // not set
assert(c->overrideCode);  // set to default value
```

Each language mapping provides an API for resetting an optional data member to its unset condition.

See Also

- [Classes](#)
- [User Exceptions](#)
- [Optional Values](#)

Type IDs

Interface, class and user exception Slice types have an internal type identifier, known as the *type ID*. The type ID is simply the fully-qualified name of each type. For example, the type ID of the `Child` interface in the [preceding example](#) is `::Family::Children::Child`. A type ID starts with a leading `::` and is formed by starting with the global scope (`::`) and forming the fully-qualified name of a type by appending each module name in which the type is nested, and ending with the name of the type itself; the components of the type ID are separated by `::`.

The type ID of the Slice `Object` type is `::Ice::Object`.

Type IDs are used internally by the Ice run time as a unique identifier for each type. For example, when an exception is raised, the marshaled form of the exception that is returned to the client is preceded by its type ID on the wire. The client-side run time first reads the type ID and, based on that, unmarshals the remainder of the data as appropriate for the type of the exception.

Type IDs are also used by the [ice_isA](#) operation.

See Also

- [ice_isA](#)

Operations on Object

The `Object` interface has a number of operations. We cannot define type `Object` in `Slice` because `Object` is a keyword; regardless, here is what (part of) the definition of `Object` would look like if it were legal:

```

Slice

sequence<string> StrSeq;

interface Object {                                     // "Pseudo" Slice!
    idempotent void    ice_ping();
    idempotent bool    ice_isA(string typeID);
    idempotent string  ice_id();
    idempotent StrSeq  ice_ids();
    // ...
};
```

Note that, apart from the illegal use of the keyword `Object` as the interface name, the operation names all contain the `ice_` prefix. This prefix is reserved for use by Ice and cannot clash with a user-defined operation. This means that all `Slice` interfaces can inherit from `Object` without name clashes. We discuss these built-in operations below.

On this page:

- [ice_ping](#)
- [ice_isA](#)
- [ice_id](#)
- [ice_ids](#)

ice_ping

All interfaces support the `ice_ping` operation. That operation is useful for debugging because it provides a basic reachability test for an object: if the object exists and a message can successfully be dispatched to the object, `ice_ping` simply returns without error. If the object cannot be reached or does not exist, `ice_ping` throws a run-time exception that provides the reason for the failure.

ice_isA

The `ice_isA` operation accepts a type identifier (such as the identifier returned by `ice_id`) and tests whether the target object supports the specified type, returning `true` if it does. You can use this operation to check whether a target object supports a particular type. For example, referring to the diagram [Implicit Inheritance from Object](#) once more, assume that you are holding a proxy to a target object of type `AlarmClock`. The table below illustrates the result of calling `ice_isA` on that proxy with various arguments. (We assume that all types in the [Implicit inheritance from Object](#) diagram are defined in a module `Times`):

Argument	Result
<code>::Ice::Object</code>	<code>true</code>
<code>::Times::Clock</code>	<code>true</code>
<code>::Times::AlarmClock</code>	<code>true</code>
<code>::Times::Radio</code>	<code>false</code>
<code>::Times::RadioClock</code>	<code>false</code>

Calling `ice_isA` on a proxy denoting an object of type `AlarmClock`.

As expected, `ice_isA` returns `true` for `::Times::Clock` and `::Times::AlarmClock` and also returns `true` for `::Ice::Object` (because all interfaces support that type). Obviously, an `AlarmClock` supports neither the `Radio` nor the `RadioClock` interfaces, so `ice_isA` returns `false` for those.

ns false for these types.

`ice_id`

The `ice_id` operation returns the [type ID](#) of the most-derived type of an interface.

`ice_ids`

The `ice_ids` operation returns a sequence of [type IDs](#) that contains all of the type IDs supported by an interface. For example, for the `RadioClock` interface in [Implicit inheritance from Object](#), `ice_ids` returns a sequence containing the type IDs `::Ice::Object`, `::Times::Clock`, `::Times::AlarmClock`, `::Times::Radio`, and `::Times::RadioClock`.

Local Types

In order to access certain features of the Ice run time, you must use APIs that are provided by libraries. However, instead of defining an API that is specific to each implementation language, Ice defines its APIs in Slice using the `local` keyword. The advantage of defining APIs in Slice is that a single definition suffices to define the API for all possible implementation languages. The actual language-specific API is then generated by the Slice compiler for each implementation language. Types that are provided by Ice libraries are defined using the Slice `local` keyword.

For example:

```

Slice

module Ice {
    local interface ObjectAdapter {
        // ...
    };
};

```

Any Slice definition (not just interfaces) can have a `local` modifier. If the `local` modifier is present, the Slice compiler does not generate marshaling code for the corresponding type. This means that a local type can *never* be accessed remotely because it cannot be transmitted between client and server. (The Slice compiler prevents use of `local` types in non-`local` contexts.)

In addition, local interfaces and local classes do *not* inherit from `Ice::Object`. Instead, local interfaces and classes have their own, completely separate inheritance hierarchy. At the root of this hierarchy is the type `Ice::LocalObject`, as shown:

Inheritance from LocalObject.

Because local interfaces form a completely separate inheritance hierarchy, you cannot pass a local interface where a non-local interface is expected, and vice-versa.

You rarely need to define local types for your own applications — the `local` keyword exists mainly to allow definition of APIs for the Ice run time. (Because local objects cannot be invoked remotely, there is little point for an application to define local objects; it might as well define ordinary programming-language objects instead.) However, there is one exception to this rule: [servant locators](#) must be implemented as local objects.

- [Servant Locators](#)

Names and Scoping

Slice has a number of rules regarding identifiers. You will typically not have to concern yourself with these. However, occasionally, it is good to know how Slice uses naming scopes and resolves identifiers.

On this page:

- [Naming Scope](#)
- [Case Sensitivity](#)
- [Qualified Names](#)
- [Names in Nested Scopes](#)
- [Introduced Identifiers](#)
- [Name Lookup Rules](#)
- [Scoping Rules for Parameters and Data Members](#)
- [Scoping Rules in Prior Ice Releases](#)

Naming Scope

The following Slice constructs establish a naming scope:

- the global (file) scope
- modules
- interfaces
- classes
- structures
- exceptions
- parameter lists

Within a naming scope, identifiers must be unique, that is, you cannot use the same identifier for different purposes. For example:

Slice

```
interface Bad {
    void op(int p, string p); // Error!
};
```

Because a parameter list forms a naming scope, it is illegal to use the same identifier `p` for different parameters. Similarly, data members, operation names, interface and class names, etc. must be unique within their enclosing scope.

Case Sensitivity

Identifiers that differ only in case are considered identical, so you must use identifiers that differ not only in capitalization within a naming scope. For example:

Slice

```
struct Bad {
    int m;
    string M; // Error!
};
```

The Slice compiler also enforces consistent capitalization for identifiers. Once you have defined an identifier, you must use the same capitalization for that identifier thereafter. For example, the following is in error:

Slice

```
sequence<string> StringSeq;

interface Bad {
    stringSeq op();    // Error!
};
```

Note that identifiers must not differ from a Slice keyword in case only. For example, the following is in error:

Slice

```
interface Module {    // Error, "module" is a keyword
    // ...
};
```

Qualified Names

The scope-qualification operator `::` allows you to refer to a type in a non-local scope. For example:

Slice

```
module Types {
    sequence<long> LongSeq;
};

module MyApp {
    sequence<Types::LongSeq> NumberTree;
};
```

Here, the qualified name `Types::LongSeq` refers to `LongSeq` defined in module `Types`. The global scope is denoted by a leading `::`, so we could also refer to `LongSeq` as `::Types::LongSeq`.

The scope-qualification operator also allows you to create mutually dependent interfaces that are defined in different modules. The obvious attempt to do this fails:

Slice

```

module Parents {
    interface Children::Child; // Syntax error!
    interface Mother {
        Children::Child* getChild();
    };
    interface Father {
        Children::Child* getChild();
    };
};

module Children {
    interface Child {
        Parents::Mother* getMother();
        Parents::Father* getFather();
    };
};

```

This fails because it is syntactically illegal to forward-declare an interface in a different module. To make it work, we must use a reopened module:

Slice

```

module Children {
    interface Child; // Forward declaration
};

module Parents {
    interface Mother {
        Children::Child* getChild(); // OK
    };
    interface Father {
        Children::Child* getChild(); // OK
    };
};

module Children { // Reopen module
    interface Child { // Define Child
        Parents::Mother* getMother();
        Parents::Father* getFather();
    };
};

```

While this technique works, it is probably of dubious value: mutually dependent interfaces are, by definition, tightly coupled. On the other hand, modules are meant to be used to place related definitions into the same module, and unrelated definitions into different modules. Of course, this begs the question: if the interfaces are so closely related that they depend on each other, why are they defined in different

modules? In the interest of clarity, you probably should avoid this construct, even though it is legal.

Names in Nested Scopes

Names defined in an enclosing scope can be redefined in an inner scope. For example, the following is legal:

```

Slice

module Outer {
    sequence<string> Seq;

    module Inner {
        sequence<short> Seq;
    };
};

```

Within module `Inner`, the name `Seq` refers to a sequence of `short` values and hides the definition of `Outer::Seq`. You can still refer to the other definition by using explicit scope qualification, for example:

```

Slice

module Outer {
    sequence<string> Seq;

    module Inner {
        sequence<short> Seq;

        struct Confusing {
            Seq      a;      // Sequence of short
            ::Outer::Seq b;  // Sequence of string
        };
    };
};

```

Needless to say, you should try to avoid such redefinitions — they make it harder for the reader to follow the meaning of a specification.

Same-named constructs cannot be nested inside each other in certain situations. For example, a module named `M` cannot (recursively) contain any construct also named `M`. The same is true for interfaces and classes, which cannot define an operation with the same name as the enclosing interface or class. For example, the following examples are all in error:

Slice

```

module M {
    interface M { /* ... */ }; // Error!

    interface I {
        void I();           // Error!
    };
};

module Outer {
    module Inner {
        interface outer { // Error, even if case differs!
            // ...
        };
    };
};

```

The reason for this restriction is that nested types that have the same name are difficult to map into some languages. For example, C++ and Java reserve the name of a class as the name of the constructor, so an interface `I` could not contain an operation named `I` without artificial rules to avoid the name clash.

Similarly, some languages (such as C# prior to version 2.0) do not permit a qualified name to be anchored at the global scope. If a nested module or type is permitted to have the same name as the name of an enclosing module, it can become impossible to generate legal code in some cases.

In the interest of simplicity, Slice prohibits the name of a nested module or type from being the same as the name of one of its enclosing modules.

Introduced Identifiers

Within a naming scope, an identifier is introduced at the point of first use; thereafter, within that naming scope, the identifier cannot change meaning.

For example:

Slice

```

module M {
    sequence<string> Seq;

    interface Bad {
        Seq op1(); // Seq and op1 introduced here
        int Seq(); // Error, Seq has changed meaning
    };
};

```

The declaration of `op1` uses `Seq` as its return type, thereby introducing `Seq` into the scope of interface `Bad`. Thereafter, `Seq` can only be used as a type name that denotes a sequence of strings, so the compiler flags the declaration of the second operation as an error.

Note that fully-qualified identifiers are not introduced into the current scope:

Slice

```

module M {
    sequence<string> Seq;

    interface Bad {
        ::M::Seq op1(); // Only op1 introduced here
        int Seq();     // OK
    };
};

```

In general, a fully-qualified name (one that is anchored at the global scope and, therefore, begins with a `::` scope resolution operator) does not introduce any name into the current scope. On the other hand, a qualified name that is not anchored at the global scope introduces only the first component of the name:

Slice

```

module M {
    sequence<string> Seq;

    interface Bad {
        M::Seq op1(); // M and op1 introduced here, but not Seq
        int Seq();   // OK
    };
};

```

Name Lookup Rules

When searching for the definition of a name that is not anchored at the global scope, the compiler first searches backward in the current scope of a definition of the name. If it can find the name in the current scope, it uses that definition. Otherwise, the compiler successively searches enclosing scopes for the name until it reaches the global scope. Here is an example to illustrate this:

Slice

```

module M1 {
    sequence<double> Seq;

    module M2 {
        sequence<string> Seq;    // OK, hides ::M1::Seq

        interface Base {
            Seq op1();          // Returns sequence of string
        };
    };

    module M3 {
        interface Derived extends M2::Base {
            Seq op2();          // Returns sequence of double
        };

        sequence<bool> Seq;     // OK, hides ::M1::Seq

        interface I {
            Seq op();           // Returns sequence of bool
        };
    };

    interface I {
        Seq op();               // Returns sequence of double
    };
};

```

Note that `M2::Derived::op2` returns a sequence of `double`, even though `M1::Base::op1` returns a sequence of `string`. That is, the meaning of a type in a base interface is irrelevant to determining its meaning in a derived interface — the compiler always searches for a definition only in the current scope and enclosing scopes, and never takes the meaning of a name from a base interface or class.

Scoping Rules for Parameters and Data Members

A Slice operation creates a new naming scope in which all parameter names must be unique:

Slice

```

interface I {
    void op1(string p, int P);    // Error, differs only in case
    void op2(int n, out int n);  // Error, duplicate
    void op3(string s, int i);   // OK
};

```

It's legal for parameters to reuse the names of symbols in enclosing scopes, including the name of the operation, class, interface or module:

Slice

```

module M {
    sequence<string> Seq;

    interface I {
        string query(string query); // OK to reuse operation name
        void op1(int I);           // OK to reuse name of enclosing
type
        void op2(Seq Seq);        // OK to reuse type name
        void op3(int M);          // OK to reuse module name
    };
};

```

The rules for data members are similar to those of parameters:

- Structures
Member names must be unique within the structure.
- Exceptions
Member names must be unique within the exception, including any members inherited from base exceptions.
- Classes
Member names must be unique within the class, including any members inherited from base classes. Members must not duplicate the names of operations defined by the class or inherited by any base classes or interfaces.

As for parameters, data members can reuse the names of symbols in enclosing scopes. The examples below illustrate these rules:

Slice

```

module M {
    struct S {
        int i;
        string s;    // OK to reuse name of enclosing type
        long I;      // Error, differs only in case
        bool M;      // OK to reuse module name
    };

    interface I {
        void op();
    };

    class Base {
        string name;
    };

    class C extends Base implements I {
        S S;         // OK to reuse type name
        byte c;      // OK to reuse name of enclosing type
        string op;   // Error, duplicates inherited I::op
        string Name; // Error, differs only in case from Base::name
    };

    exception ErrorBase {
        string reason;
    };

    exception Error extends ErrorBase {
        long error; // OK to reuse name of enclosing type
        int reason; // Error, duplicates inherited ErrorBase::reason
    };
};

```

Scoping Rules in Prior Ice Releases

The scoping rules for parameters and data members were more restrictive in Ice 3.5 and earlier releases:

- A data member cannot have the same name as its enclosing type

Slice

```
class C {
    int c; // Error
};
```

- A data member cannot have the same name as its type

Slice

```
module M {
    sequence<string> Seq;
    struct S {
        Seq Seq; // Error, use ::M::Seq as the type instead
    };
};
```

You can work around this limitation by using the fully-qualified type name.

- A parameter cannot have the same name as its operation

Slice

```
void op(int op); // Error
```

- A parameter cannot have the same name as its type

Slice

```
module M {
    sequence<string> Seq;
    interface I {
        void op(Seq Seq); // Error, use ::M::Seq as the type
    };
};
```

You can work around this limitation by using the fully-qualified type name.

You must adhere to these more-restrictive rules if your Slice definitions need to maintain backward compatibility with Ice 3.5 or earlier.

See Also

- [Lexical Rules](#)

Metadata

Slice has the concept of a *metadata* directive. For example:

Slice
<pre>["java:type:java.util.LinkedList<Integer>"] sequence<int> IntSeq;</pre>

A metadata directive can appear as a prefix to any Slice definition. Metadata directives appear in a pair of square brackets and contain one or more string literals separated by commas. For example, the following is a syntactically valid metadata directive containing two strings:

Slice
<pre>["a", "b"] interface Example {};</pre>

Metadata directives are not part of the Slice language per se: the presence of a metadata directive has no effect on the client-server contract, that is, metadata directives do not change the Slice type system in any way. Instead, metadata directives are targeted at specific back-ends, such as the code generator for a particular language mapping. In the preceding example, the `java:` prefix indicates that the directive is targeted at the Java code generator.

Metadata directives permit you to provide supplementary information that does not change the Slice types being defined, but somehow influences how the compiler will generate code for these definitions. For example, a metadata directive `java:type:java.util.LinkedList<T>` instructs the Java code generator to map a sequence to a linked list instead of an array (which is the default).

Metadata directives are also used to create skeletons that support *Asynchronous Method Dispatch (AMD)*.

Apart from metadata directives that are attached to a specific definition, there are also global metadata directives. For example:

Slice
<pre>[["java:package:com.acme"]]</pre>

Note that a global metadata directive is enclosed by double square brackets, whereas a local metadata directive (one that is attached to a specific definition) is enclosed by single square brackets. Global metadata directives are used to pass instructions that affect the entire compilation unit. For example, the preceding metadata directive instructs the Java code generator to generate the contents of the source file into the Java package `com.acme`. Global metadata directives must precede any definitions in a file (but can appear following any `#include` directives).

We discuss specific metadata directives in the relevant chapters to which they apply.

You can find a summary of all metadata directives in [Slice Metadata Directives](#).

- [Slice Metadata Directives](#)

Serializable Objects

Ice for Java and Ice for .NET allow you to send native Java and CLR objects as operation parameters. The Ice run time automatically serializes and deserializes the objects as part of an invocation. This mechanism allows you to transmit Java and CLR objects that do not have a corresponding Slice definition.

On this page:

- [The serializable Metadata Directive](#)
- [Architectural Implications](#)

The serializable Metadata Directive

To enable serialization, the parameter type must be a byte sequence with appropriate metadata. For example:

Slice
<pre>["java:serializable:SomePackage.JavaClass"] sequence<byte> JavaObj; interface JavaExample { void sendJavaObj(JavaObj o); }; ["clr:serializable:SomeNamespace.CLRClass"] sequence<byte> CLRObj; interface CLRExample { void sendCLRObj(CLRObj o); };</pre>

The `java:serializable` metadata indicates that the corresponding byte sequence holds a [Java serializable type](#) named `SomePackage.JavaClass`. Your program must provide an implementation of this class; the class must implement `java.io.Serializable`.

Similarly, the `clr:serializable` metadata indicates that the corresponding byte sequences holds a [CLR serializable type](#) named `SomeNamespace.CLRClass`. Your program must provide an implementation of this class; the class must be marked with the `Serializable` attribute.

Architectural Implications

The `serializable` metadata directive permits you to transmit arbitrary Java and CLR objects across the network without the need to define corresponding Slice classes or structures. This is mainly a convenience feature: you could achieve the same thing by using ordinary Slice byte sequences and explicitly serializing your Java or CLR objects into byte sequences at the sending end, and deserializing them at the receiving end. The `serializable` metadata conveniently takes care of these chores for you and so is simpler to use.

Despite its convenience, you should use this feature with caution because it destroys language transparency. For example, a serialized Java object is useless to a C++ server. All the C++ server can do with such an object is to pass it on to some other process as a byte sequence. (Of course, if that receiving process is a Java process, it can deserialize the byte sequence.)

Further, similar to [Slice classes with methods](#), a serialized object can be deserialized only if client and server agree on the definition of the serialized class. In Java, this is enforced by the `serialVersionUID` field of each instance; in the CLR, client and server must reference identical assembly versions. This creates much tighter coupling of client and server than exchanging Slice-defined types.

And, of course, if you build a system that relies on, for example, the exchange of serialized Java objects and you later find that you need to add C++ or C# components to the system, these components cannot do anything with the serialized Java objects other than pass them around as a blob of bytes.

So, if you do use these features, be clear that this implies tighter coupling between client and server, and that it creates additional library versioning and distribution issues because all parts of the system must agree on the implementation of the serialized objects.

- [Serializable Objects in C#](#)
- [Architectural Implications of Classes](#)

Deprecating Slice Definitions

All Slice compilers support a metadata directive that allows you to deprecate a Slice definition. For example:

```

Slice

```
interface Example {
 ["deprecate:someOperation() has been deprecated, use alternativeOpe
ration() instead."]
 void someOperation();

 void alternativeOperation();
};
```

```

The ["deprecate"] metadata directive causes the compiler to emit code that generates a warning if you compile application code that uses a deprecated feature. This is useful if you want to remove a feature from a Slice definition but do not want to cause a hard error.

The message that follows the colon is optional; if you omit the message and use ["deprecate"], the Slice compilers insert a default message into the generated code.

You can apply the ["deprecate"] metadata directive to Slice constructs other than operations (for example, a structure or sequence definition).

- [Generating Slice Documentation](#)

Using the Slice Compilers

Ice provides a separate Slice compiler for each language mapping, as shown below:

Language	Compiler	Freeze Compiler
C++	<code>slice2cpp</code>	<code>slice2freeze</code>
Java	<code>slice2java</code>	<code>slice2freezej</code>
JavaScript	<code>slice2js</code>	
C#	<code>slice2cs</code>	
Objective-C	<code>slice2objc</code>	
Python	<code>slice2py</code>	
Ruby	<code>slice2rb</code>	
PHP	<code>slice2php</code>	

The Slice compilers.

The compilers share a similar command-line syntax:

```
<compiler-name> [options] file...
```

Regardless of which compiler you use, a number of command-line options are common to the compilers for any language mapping. (See the appropriate language mapping chapter for options that are specific to a particular language mapping.) The common command-line options are:

- `-h, --help`
Displays a help message.
- `-v, --version`
Displays the compiler version.
- `-DNAME`
Defines the preprocessor symbol *NAME*.
- `-DNAME=DEF`
Defines the preprocessor symbol *NAME* with the value *DEF*.
- `-UNAME`
Undefines the preprocessor symbol *NAME*.
- `-IDIR`
Add the directory *DIR* to the search path for `#include` directives.
- `-E`
Print the preprocessor output on `stdout`.
- `--output-dir DIR`
Place the generated files into directory *DIR*.
- `-d, --debug`
Print debug information showing the operation of the Slice parser.
- `--ice`
Permit use of the reserved *Ice* prefix in Slice identifiers. This is useful when building Ice itself, or when compiling a Slice file that includes another Slice file with Ice-prefixed identifiers, such as `Ice/BuiltinSequences.ice`.
- `--underscore`
Permit use of underscores in Slice identifiers.

- `--depend`
Print dependency information to standard output by default, or to the file specified by the `--depend-file` option. No code is generated when this option is specified. The output includes the complete list of Slice files that the input Slice files depend on through direct or indirect inclusion; this output may include other files depending on the target programming language. The Ice for C++ build system uses the script `config/makedepend.py` to process and include this output in `Makefiles`.
- `--depend-xml`
Print dependency information in XML format to standard output by default, or to the file specified by the `--depend-file` option. No code is generated when this option is specified. The output consists of the complete list of Slice files that the input Slice files depend on through direct or indirect inclusion, and is identical will all Slice compilers.
- `--depend-file FILE`
Directs dependency information to the specified file. The output format depends on whether `--depend` or `--depend-xml` is also specified.
- `--validate`
Checks the provided command-line options for correctness, and does not generate any code.

The Slice compilers permit you to compile more than a single source file, so you can compile several Slice definitions at once, for example:

```
slice2cpp -I. file1.ice file2.ice file3.ice
```

Slice Checksums

As distributed applications evolve, developers and system administrators must be careful to ensure that deployed components are using the same client-server contract. Unfortunately, mistakes do happen, and it is not always readily apparent when they do.

To minimize the chances of this situation, the Slice compilers support an option that generates checksums for Slice definitions, thereby enabling two peers to verify that they share an identical client-server contract. The checksum for a Slice definition includes details such as parameter and member names and the order in which operations are defined, but ignores information that is not relevant to the client-server contract, such as metadata, comments, and formatting.

This option causes the Slice compiler to construct a dictionary that maps Slice type identifiers to checksums. A server typically supplies an operation that returns its checksum dictionary for the client to compare with its local version, at which point the client can take action if it discovers a mismatch.

The dictionary type is defined in the file `Ice/SliceChecksumDict.ice` as follows:

```

Slice

module Ice {
    dictionary<string, string> SliceChecksumDict;
};

```

This type can be incorporated into an application's Slice definitions like this:

```

Slice

#include <Ice/SliceChecksumDict.ice>

interface MyServer {
    idempotent Ice::SliceChecksumDict getSliceChecksums();
    // ...
};

```

The key of each element in the dictionary is a Slice [type ID](#), and the value is the checksum of that type.

For more information on generating and using Slice checksums, see the appropriate language mapping chapter.

Generating Slice Documentation

The [Slice API reference](#) documents all of the Slice definitions for Ice and its services by extracting comments from their Slice files. You can generate HTML documentation from your own Slice definitions using `slice2html`. As an example of the comment syntax supported by `slice2html`, here is the definition of `Ice::Current`:

Slice
<pre> /** * * Information about the current method invocation for servers. Each * operation on the server has a <tt>Current</tt> as its implicit final * parameter. <tt>Current</tt> is mostly used for Ice services. Most * applications ignore this parameter. * **/ local struct Current { /** * The object adapter. **/ ObjectAdapter adapter; /** * Information about the connection over which the current * method invocation was received. If the invocation is direct * due to collocation optimization, this value is set to null. **/ Connection con; /** * The Ice object identity. **/ Identity id; /** * The facet. ***/ string facet; /** * The operation name. </pre>

```
    **/  
string operation;  
  
/**  
 * The mode of the operation.  
 **/  
OperationMode mode;  
  
/**  
 * The request context, as received from the client.  
 **/  
Context ctx;  
  
/**  
 * The request id unless oneway (0) or collocated (-1).  
 **/  
int requestId;  
  
/**  
 * The encoding version used to encode the input and output  
parameters.  
 **/
```

```
Ice::EncodingVersion encoding;
};
```

If you look at the comments, you will see these reflected in the documentation for `Ice::Current` in the online [Slice API reference](#).

Documentation Comments

A documentation comment:

- starts with `/**`
- ends with `**/`

Such a comment can precede any Slice construct, such as a module, interface, structure, operation, and so on. Within a documentation comment, you can either start each line with a `*`, or you can leave the beginning of the line blank — `slice2html` can handle either convention:

Slice
<pre>/** * * This is a documentation comment for which every line * starts with a '*' character. **/ /** This is a documentation comment without a leading '*' for each line. Either style of comment is fine. **/</pre>

The first sentence of the documentation comment for a Slice construct should be a summary sentence. `slice2html` generates an index of all Slice constructs; the first sentence of the comments for each Slice construct is used as a summary in that index.

Hyperlinks

Any Slice identifier enclosed in `{@link ...}` is presented as a hyperlink in code font. For example:

Slice
<pre>/** * An empty {@link name} denotes a null object. **/</pre>

This generates a hyperlink for the `name` markup that points at the definition of the corresponding Slice symbol. (The symbol can denote any Slice construct, such as a type, interface, parameter, or structure member.)

Explicit Cross-References

The directive `@see` is recognized by `slice2html`. Where it appears, the generated HTML contains a separate section titled "See Also",

followed by a list of Slice identifiers. For example:

Slice
<pre> /** * The object adapter, which is responsible for receiving requests * from endpoints, and for mapping between servants, identities, * and proxies. * * @see Communicator * @see ServantLocator **/ </pre>

The Slice identifiers are listed in the corresponding "See Also" section as hyperlinks in code font.

Markup for Operations

There are three directives specifically to document Slice operations: `@param`, `@return`, and `@throws`. For example:

Slice
<pre> /** * Look for an item with the specified * primary and secondary key. * * @param p The primary search key. * * @param s The secondary search key. * * @return The item that matches the specified keys. * * @throws NotFound Raised if no item matches the specified keys. **/ Item findItem(Key p, Key s) throws NotFound; </pre>

`slice2html` generates separate "Parameters", "Return Value", and "Exceptions" sections for these directives. Parameters are listed in the same order as they appear in the comments. (For clarity, that order should match the order of declaration of parameters for the corresponding operation.)

General HTML Markup

A documentation comment can contain any markup that is permitted by HTML in that place. For example, you can create separate paragraphs with `<P>` and `</P>` elements:

Slice

```
/**
 * This is a comment for some Slice construct.</p>
 *
 * <p>This comment appears in a separate paragraph.
 **/
```

Note that you must neither begin a documentation comment with a `<p>` element nor end it with a `</p>` element because, in the generated HTML, documentation comments are already surrounded by `<p>` and `</p>` elements.

There are various other ways to create markup — for example, you can use `<table>` or `` elements. Please see the [HTML specification](#) for details.

Using `slice2html`

`slice2html` uses the following syntax:

```
slice2html [options] slice_file...
```

If you have cross-references that span Slice files, you must compile all of the Slice files with a single invocation of `slice2html`.

The command supports the following options:

- `-h, --help`
Displays a help message.
- `-v, --version`
Displays the compiler version.
- `-DNAME`
Defines the preprocessor symbol `NAME`.
- `-DNAME=DEF`
Defines the preprocessor symbol `NAME` with the value `DEF`.
- `-UNAME`
Undefines the preprocessor symbol `{NAME}`.
- `-IDIR`
Add the directory `DIR` to the search path for `#include` directives.
- `-E`
Print the preprocessor output on `stdout`.
- `--output-dir DIR`
Place the generated files into directory `DIR`.
- `-d, --debug`
Print debug information showing the operation of the Slice parser.
- `--ice`
Permit use of the normally reserved prefix `Ice` for identifiers. Use this option only when compiling the source code for the Ice run time.
- `--underscore`
Permit use of underscores in Slice identifiers.
- `--hdr FILE`
Prepend `FILE` to each generated HTML file (except for `_sindex.html`). This allows you to replace the HTML header and other

preamble information with a custom version, so you can connect style sheets to the generated pages. The specified file must include the `<body>` tag (but need not end with a `<body>` tag). *FILE* is expected to contain the string `TITLE` on a line by itself, starting in column one. `slice2html` replaces the `TITLE` string with the fully-scoped name of the Slice symbol that is documented on the corresponding page.

- `--ftr FILE`
Append *FILE* to each generated HTML file (except for `_sindex.html`). This allows you to add, for example, a custom footer to each generated page. *FILE* must end with a `</body>` tag.
- `--indexhdr FILE`
`slice2html` generates a file `_sindex.html` that contains a table of contents of all Slice symbols that hyperlink to the corresponding page. This option allows you to replace the standard header with a custom header, for example, to attach a JavaScript. The specified file must include the `<body>` tag (but need not end with a `<body>` tag). The default value is the setting of `--hdr` (if any).
- `--indexftr FILE`
Append *FILE* to the generated `sindex.html` page. This allows you to add, for example, a custom footer to the table of contents, or to invoke a JavaScript. *FILE* must end with a `</body>` tag. The default value is the setting of `--ftr` (if any).
- `--image-dir DIR`
With this option, `slice2html` looks in the specified directory for images to use for the generated navigation hyperlinks. (Without this option, text links are used instead.) Please see the generated HTML for the names of the various image files. (They can easily be found by looking for `img` elements.)
- `--logo-url URL`
Use the specified URL as a hyperlink for the company logo that is added to each page (if `--image-dir` is specified). The company logo is expected to be in `<image_dir>/logo.gif`.
- `--search ACTION`
If this option is specified, the generated pages contain a search box that allows you to connect the generated pages to a search engine. On pressing the "Search" button, the specified *ACTION* is carried out.
- `--index NUM`
`slice2html` generates sub-indexes for various Slice symbols. This option controls how many entries must be present before a sub-index is generated. For example, if *NUM* is set to 3, a sub-index will be generated only if there are three or more symbols that appear in that index. The default settings is 1, meaning that a sub-index is always generated. To disable sub-indexes entirely, set *NUM* to 0.
- `--summary NUM`
If this option is set, summary sentences that exceed *NUM* characters generate a warning.

Slice Keywords

The following identifiers are Slice keywords:

bool	extends	LocalObject	string
byte	false	long	struct
class	float	module	throws
const	idempotent	Object	true
dictionary	implements	optional	void
double	int	out	
enum	interface	sequence	
exception	local	short	

Keywords must be capitalized as shown.

Slice Metadata Directives

On this page:

- [General Metadata Directives](#)
- [Metadata Directives for C++](#)
- [Metadata Directives for Java](#)
- [Metadata Directives for C#](#)
- [Metadata Directives for .NET](#)
- [Metadata Directives for Objective-C](#)
- [Metadata Directives for Python](#)
- [Metadata Directives for Freeze](#)

General Metadata Directives

`amd`

This directive applies to interfaces, classes, and individual operations. It enables code generation for asynchronous method dispatch. (See the relevant language mapping chapter for details.)

`deprecate`

This directive allows you to emit a deprecation warning for Slice constructs.

`format`

This directive defines the [encoding format](#) used for any classes or exceptions marshaled as the arguments or results of an operation. The tag can be applied to an interface, which affects all of its operations, or to individual operations. Legal values for the tag are `format:sliced`, `format:compact`, and `format:default`. A tag specified for an operation overrides any setting applied to its enclosing interface. The `Ice.Default.SlicedFormat` property defines the behavior when no tag is present.

`preserve-slice`

This directive applies to classes and exceptions, allowing an intermediary to [forward an instance](#) of the annotated type, or any of its subtypes, with all of its slices intact. Operations that transfer such types must be annotated with `format:sliced`. It is not necessary to repeat the `preserve-slice` tag on derived types, but you may wish to do so for documentation purposes.

`protected`

This directive applies to data members of classes and changes code generation to make these members protected. See class mapping of the relevant language mapping chapter for more information.

`UserException`

This directive applies only to operations on local interfaces. The metadata directive indicates that the operation can throw any user exception, regardless of its specific definition. (This directive is used for the `locate` and `finished` operations on servant locators, which can throw any user exception.)

Metadata Directives for C++

`cpp:array` and `cpp:range`

These directives apply to sequences. They direct the code generator to create zero-copy APIs for [passing sequences as parameters](#).

cpp:class

This directive applies to [structures](#). It directs the code generator to create a C++ class (instead of a C++ structure) to represent a Slice structure.

cpp:comparable

This directive applies to [structures](#). It directs the code generator to generate comparison operators for a structure regardless of whether it qualifies as a legal dictionary key type.

cpp:const

This directive applies to operations. It directs the code generator to create a `const` pure virtual member function for the [skeleton class](#).

cpp:header-ext

This global directive allows you to use a [file extension for C++ header files](#) other than the default `.h` extension.

cpp:ice_print

This directive applies to exceptions. It directs the code generator to declare (but not implement) an `ice_print` member function that overrides the `ice_print` virtual function in `Ice::Exception`. The application must provide the implementation of this `ice_print` function.

cpp:include

This global directive allows you inject additional `#include` directives into the generated code. This is useful for [custom types](#).

cpp:type:c++-type

This directive applies to [sequences](#) and [dictionaries](#). It directs the code generator to map the Slice type or parameter to the provided C++ type.

cpp:type:string and cpp:type:wstring

These directives apply to data members of type string as well as to containers, such as structures, classes, exceptions, and modules. String members [map by default](#) to `std::string`. You can use the `cpp:type:wstring` metadata to cause a string data member (or all string data members in a structure, class or exception) to map to `std::wstring` instead. Use the `cpp:type:string` metadata to force string members to use the default mapping regardless of any enclosing metadata.

Slice

```

["cpp:type:wstring"]
module A { // All string members in this module map by default to
std::wstring
    struct Struct1 {
        string s; // Maps to std::wstring
    };
    struct Struct2 {
        ["cpp:type:string"] string s; // Maps to std::string
    };

    ["cpp:type:string"] // All string members in this module map by
default to std::string
    module Inner {
        struct Struct4 {
            string s; // Maps to std::string
        };

        ["cpp:type:wstring"] // All string members of Struct4 map by
default to std::wstring
        struct Struct3 {
            string s; // Maps to std::wstring
        };
    };
};

```

`cpp:view-type:c++-view-type`

This directive applies to string, sequence and dictionary parameters. It directs the code generator to map this parameter to the provided C++ type when this parameter does not need to hold any memory, for example when mapping an in-parameter to a proxy function.

`cpp:virtual`

This directive applies to classes. If the directive is present and a class has base classes, the generated C++ class derives virtually from its bases; without this directive, slice2cpp generates the class so it derives non-virtually from its bases.

This directive is useful if you use Slice classes as servants and want to inherit the implementation of operations in the base class in the derived class. For example:

Slice

```
class Base {
    int baseOp();
};

["cpp:virtual"]
class Derived extends Base {
    string derivedOp();
};
```

The metadata directive causes slice2cpp to generate the class definition for `Derived` using virtual inheritance:

C++

```
class Base : virtual public Ice::Object {
    // ...
};

class Derived : virtual public Base {
    // ...
};
```

This allows you to reuse the implementation of `baseOp` in the servant for `Derived` using ladder inheritance:

C++

```
class BaseI : public virtual Base {
    Ice::Int baseOp(const Ice::Current&);
    // ...
};

class DerivedI : public virtual Derived, public virtual BaseI {
    // Re-use inherited baseOp()
};
```

Note that, if you have data member in classes and use virtual inheritance, you need to take care to correctly call base class constructors if you implement your own one-shot constructor. For example:

Slice

```
class Base {
    int baseInt;
};

class Derived extends Base {
    int derivedInt;
};
```

The generated one-shot constructor for `Derived` initializes both `baseInt` and `derivedInt`:

C++

```
Derived::Derived(Ice::Int __ice_baseInt, Ice::Int __ice_derivedInt)
    : M::Base(__ice_baseInt),
      derivedInt(__ice_derivedInt)
{
}
```

If you derive your own class from `Derived` and add a one-shot constructor to your class, you must explicitly call the constructor of all the base classes, including `Base`. Failure to call the `Base` constructor will result in `Base` being default-constructed instead of getting a defined value. For example:

C++

```
class DerivedI : public virtual Derived {
public:
    DerivedI(int baseInt, int derivedInt, const string& s)
        : Base(baseInt), Derived(baseInt, derivedInt), _s(s)
    {
    }

private:
    string _s;
};
```

This code correctly initializes the `baseInt` member of the `Base` part of the class. Note that the following does not work as intended and leaves the `Base` part default-constructed (meaning that `baseInt` is not initialized):

C++

```

class DerivedI : public virtual Derived {
public:
    DerivedI(int baseInt, int derivedInt, const string& s)
        : Derived(baseInt, derivedInt), _s(s)
    {
        // WRONG: Base::baseInt is not initialized.
    }

private:
    string _s;
};

```

Metadata Directives for Java**java:buffer**

This directive applies to [sequences](#) of certain primitive types. It directs the translator to map the sequence to a subclass of `java.nio.Buffer`.

java:getset

This directive applies to data members and structures, classes, and exceptions. It adds accessor and modifier methods ([JavaBean methods](#)) for data members.

java:optional

This directive forces [optional output parameters](#) to use the optional mapping instead of the default required mapping in servants.

java:package

This global directive instructs the code generator to place the generated classes into a [specific package](#).

java:serializable

This directive allows you to use Ice to transmit [serializable Java classes](#) as native objects, without having to define corresponding Slice definitions for these classes.

java:serialVersionUID

This directive [overrides](#) the default (generated) value of `serialVersionUID` for a Slice type.

java:type

This directive allows you to use [custom types](#) for sequences and dictionaries.

Metadata Directives for C#

Note that C# (and other Common Language Runtime languages) are also affected by metadata with a `clr:` prefix. (See [Metadata Directives for .NET](#).)

`cs:attribute`

This directive can be used both as a global directive and as directive for specific Slice constructs. It injects C# attribute definitions into the generated code. (See [C-Sharp Specific Metadata Directives](#).)

Metadata Directives for .NET

`clr:class`

This directive applies to Slice structures. It directs the code generator to emit a [C# class](#) instead of a structure.

`clr:generic:List`, `clr:generic:LinkedList`, `clr:generic:Queue` and `clr:generic:Stack`

These directives apply to [sequences](#) and map them to the specified sequence type.

`clr:generic:SortedDictionary`

This directive applies to [dictionaries](#) and maps them to `SortedDictionary`.

`clr:generic`

This directive applies to [sequences](#) and allows you map them to custom types.

`clr:implements:type`

This directive adds the specified base type to the generated code for a Slice structure, class or interface. For example, Ice defines the `Communicator` interface as shown below:

```

Slice

["clr:implements:_System.IDisposable"]
local interface Communicator { ... };

```

Consequently, the generated C# interface `Ice.Communicator` implements `IDisposable`.

Every Slice-generated C# source file defines two namespace aliases:

```
using _System = global::System;
using _Microsoft = global::Microsoft;
```

We recommend using these aliases if your metadata refers to the `System` or `Microsoft` namespaces.

`clr:property`

This directive applies to Slice structures and classes. It directs the code generator to create [C# property definitions](#) for data members.

`clr:serializable`

This directive allows you to use Ice to transmit [serializable CLR classes as native objects](#), without having to define corresponding Slice

definitions for these classes.

Metadata Directives for Objective-C

`objc:prefix`

This directive applies to modules and changes the [default mapping for modules](#) to use a specified prefix.

Metadata Directives for Python

`python:package`

This global directive instructs the code generator to place the generated code into a [specified Python package](#).

`python:seq:default`, `python:seq:list` and `python:seq:tuple`

These directives allow you to change the [mapping for Slice sequences](#).

Metadata Directives for Freeze

`freeze:read` and `freeze:write`

These directives inform a Freeze evictor whether an operation [updates the state](#) of an object, so the evictor knows whether it must save an object before evicting it.

Slice for a Simple File System

For this manual, we use a file system application to illustrate various aspects of Ice. Throughout, we progressively improve and modify the application such that it evolves into an application that is realistic and illustrates the architectural and coding aspects of Ice. This allows us to explore the capabilities of the platform to a realistic degree of complexity without overwhelming you with an inordinate amount of detail early on.

In this section:

- [File System Application](#) outlines the file system functionality
- [Slice Definitions for the File System](#) develops the data types and interfaces that are required for the file system
- [Complete Definition](#) presents the complete Slice definition for the application.

File System Application

Our file system application implements a simple hierarchical file system, similar to the file systems we find in Windows or Unix. To keep code examples to manageable size, we ignore many aspects of a real file system, such as ownership, permissions, symbolic links, and a number of other features. However, we build enough functionality to illustrate how you could implement a fully-featured file system, and we pay attention to things such as performance and scalability. In this way, we can create an application that presents us with real-world complexity without getting buried in large amounts of code.

Our file system consists of directories and files. Directories are containers that can contain either directories or files, meaning that the file system is hierarchical. A dedicated directory is at the root of the file system. Each directory and file has a name. Files and directories with a common parent directory must have different names (but files and directories with different parent directories can have the same name). In other words, directories form a naming scope, and entries with a single directory must have unique names. Directories allow you to list their contents.

For now, we do not have a concept of pathnames, or the creation and destruction of files and directories. Instead, the server provides a fixed number of directories and files. (We will address the creation and destruction of files and directories in [Object Life Cycle](#).)

Files can be read and written but, for now, reading and writing always replace the entire contents of a file; it is impossible to read or write only parts of a file.

Slice Definitions for the File System

Given the very simple requirements we just outlined, we can start designing interfaces for the system. Files and directories have something in common: they have a name and both files and directories can be contained in directories. This suggests a design that uses a base type that provides the common functionality, and derived types that provide the functionality specific to directories and files, as shown:

Inheritance Diagram of the File System.

The Slice definitions for this look as follows:

Slice

```
interface Node {
    // ...
};

interface File extends Node {
    // ...
};

interface Directory extends Node {
    // ...
};
```

Next, we need to think about what operations should be provided by each interface. Seeing that directories and files have names, we can add an operation to obtain the name of a directory or file to the `Node` base interface:

Slice

```
interface Node {
    idempotent string name();
};
```

The `File` interface provides operations to read and write a file. For simplicity, we limit ourselves to text files and we assume that `read` operations never fail and that only `write` operations can encounter error conditions. This leads to the following definitions:

Slice

```
exception GenericError {
    string reason;
};

sequence<string> Lines;

interface File extends Node {
    idempotent Lines read();
    idempotent void write (Lines text) throws GenericError;
};
```

Note that `read` and `write` are marked idempotent because either operation can safely be invoked with the same parameter value twice in a row: the net result of doing so is the same as having (successfully) called the operation only once.

The `write` operation can raise an exception of type `GenericError`. The exception contains a single `reason` data member, of type `string`. If a `write` operation fails for some reason (such as running out of file system space), the operation throws a `GenericError` exception, with an explanation of the cause of the failure provided in the `reason` data member.

Directories provide an operation to list their contents. Because directories can contain both directories and files, we take advantage of the polymorphism provided by the `Node` base interface:

Slice

```
sequence<Node*> NodeSeq;

interface Directory extends Node {
    idempotent NodeSeq list();
};
```

The `NodeSeq` sequence contains elements of type `Node*`. Because `Node` is a base interface of both `Directory` and `File`, the `NodeSeq` sequence can contain proxies of either type. (Obviously, the receiver of a `NodeSeq` must down-cast each element to either `File` or `Directory` in order to get at the operations provided by the derived interfaces; only the `name` operation in the `Node` base interface can be invoked directly, without doing a down-cast first. Note that, because the elements of `NodeSeq` are of type `Node*` (not `Node`), we are using pass-by-reference semantics: the values returned by the `list` operation are proxies that each point to a remote node on the server.

These definitions are sufficient to build a simple (but functional) file system. Obviously, there are still some unanswered questions, such as how a client obtains the proxy for the root directory. We will address these questions in the relevant implementation chapter.

Complete Definition

We wrap our definitions in a module, resulting in the final definition as follows:

Slice

```
module Filesystem {
    interface Node {
        idempotent string name();
    };

    exception GenericError {
        string reason;
    };

    sequence<string> Lines;

    interface File extends Node {
        idempotent Lines read();
        idempotent void write(Lines text) throws GenericError;
    };

    sequence<Node*> NodeSeq;

    interface Directory extends Node {
        idempotent NodeSeq list();
    };
};
```

Client-Side Slice-to-C++ Mapping

The client-side Slice-to-C++ mapping defines how Slice data types are translated to C++ types, and how clients invoke operations, pass parameters, and handle errors. Much of the C++ mapping is intuitive. For example, Slice sequences map to STL vectors, so there is essentially nothing new you have to learn in order to use Slice sequences in C++.

The rules that make up the C++ mapping are simple and regular. In particular, the mapping is free from the potential pitfalls of memory management: all types are self-managed and automatically clean up when instances go out of scope. This means that you cannot accidentally introduce a memory leak by, for example, ignoring the return value of an operation invocation or forgetting to deallocate memory that was allocated by a called operation.

The C++ mapping is fully thread-safe. For example, the [reference counting mechanism](#) for classes is interlocked against parallel access, so reference counts cannot be corrupted if a class instance is shared among a number of threads. Obviously, you must still synchronize access to data from different threads. For example, if you have two threads sharing a sequence, you cannot safely have one thread insert into the sequence while another thread is iterating over the sequence. However, you only need to concern yourself with concurrent access to your own data — the Ice run time itself is fully thread safe, and none of the Ice API calls require you to acquire or release a lock before you safely can make the call.

Much of what appears in this chapter is reference material. We suggest that you skim the material on the initial reading and refer back to specific sections as needed. However, we recommend that you read at least the mappings for [exceptions](#), [interfaces](#), and [operations](#) in detail because these sections cover how to call operations from a client, pass parameters, and handle exceptions.

In order to use the C++ mapping, you should need no more than the Slice definition of your application and knowledge of the C++ mapping rules. In particular, looking through the generated header files in order to discern how to use the C++ mapping is likely to be confusing because the header files are not necessarily meant for human consumption and, occasionally, contain various cryptic constructs to deal with operating system and compiler idiosyncrasies. Of course, occasionally, you may want to refer to a header file to confirm a detail of the mapping, but we recommend that you otherwise use the material presented here to see how to write your client-side code.

The Ice Namespace

All of the APIs for the Ice run time are nested in the `Ice` namespace, to avoid clashes with definitions for other libraries or applications. Some of the contents of the `Ice` namespace are generated from Slice definitions; other parts of the `Ice` namespace provide special-purpose definitions that do not have a corresponding Slice definition. We will incrementally cover the contents of the `Ice` namespace throughout the remainder of the manual.

C++ Mapping for Identifiers

A Slice [identifier](#) maps to an identical C++ identifier. For example, the Slice identifier `clock` becomes the C++ identifier `clock`. There is one exception to this rule: if a Slice identifier is the same as a C++ keyword, the corresponding C++ identifier is prefixed with `_cpp_`. For example, the Slice identifier `while` is mapped as `_cpp_while`.

A single Slice identifier often results in several C++ identifiers. For example, for a Slice interface named `Foo`, the generated C++ code uses the identifiers `Foo` and `FooPrx` (among others). If the interface has the name `while`, the generated identifiers are `_cpp_while` and `whilePrx` (*not* `_cpp_whilePrx`), that is, the prefix is applied only to those generated identifiers that actually require it.

You should try to avoid such identifiers as much as possible.

C++ Mapping for Modules

A Slice `module` maps to a C++ namespace. The mapping preserves the nesting of the Slice definitions. For example:

Slice
<pre> module M1 { module M2 { // ... }; // ... }; // ... module M1 { // Reopen M1 // ... }; </pre>

This definition maps to the corresponding C++ definition:

C++
<pre> namespace M1 { namespace M2 { // ... } // ... } // ... namespace M1 { // Reopen M1 // ... } </pre>

If a Slice module is reopened, the corresponding C++ namespace is reopened as well.

C++ Mapping for Built-In Types

On this page:

- [Mapping of Slice Built-In Types to C++ Types](#)
- [Alternative String Mapping for C++](#)
- [String View Mapping in C++](#)

Mapping of Slice Built-In Types to C++ Types

The Slice [built-in types](#) are mapped to C++ types as shown in this table:

Slice	C++
bool	bool
byte	Ice::Byte
short	Ice::Short
int	Ice::Int
long	Ice::Long
float	Ice::Float
double	Ice::Double
string	std::string

Slice `bool` and `string` map to C++ `bool` and `std::string`. The remaining built-in Slice types map to C++ type definitions instead of C++ native types. This allows the Ice run time to provide a definition as appropriate for each target architecture. (For example, `Ice::Int` might be defined as `long` on one architecture and as `int` on another.)

Note that `Ice::Byte` is a typedef for `unsigned char`. This guarantees that byte values are always in the range 0..255.

All the basic types are guaranteed to be distinct C++ types, that is, you can safely overload functions that differ in only the types listed in the table above.

Alternative String Mapping for C++

You can use a metadata directive, `"cpp:type:wstring"`, to map strings to C++ `std::wstring`. This is useful for applications that use languages with alphabets that cannot be represented in 8-bit characters. The metadata directive can be applied to any Slice construct. For containers (such as modules, interfaces, or structures), the metadata directive applies to all strings within the container. A corresponding metadata directive, `"cpp:type:string"`, can be used to selectively override the mapping defined by the enclosing container. For example:

Slice

```
["cpp:type:wstring"]
struct S1 {
    string x;           // Maps to std::wstring
    ["cpp:type:wstring"]
    string y;           // Maps to std::wstring
    ["cpp:type:string"]
    string z;           // Maps to std::string
};

struct S2 {
    string x;           // Maps to std::string
    ["cpp:type:string"]
    string y;           // Maps to std::string
    ["cpp:type:wstring"]
    string z;           // Maps to std::wstring
};
```

With these metadata directives, the strings are mapped as indicated by the comments. By default, narrow strings are encoded as UTF-8, and wide strings use Unicode in an encoding that is appropriate for the platform on which the application executes. You can override the encoding for narrow and wide strings by registering a [string converter](#) with the Ice run time.

String View Mapping in C++

You can use the metadata directive `cpp:view-type:string-view-type` to map some string parameters to a custom C++ "view-type" of your choice. This view-type can reference memory without owning it, like the experimental `string_view` type. For example:

Slice

```
void sendString(["cpp:view-type:std::experimental::string_view"] string
data);
```

maps to:

C++

```
// Proxy function for synchronous call: input parameter mapped to
string_view type.
void sendString(const std::experimental::string_view&);
```

See [Customizing the C++ Mapping](#) for a detailed description of the `cpp:view-type` metadata directive.

C++ Mapping for Enumerations

A Slice enumeration maps to the corresponding enumeration in C++. For example:

```
Slice
```

```
enum Fruit { Apple, Pear, Orange };
```

Not surprisingly, the generated C++ definition is identical:

```
C++
```

```
enum Fruit { Apple, Pear, Orange };
```

Suppose we modify the Slice definition to include a custom enumerator value:

```
Slice
```

```
enum Fruit { Apple, Pear = 3, Orange };
```

The generated C++ definition now includes an explicit initializer for every enumerator:

```
C++
```

```
enum Fruit { Apple = 0, Pear = 3, Orange = 4 };
```

- [Enumerations](#)
- [C++ Mapping for Structures](#)
- [C++ Mapping for Sequences](#)
- [C++ Mapping for Dictionaries](#)

C++ Mapping for Structures

A Slice [structure](#) maps to a C++ structure by default. In addition, you can use a metadata directive to map structures to C++ [classes](#).

On this page:

- [Default Mapping for Structures in C++](#)
- [Class Mapping for Structures in C++](#)
- [Default Constructors for Structures in C++](#)

Default Mapping for Structures in C++

Slice structures map to C++ structures with the same name. For each Slice data member, the C++ structure contains a public data member. For example, here is our [Employee](#) structure once more:

Slice
<pre>struct Employee { long number; string firstName; string lastName; };</pre>

The Slice-to-C++ compiler generates the following definition for this structure:

C++
<pre>struct Employee { Ice::Long number; std::string firstName; std::string lastName; bool operator==(const Employee&) const; bool operator!=(const Employee&) const; bool operator<(const Employee&) const; bool operator<=(const Employee&) const; bool operator>(const Employee&) const; bool operator>=(const Employee&) const; };</pre>

For each data member in the Slice definition, the C++ structure contains a corresponding public data member of the same name. Constructors are intentionally omitted so that the C++ structure qualifies as a *plain old datatype* (POD).

The structure may also contain comparison operators to allow its use as the key type of [Slice dictionaries](#), which are mapped to `std::map` in C++. These operators have the following behavior:

- `operator==`
Two structures are equal if (recursively), all its members are equal.
- `operator!=`
Two structures are not equal if (recursively), one or more of its members are not equal.
- `operator<`
`operator<=`
`operator>`

`operator>=`

The comparison operators treat the members of a structure as sort order criteria: the first member is considered the first criterion, the second member the second criterion, and so on. Assuming that we have two `Employee` structures, `s1` and `s2`, this means that the generated code uses the following algorithm to compare `s1` and `s2`:

C++

```
bool Employee::operator<(const Employee& rhs) const
{
    if (this == &rhs)    // Short?cut self?comparison
        return false;

    // Compare first members
    //
    if (number < rhs.number)
        return true;
    else if (rhs.number < number)
        return false;

    // First members are equal, compare second members
    //
    if (firstName < rhs.firstName)
        return true;
    else if (rhs.firstName < firstName)
        return false;

    // Second members are equal, compare third members
    //
    if (lastName < rhs.lastName)
        return true;
    else if (rhs.lastName < lastName)
        return false;

    // All members are equal, so return false
    return false;
}
```

As of Ice 3.5, the comparison operators are only generated for structures that qualify as [legal dictionary keys](#). You can force the Slice compiler to generate the comparison operators for non-qualifying structures by using the `cpp:comparable` metadata:

Slice

```
[ "cpp:comparable" ]
struct NoKey
{
    float f;
};
```

Note that the ordering behavior for non-qualifying structures may not be deterministic.

Copy construction and assignment always have deep-copy semantics. You can freely assign structures or structure members to each other without having to worry about memory management. The following code fragment illustrates both comparison and deep-copy semantics:

C++

```
Employee e1, e2;
e1.firstName = "Bjarne";
e1.lastName = "Stroustrup";
e2 = e1; // Deep copy
assert(e1 == e2);
e2.firstName = "Andrew"; // Deep copy
e2.lastName = "Koenig"; // Deep copy
assert(e2 < e1);
```

Because strings are mapped to `std::string`, there are no memory management issues in this code and structure assignment and copying work as expected. (The default member-wise copy constructor and assignment operator generated by the C++ compiler do the right thing.)

Class Mapping for Structures in C++

Occasionally, the mapping of Slice structures to C++ structures can be inefficient. For example, you may need to pass structures around in your application, but want to avoid having to make expensive copies of the structures. (This overhead becomes noticeable for structures with many complex data members, such as sequences or strings.) Of course, you could pass the structures by const reference, but that can create its own share of problems, such as tracking the life time of the structures to avoid ending up with dangling references.

For this reason, you can enable an alternate mapping that maps Slice structures to C++ classes. Classes (as opposed to structures) are reference-counted. Because the Ice C++ mapping provides [smart pointers for classes](#), you can keep references to a class instance in many places in the code without having to worry about either expensive copying or life time issues.

The alternate mapping is enabled by a metadata directive, ["cpp:class"]. Here is our Employee structure once again, but this time with the additional metadata directive:

Slice

```
["cpp:class"] struct Employee {
    long number;
    string firstName;
    string lastName;
};
```

Here is the generated class:

C++

```
class Employee : public IceUtil::Shared {
public:
    Employee() {}
    Employee(::Ice::Long,
            const ::std::string&,
            const ::std::string&);
    ::Ice::Long number;
    ::std::string firstName;
    ::std::string lastName;

    bool operator==(const Employee&) const;
    bool operator!=(const Employee&) const;
    bool operator<(const Employee&) const;
    bool operator<=(const Employee&) const;
    bool operator>(const Employee&) const;
    bool operator>=(const Employee&) const;
};
```

Note that the generated class, apart from a default constructor, has a constructor that accepts one argument for each member of the structure. This allows you to instantiate and initialize the class in a single statement (instead of having to first instantiate the class and then assign to its members).

As for the default structure mapping, the class contains one public data member for each data member of the corresponding Slice structure.

The comparison operators behave as for the default structure mapping.

You can learn how to [instantiate classes](#), and how to access them via [smart pointers](#), in the sections describing the mapping for Slice classes — the API described there applies equally to Slice structures that are mapped to classes.

Default Constructors for Structures in C++

Structures have an implicit default constructor that default-constructs each data member. Members having a complex type, such as strings, sequences, and dictionaries, are initialized by their own default constructor. However, the default constructor performs no initialization for members having one of the simple built-in types boolean, integer, floating point, or enumeration. For such a member, it is not safe to assume that the member has a reasonable default value. This is especially true for enumerated types as the member's default value may be outside the legal range for the enumeration, in which case an exception will occur during marshaling unless the member is explicitly set to a legal value.

To ensure that data members of primitive types are initialized to reasonable values, you can declare default values in your [Slice definition](#).

The default constructor initializes each of these data members to its declared value.

If you declare a default value for at least one member of a structure, or use the class mapping for the structure, the Slice compiler also generates a second constructor. This *one-shot* constructor has one parameter for each data member, allowing you to construct and initialize an instance in a single statement (instead of first having to construct the instance and then assign to its members).

C++ Mapping for Sequences

On this page:

- [Default Sequence Mapping in C++](#)
- [Custom Sequence Mapping in C++](#)
- [Custom Mapping for Sequence Parameters in C++](#)
 - [Array Mapping for Sequence Parameters in C++](#)
 - [Range Mapping for Sequence Parameters in C++](#)

Default Sequence Mapping in C++

Here is the definition of our `FruitPlatter` sequence once more:

```

Slice

sequence<Fruit> FruitPlatter;
```

The Slice compiler generates the following definition for the `FruitPlatter` sequence:

```

C++

typedef std::vector<Fruit> FruitPlatter;
```

As you can see, the sequence simply maps to a standard `std::vector`, so you can use the sequence like any other vector. For example:

```

C++

// Make a small platter with one Apple and one Orange
//
FruitPlatter p;
p.push_back(Apple);
p.push_back(Orange);
```

Custom Sequence Mapping in C++

You can override the default mapping of Slice sequences to C++ vectors with the `cpp:type` and `cpp:view-type` metadata directives.

For example:

Slice

```

[["cpp:include:list"]]

module Food {

    enum Fruit { Apple, Pear, Orange };

    ["cpp:type:std::list< ::Food::Fruit>"]
    sequence<Fruit> FruitPlatter;

};

```

With this metadata directive, the sequence now maps to a C++ `std::list`:

C++

```

#include <list>

namespace Food {

    typedef std::list<Food::Fruit> FruitPlatter;

    // ...

}

```

Custom Mapping for Sequence Parameters in C++

In addition to the default and custom mappings of sequence types as a whole, you can use metadata to customize the mapping of a single operation parameter of type sequence.

Ice provides two metadata directives for this purpose, `["cpp:array"]` and `["cpp:range"]`.

Array Mapping for Sequence Parameters in C++

The array mapping for sequence parameters applies only to:

- In parameters, on the client-side and on the server-side
- Out and return parameters provided by the Ice run-time to [AMI type-safe callbacks](#) and [AMI lambdas](#)
- Out and return parameters provided to [AMD](#) callbacks

For example:

Slice

```

interface File {
    void write(["cpp:array"] Ice::ByteSeq contents);
};

```

The `cpp:array` metadata directive instructs the compiler to map the `contents` parameter to a pair of pointers. With this directive, the `wri`

te method on the proxy has the following signature:

```
C++
```

```
void write(const std::pair<const Ice::Byte*,
const Ice::Byte*>& contents);
```

To pass a byte sequence to the server, you pass a pair of pointers; the first pointer points at the beginning of the sequence, and the second pointer points one element past the end of the sequence.

Similarly, for the server side, the `write` method on the skeleton has the following signature:

```
C++
```

```
virtual void write(const ::std::pair<const ::Ice::Byte*,
const ::Ice::Byte*>&,
const ::Ice::Current& = ::Ice::Current()) = 0;
```

The passed pointers denote the beginning and end of the sequence as a range `[first, last)` (that is, they use the usual semantics for iterators).

The array mapping is useful to achieve zero-copy passing of sequences. The pointers point directly into the server-side transport buffer; this allows the server-side run time to avoid creating a `vector` to pass to the operation implementation, thereby avoiding both allocating memory for the sequence and copying its contents into that memory.

You can use the array mapping for any sequence type. However, it provides a performance advantage only for byte sequences (on all platforms) and for sequences of integral or floating point types (on some platforms).

Range Mapping for Sequence Parameters in C++

The range mapping for sequences is similar to the array mapping and exists for the same purpose, namely, to enable zero-copy of sequence parameters:

```
Slice
```

```
interface File {
    void write(["cpp:range"] Ice::ByteSeq contents);
};
```

The `cpp:range` metadata directive instructs the compiler to map the `contents` parameter to a pair of `const_iterator`. With this directive, the `write` method on the proxy has the following signature:

```
C++
```

```
void write(const std::pair<Ice::ByteSeq::const_iterator,
Ice::ByteSeq::const_iterator>& contents);
```

Similarly, for the server side, the `write` method on the skeleton has the following signature:

C++

```
virtual void write(
    const ::std::pair<::Ice::ByteSeq::const_iterator,
    ::Ice::ByteSeq::const_iterator>&,
    const ::Ice::Current& = ::Ice::Current()) = 0;
```

The passed iterators denote the beginning and end of the sequence as a range `[first, last)` (that is, they use the usual semantics for iterators).

The motivation for the range mapping is the same as for the array mapping: the passed iterators point directly into the server-side transport buffer and so avoid the need to create a temporary `vector` to pass to the operation.

As for the array mapping, the range mapping can be used with any sequence type, but offers a performance advantage only for byte sequences (on all platforms) and for sequences of integral type (x86 platforms only).

You can optionally add a type name to the `cpp:range` metadata directive, for example:

Slice

```
interface File {
    void write(["cpp:range:std::deque<Ice::Byte>"]
Ice::ByteSeq contents);
};
```

This instructs the compiler to generate a pair of `const_iterator` for the specified type:

C++

```
virtual void write(
    const ::std::pair<std::deque<Ice::Byte>::const_iterator,
    std::deque<Ice::Byte>::const_iterator>&,
    const ::Ice::Current& = ::Ice::Current()) = 0;
```

This is useful if you want to combine the range mapping with a custom sequence type that behaves like an standard container.

C++ Mapping for Dictionaries

On this page:

- [Default Dictionary Mapping in C++](#)
- [Custom Dictionary Mapping in C++](#)

Default Dictionary Mapping in C++

Here is the definition of our `EmployeeMap` once more:

Slice
<pre>dictionary<long, Employee> EmployeeMap;</pre>

The following code is generated for this definition:

C++
<pre>typedef std::map<Ice::Long, Employee> EmployeeMap;</pre>

Again, there are no surprises here: a Slice dictionary simply maps to a standard `std::map`. As a result, you can use the dictionary like any other `map`, for example:

C++
<pre>EmployeeMap em; Employee e; e.number = 42; e.firstName = "Stan"; e.lastName = "Lippman"; em[e.number] = e; e.number = 77; e.firstName = "Herb"; e.lastName = "Sutter"; em[e.number] = e;</pre>

Custom Dictionary Mapping in C++

You can override the default mapping of Slice dictionaries to C++ maps with a `cpp:type` or `cpp:view-type` metadata directive, for example:

Slice

```
[["cpp:include:unordered_map"]]

["cpp:type:std::unordered_map<Ice::Long, Employee>"] dictionary<long,
Employee> EmployeeMap;
```

With this metadata directive, the dictionary now maps to a C++ `std::unordered_map`:

C++

```
#include <unordered_map>

typedef std::unordered_map<Ice::Long, Employee> EmployeeMap;
```

See [Customizing the C++ Mapping](#) for detailed information about the `cpp:type` and `cpp:view-type` metadata directives.

See Also

- [Dictionaries](#)
- [Customizing the C++ Mapping](#)
- [C++ Mapping for Enumerations](#)
- [C++ Mapping for Structures](#)
- [C++ Mapping for Sequences](#)

C++ Mapping for Constants

Slice constant definitions map to corresponding C++ constant definitions. For example:

Slice	
<code>const bool</code>	<code>AppendByDefault = true;</code>
<code>const byte</code>	<code>LowerNibble = 0x0f;</code>
<code>const string</code>	<code>Advice = "Don't Panic!";</code>
<code>const short</code>	<code>TheAnswer = 42;</code>
<code>const double</code>	<code>PI = 3.1416;</code>
<code>enum Fruit { Apple, Pear, Orange };</code>	
<code>const Fruit</code>	<code>FavoriteFruit = Pear;</code>

Here are the generated definitions for these constants:

C++	
<code>const bool</code>	<code>AppendByDefault = true;</code>
<code>const Ice::Byte</code>	<code>LowerNibble = 15;</code>
<code>const std::string</code>	<code>Advice = "Don't Panic!";</code>
<code>const Ice::Short</code>	<code>TheAnswer = 42;</code>
<code>const Ice::Double</code>	<code>PI = 3.1416;</code>
<code>enum Fruit { Apple, Pear, Orange };</code>	
<code>const Fruit</code>	<code>FavoriteFruit = Pear;</code>

All constants are initialized directly in the header file, so they are compile-time constants and can be used in contexts where a compile-time constant expression is required, such as to dimension an array or as the `case` label of a `switch` statement.

A Slice string literal that contains non-ASCII characters is mapped by default to a narrow C++ string literal with the non-ASCII characters replaced by their UTF-8 encoding in octal escapes. For example:

Slice	
<code>const string</code>	<code>Egg = "æuf";</code>

is mapped to:

C++	
<code>const std::string</code>	<code>Egg = "\305\223uf";</code>

If you map a string constant to a `std::wstring`, the non-ASCII characters in the string literal are replaced by universal character names, except for non-ASCII characters in the range `\u0000` to `\u009f` that are replaced by octal escapes with the same value. For example:

Slice

```
const ["cpp:type:wstring"] string LargeEgg = "gros œuf";
```

is mapped to:

C++

```
const std::wstring LargeEgg = L"gros \u0153uf";
```

Likewise, a Slice string literal that contains universal character names is mapped to a narrow C++ string with the universal character names replaced by their UTF-8 encoding in octal escapes, or to a wide C++ string with the universal character names preserved (except for characters in the range `\u0000` to `\u009f` that are replaced by octal escapes with the same value). For example:

Slice

```
const string Heart = "c\u0153ur";
const ["cpp:type:wstring"] string BigHeart = "grand c\u0153ur";
const ["cpp:type:wstring"] string Banana = "\U0001F34C";

const string DoubleTilde = "~\u007e";
const ["cpp:type:wstring"] string WDoubleTilde = "~\u007e";
```

is mapped to:

C++

```
const std::string Heart = "c\305\223ur";
const std::wstring BigHeart = L"grand c\u0153ur";
const std::wstring Banana = L"\U0001F34C";

const std::string DoubleTilde = "~\176";
const std::string WDoubleTilde = L"~\176";
```

C++ Mapping for Exceptions

On this page:

- [C++ Mapping for User Exceptions](#)
- [C++ Default Constructors for Exceptions](#)
- [C++ Mapping for Run-Time Exceptions](#)

C++ Mapping for User Exceptions

Here is a fragment of the `Slice` definition for our world time server once more:

```

Slice

```
exception GenericError {
 string reason;
};
exception BadTimeVal extends GenericError {};
exception BadZoneName extends GenericError {};
```

```

These exception definitions map as follows:

C++

```

class GenericError: public Ice::UserException {
public:
    std::string reason;

    GenericError() {}
    explicit GenericError(const string&);

    virtual const std::string& ice_name() const;
    virtual Ice::Exception* ice_clone() const;
    virtual void ice_throw() const;
    // Other member functions here...
};

class BadTimeVal: public GenericError {
public:
    BadTimeVal() {}
    explicit BadTimeVal(const string&);

    virtual const std::string& ice_name() const;
    virtual Ice::Exception* ice_clone() const;
    virtual void ice_throw() const;
    // Other member functions here...
};

class BadZoneName: public GenericError {
public:
    BadZoneName() {}
    explicit BadZoneName(const string&);

    virtual const std::string& ice_name() const;
    virtual Ice::Exception* ice_clone() const;
    virtual void ice_throw() const;
};

```

Each Slice exception is mapped to a C++ class with the same name. For each exception member, the corresponding class contains a public data member. (Since `BadTimeVal` and `BadZoneName` do not have members, the generated classes for these exceptions also do not have members.) [Optional data members](#) are mapped to instances of the `IceUtil::Optional` template.

The inheritance structure of the Slice exceptions is preserved for the generated classes, so `BadTimeVal` and `BadZoneName` inherit from `GenericError`.

Each exception has three additional member functions:

- `ice_name`
As the name suggests, this member function returns the name of the exception. For example, if you call the `ice_name` member function of a `BadZoneName` exception, it (not surprisingly) returns the string `"BadZoneName"`. The `ice_name` member function is useful if you catch exceptions generically and want to produce a more meaningful diagnostic, for example:

C++

```
try {
    // ...
} catch(const GenericError& e) {
    cerr << "Caught an exception: " << e.ice_name() << endl;
}
```

If an exception is raised, this code prints the name of the actual exception (`BadTimeVal` or `BadZoneName`) because the exception is being caught by reference (to avoid slicing).

- `ice_clone`
This member function allows you to polymorphically clone an exception. For example:

C++

```
try {
    // ...
} catch(const Ice::UserException& e) {
    Ice::UserException* copy = e.clone();
}
```

`ice_clone` is useful if you need to make a copy of an exception without knowing its precise run-time type. This allows you to remember the exception and throw it later by calling `ice_throw`.

- `ice_throw`
`ice_throw` allows you to throw an exception without knowing its precise run-time type. It is implemented as:

C++

```
void
GenericError::ice_throw() const
{
    throw *this;
}
```

You can call `ice_throw` to throw an exception that you previously cloned with `ice_clone`.

Each exception has a default constructor. Members having a complex type, such as strings, sequences, and dictionaries, are initialized by their own default constructor. However, the default constructor performs no initialization for members having one of the simple built-in types boolean, integer, floating point, or enumeration. For such a member, it is not safe to assume that the member has a reasonable default value. This is especially true for enumerated types as the member's default value may be outside the legal range for the enumeration, in which case an exception will occur during marshaling unless the member is explicitly set to a legal value.

To ensure that data members of primitive types are initialized to reasonable values, you can declare default values in your [Slice definition](#). The default constructor initializes each of these data members to its declared value. Optional data members are unset unless they declare default values.

An exception also has a second constructor that accepts one argument for each exception member. This constructor allows you to instantiate and initialize an exception in a single statement, instead of having to first instantiate the exception and then assign to its members. For each optional data member, its corresponding constructor parameter uses the same mapping as for [operation parameters](#), allowing you to pass its initial value or `IceUtil::None` to indicate an unset value.

For derived exceptions, the constructor accepts one argument for each base exception member, plus one argument for each derived exception member, in base-to-derived order.

Note that the generated exception classes contain other member functions that are not shown here. However, those member functions are internal to the C++ mapping and are not meant to be called by application code.

All user exceptions ultimately inherit from `Ice::UserException`. In turn, `Ice::UserException` inherits from `Ice::Exception` (which is an alias for `IceUtil::Exception`):

```

C++

namespace IceUtil {
    class Exception : public std::exception {
        virtual const std::string& ice_name() const;
        Exception* ice_clone() const;
        void ice_throw() const;
        virtual void ice_print(std::ostream&) const;
        // ...
    };
    std::ostream& operator<<(std::ostream&, const Exception&);
    // ...
}

namespace Ice {
    typedef IceUtil::Exception Exception;

    class UserException: public Exception {
    public:
        virtual const std::string& ice_name() const = 0;
        // ...
    };
}

```

`Ice::Exception` forms the root of the exception inheritance tree. Apart from the usual `ice_name`, `ice_clone`, and `ice_throw` member functions, it contains the `ice_print` member functions. `ice_print` prints the name of the exception. For example, calling `ice_print` on a `BadTimeVal` exception prints:

```
BadTimeVal
```

To make printing more convenient, `operator<<` is overloaded for `Ice::Exception`, so you can also write:

```

C++

try {
    // ...
} catch(const Ice::Exception& e) {
    cerr << e << endl;
}

```

This produces the same output because `operator<<` calls `ice_print` internally. You can optionally provide your own `ice_print` implementation using the `cpp::ice_print` metadata directive.

For Ice run time exceptions, `ice_print` also shows the file name and line number at which the exception was thrown.

C++ Default Constructors for Exceptions

Exceptions have a default constructor that default-constructs each data member. Members having a complex type, such as strings, sequences, and dictionaries, are initialized by their own default constructor. However, the default constructor performs no initialization for members having one of the simple built-in types boolean, integer, floating point, or enumeration. For such a member, it is not safe to assume that the member has a reasonable default value. This is especially true for enumerated types as the member's default value may be outside the legal range for the enumeration, in which case an exception will occur during marshaling unless the member is explicitly set to a legal value.

To ensure that data members of primitive types are initialized to reasonable values, you can declare [default values](#) in your Slice definition. The default constructor initializes each of these data members to its declared value.

Exceptions also have a second constructor that has one parameter for each data member. This allows you to construct and initialize a class instance in a single statement (instead of first having to construct the instance and then assign to its members). For derived exceptions, this constructor has one parameter for each of the base class's data members, plus one parameter for each of the derived class's data members, in base-to-derived order.

C++ Mapping for Run-Time Exceptions

The Ice run time throws run-time exceptions for a number of pre-defined error conditions. All run-time exceptions directly or indirectly derive from `Ice::LocalException` (which, in turn, derives from `Ice::Exception`). `Ice::LocalException` has the usual member functions: `ice_name`, `ice_clone`, `ice_throw`, and (inherited from `Ice::Exception`), `ice_print`, `ice_file`, and `ice_line`.

Recall the [inheritance diagram](#) for user and run-time exceptions. By catching exceptions at the appropriate point in the hierarchy, you can handle exceptions according to the category of error they indicate:

- `Ice::Exception`
This is the root of the complete inheritance tree. Catching `Ice::Exception` catches both user and run-time exceptions. As shown earlier, `Ice::Exception` is a typedef for `IceUtil::Exception`, and `IceUtil::Exception` inherits from `std::exception`.
- `Ice::UserException`
This is the root exception for all user exceptions. Catching `Ice::UserException` catches all user exceptions (but not run-time exceptions).
- `Ice::LocalException`
This is the root exception for all run-time exceptions. Catching `Ice::LocalException` catches all run-time exceptions (but not user exceptions).
- `Ice::TimeoutException`
This is the base exception for both operation-invocation and connection-establishment timeouts.
- `Ice::ConnectTimeoutException`
This exception is raised when the initial attempt to establish a connection to a server times out.

For example, a `ConnectTimeoutException` can be handled as `ConnectTimeoutException`, `TimeoutException`, `LocalException`, or `Exception`.

You will probably have little need to catch run-time exceptions as their most-derived type and instead catch them as `LocalException`; the fine-grained error handling offered by the remainder of the hierarchy is of interest mainly in the implementation of the Ice run time. Exceptions to this rule are the exceptions related to [facet](#) and [object](#) life cycles, which you may want to catch explicitly. These exceptions are `FacetNotExistException` and `ObjectNotExistException`, respectively.

C++ Mapping for Interfaces

The mapping of Slice [interfaces](#) revolves around the idea that, to invoke a remote operation, you call a member function on a local class instance that is a [proxy](#) for the remote object. This makes the mapping easy and intuitive to use because making a remote procedure call is no different from making a local procedure call (apart from error semantics).

Proxy Classes and Proxy Handles

On the client side, a Slice interface maps to a class with member functions that correspond to the operations on that interface. Consider the following simple interface:

Slice

```

module M {
    interface Simple {
        void op();
    };
};

```

The Slice compiler generates the following definitions for use by the client:

C++

```

namespace IceProxy {
    namespace M {
        class Simple;
    }
}

namespace M {
    class Simple;
    typedef IceInternal::ProxyHandle< ::IceProxy::M::Simple> SimplePrx;
    typedef IceInternal::Handle< ::M::Simple> SimplePtr;
}

namespace IceProxy {
    namespace M {
        class Simple : public virtual IceProxy::Ice::Object {
        public:
            void op();
            void op(const Ice::Context&);
            // ...
        };
    };
}

```

As you can see, the compiler generates a *proxy class* `Simple` in the `IceProxy::M` namespace, as well as a *proxy handle* `M::SimplePrx`. In general, for a module `M`, the generated names are `::IceProxy::M::<interface-name>` and `::M::<interface-name>Prx`.

In the client's address space, an instance of `IceProxy::M::Simple` is the local ambassador for a remote instance of the `Simple` interface in a server and is known as a *proxy class instance*. All the details about the server-side object, such as its address, what protocol to use, and its object identity are encapsulated in that instance.

Inheritance from `Ice::Object`

`Simple` inherits from `IceProxy::Ice::Object`, reflecting the fact that all Ice interfaces implicitly inherit from `Ice::Object`. For each operation in the interface, the proxy class has two overloaded member functions of the same name. For the preceding example, we find that the operation `op` has been mapped to two member functions `op`.

One of the overloaded member functions has a trailing parameter of type `Ice::Context`. This parameter is for use by the Ice run time to store information about how to deliver a request; normally, you do not need to supply a value here and can pretend that the trailing parameter does not exist. (The parameter is also used by `IceStorm`.)

Proxy Handles

Client-side application code never manipulates proxy class instances directly. In fact, you are not allowed to instantiate a proxy class directly. The following code will not compile because the proxy class does not provide a public default constructor:

C++

```
IceProxy::M::Simple s; // Compile-time error!
```

Proxy instances are always instantiated on behalf of the client by the Ice run time, so client code never has any need to instantiate a proxy directly. When the client receives a proxy from the run time, it is given a *proxy handle* to the proxy, of type `<interface-name>Prx` (`SimplePrx`).

ePrx for the preceding example). The client accesses the proxy via its proxy handle; the handle takes care of forwarding operation invocations to its underlying proxy, as well as reference-counting the proxy. This means that no memory-management issues can arise: deallocation of a proxy is automatic and happens once the last handle to the proxy disappears (goes out of scope).

Because the application code always uses proxy handles and never touches the proxy class directly, we usually use the term proxy to denote both proxy handle and proxy class. This reflects the fact that, in actual use, the proxy handle looks and feels like the underlying proxy class instance. If the distinction is important, we use the terms *proxy class*, *proxy class instance*, and *proxy handle*.

Methods on Proxy Handles

As we saw for the preceding example, the handle is actually a template of type `IceInternal::ProxyHandle` that takes the proxy class as the template parameter. This template has the usual default constructor, copy constructor, and assignment operator.

Default constructor

You can default-construct a proxy handle. The default constructor creates a proxy that points nowhere (that is, points at no object at all). If you invoke an operation on such a null proxy, you get an `IceUtil::NullHandleException`:

```

C++

try {
    SimplePrx s;           // Default-constructed proxy
    s->op();               // Call via nil proxy
    assert(0);            // Can't get here
} catch (const IceUtil::NullHandleException&) {
    cout << "As expected, got a NullHandleException" << endl;
}

```

Copy constructor

The copy constructor ensures that you can construct a proxy handle from another proxy handle. Internally, this increments a reference count on the proxy; the destructor decrements the reference count again and, once the count drops to zero, deallocates the underlying proxy class instance. That way, memory leaks are avoided:

```

C++

{
    SimplePrx s1 = ...;    // Get a proxy from somewhere
    SimplePrx s2(s1);     // Copy-construct s2
    assert(s1 == s2);     // Assertion passes
}
// Leave scope; s1, s2, and the
// underlying proxy instance
// are deallocated

```

Note the assertion in this example: [proxy handles support comparison](#).

Assignment operator

You can freely assign proxy handles to each other. The handle implementation ensures that the appropriate memory-management activities take place. Self-assignment is safe and you do not have to guard against it:

C++

```
SimplePrx s1 = ...;    // Get a proxy from somewhere
SimplePrx s2;        // s2 is nil
s2 = s1;             // both point at the same object
s1 = 0;              // s1 is nil
s2 = 0;              // s2 is nil
```

Widening assignments work implicitly. For example, if we have two interfaces, `Base` and `Derived`, we can widen a `DerivedPrx` to a `BasePrx` implicitly:

C++

```
BasePrx base;
DerivedPrx derived;
base = derived;      // Fine, no problem
derived = base;     // Compile-time error
```

Implicit narrowing conversions result in a compile error, so the usual C++ semantics are preserved: you can always assign a derived type to a base type, but not vice versa.

Checked cast

Proxy handles provide a `checkedCast` method:

C++

```
namespace IceInternal {
    template<typename T>
    class ProxyHandle : public IceUtil::HandleBase<T> {
    public:
        template<class Y>
        static ProxyHandle checkedCast(const ProxyHandle<Y>& r);

        template<class Y>

    static ProxyHandle checkedCast(const ProxyHandle<Y>& r, const ::Ice::Co
ntext& c);

        // ...
    };
}
```

A checked cast has the same function for proxies as a C++ `dynamic_cast` has for pointers: it allows you to assign a base proxy to a derived proxy. If the type of the base proxy's target object is compatible with the derived proxy's static type, the assignment succeeds and, after the assignment, the derived proxy denotes the same object as the base proxy. Otherwise, if the type of the base proxy's target object is incompatible with the derived proxy's static type, the derived proxy is set to null. Here is an example to illustrate this:

C++

```

BasePrx base = ...;    // Initialize base proxy
DerivedPrx derived = DerivedPrx::checkedCast(base);
if (derived) {
    // Base has run-time type Derived,
    // use derived...
} else {
    // Base has some other, unrelated type
}

```

The expression `DerivedPrx::checkedCast(base)` tests whether `base` points at an object of type `Derived` (or an object with a type that is derived from `Derived`). If so, the cast succeeds and `derived` is set to point at the same object as `base`. Otherwise, the cast fails and `derived` is set to the null proxy.

Note that `checkedCast` is a static member function so, to do a down-cast, you always use the syntax `<interface-name>Prx::checkedCast`.

Also note that you can use proxies in boolean contexts. For example, `if (proxy)` returns true if the proxy is not null.

A `checkedCast` typically results in a remote message to the server. The message effectively asks the server "is the object denoted by this reference of type `Derived`?"

Calling `checkedCast` on a proxy that is already of the desired proxy type returns immediately that proxy. Otherwise, `checkedCast` always calls `ice_isA` on the target object, and upon success, creates a new instance of the desired proxy class.

The reply from the server is communicated to the application code in form of a successful (non-null) or unsuccessful (null) result. Sending a remote message is necessary because, as a rule, there is no way for the client to find out what the actual run-time type of the target object is without confirmation from the server. (For example, the server may replace the implementation of the object for an existing proxy with a more derived one.) This means that you have to be prepared for a `checkedCast` to fail. For example, if the server is not running, you will receive a `ConnectFailedException`; if the server is running, but the object denoted by the proxy no longer exists, you will receive an `ObjectNotExistException`.

Unchecked cast

In some cases, it is known that an object supports a more derived interface than the static type of its proxy. For such cases, you can use an unchecked down-cast:

C++

```

namespace IceInternal {
    template<typename T>
    class ProxyHandle : public IceUtil::HandleBase<T> {
    public:
        template<class Y>
        static ProxyHandle uncheckedCast(const ProxyHandle<Y>& r);
        // ...
    };
}

```

An `uncheckedCast` provides a down-cast *without* consulting the server as to the actual run-time type of the object, for example:

C++

```
BasePrx base = ...;    // Initialize to point at a Derived
DerivedPrx derived;
derived = DerivedPrx::uncheckedCast(base);
// Use derived...
```

You should use an `uncheckedCast` only if you are certain that the target object indeed supports the more derived type: an `uncheckedCast`, as the name implies, is not checked in any way; it does not contact the object in the server and, if it fails, it does not return null. If you use the proxy resulting from an incorrect `uncheckedCast` to invoke an operation, the behavior is undefined. Most likely, you will receive an `OperationNotExistException`, but, depending on the circumstances, the Ice run time may also report an exception indicating that unmarshaling has failed, or even silently return garbage results.

Calling `uncheckedCast` on a proxy that is already of the desired proxy type returns immediately that proxy. Otherwise, `uncheckedCast` creates a new instance of the desired proxy class.

Despite its dangers, `uncheckedCast` is still useful because it avoids the cost of sending a message to the server. And, particularly during [initialization](#), it is common to receive a proxy of static type `Ice::Object`, but with a known run-time type. In such cases, an `uncheckedCast` saves the overhead of sending a remote message.

Stream insertion and stringification

For convenience, proxy handles also support insertion of a proxy into a stream, for example:

C++

```
Ice::ObjectPrx p = ...;
cout << p << endl;
```

This code is equivalent to writing:

C++

```
Ice::ObjectPrx p = ...;
cout << p->ice_toString() << endl;
```

Either code prints the [stringified proxy](#). You could also achieve the same thing by writing:

C++

```
Ice::ObjectPrx p = ...;
cout << communicator->proxyToString(p) << endl;
```

The advantage of using the `ice_toString` member function instead of `proxyToString` is that you do not need to have the communicator available at the point of call.

Static id

The `ice_staticId` method returns the type ID of the proxy's Slice interface:

C++

```

namespace IceInternal {
    template<typename T>
    class ProxyHandle : public IceUtil::HandleBase<T> {
    public:
        static const std::string& ice_staticId();
        // ...
    };
}

```

Here's an example that shows how to use it:

C++

```

BasePrx base = ...;
if(base->ice_id() == Derived::ice_staticId())
    // target object implements Derived

```

Applications normally use `checkedCast` instead of calling `ice_id` directly.

Using Proxy Methods in C++

The base proxy class `ObjectPrx` supports a variety of [methods for customizing a proxy](#). Since proxies are immutable, each of these "factory methods" returns a copy of the original proxy that contains the desired modification. For example, you can obtain a proxy configured with a ten second timeout as shown below:

C++

```

Ice::ObjectPrx proxy = communicator->stringToProxy(...);
proxy = proxy->ice_timeout(10000);

```

A factory method returns a new proxy object if the requested modification differs from the current proxy, otherwise it returns the current proxy. With few exceptions, factory methods return a proxy of the same type as the current proxy, therefore it is generally not necessary to repeat a down-cast after using a factory method. The example below demonstrates these semantics:

C++

```

Ice::ObjectPrx base = communicator->stringToProxy(...);
HelloPrx hello = HelloPrx::checkedCast(base);
hello = hello->ice_timeout(10000); // Type is preserved
hello->sayHello();

```

The only exceptions are the factory methods `ice_facet` and `ice_identity`. Calls to either of these methods may produce a proxy for an object of an unrelated type, therefore they return a base proxy that you must subsequently down-cast to an appropriate type.

Object Identity and Proxy Comparison in C++

Proxy handles support comparison using the following operators:

- `operator bool`
Proxies have a conversion operator to `bool`. The operator returns `true` if a proxy is not null, and `false` otherwise. This allows you to write:

```

C++

BasePrx base = ...;
if (base)
    // It's a non-nil proxy
if (!base)
    // It's a nil proxy
```

- `operator==`
`operator!=`
These operators permit you to compare proxies for equality and inequality. It's also legal to compare a proxy against the literal `0` to test whether a proxy is null, but we recommend using the `bool` operator instead.
- `operator<`
`operator<=`
`operator>`
`operator>=`
Proxies support comparison. This allows you to place proxies into STL containers such as maps or sorted lists.

Note that proxy comparison uses *all* of the information in a proxy for the comparison. This means that not only the object identity must match for a comparison to succeed, but other details inside the proxy, such as the protocol and endpoint information, must be the same. In other words, comparison with `==` and `!=` tests for *proxy* identity, *not* object identity. A common mistake is to write code along the following lines:

```

C++

Ice::ObjectPrx p1 = ...; // Get a proxy...
Ice::ObjectPrx p2 = ...; // Get another proxy...

if (p1 != p2) {
    // p1 and p2 denote different objects // WRONG!
} else {
    // p1 and p2 denote the same object // Correct
}
```

Even though `p1` and `p2` differ, they may denote the same Ice object. This can happen because, for example, both `p1` and `p2` embed the same object identity, but each use a different protocol to contact the target object. Similarly, the protocols may be the same, but denote different endpoints (because a single Ice object can be contacted via several different transport endpoints). In other words, if two proxies compare equal with `==`, we know that the two proxies denote the same object (because they are identical in all respects); however, if two proxies compare unequal with `==`, we know absolutely nothing: the proxies may or may not denote the same object.

To compare the object identities of two proxies, you can use helper functions in the `Ice` namespace:

C++

```

namespace Ice {

    bool proxyIdentityLess(const ObjectPrx&, const ObjectPrx&);
    bool proxyIdentityEqual(const ObjectPrx&, const ObjectPrx&);
    bool proxyIdentityAndFacetLess(const ObjectPrx&, const ObjectPrx&);
    bool proxyIdentityAndFacetEqual(const ObjectPrx&, const ObjectPrx&);

}

```

The `proxyIdentityEqual` function returns true if the object identities embedded in two proxies are the same and ignores other information in the proxies, such as facet and transport information. To include the `facet name` in the comparison, use `proxyIdentityAndFacetEqual` instead.

The `proxyIdentityLess` function establishes a total ordering on proxies. It is provided mainly so you can use object identity comparison with STL sorted containers. (The function uses `name` as the major ordering criterion, and `category` as the minor ordering criterion.) The `proxyIdentityAndFacetLess` function behaves similarly to `proxyIdentityLess`, except that it also compares the facet names of the proxies when their identities are equal.

`proxyIdentityEqual` and `proxyIdentityAndFacetLess` allow you to correctly compare proxies for object identity. The example below demonstrates how to use `proxyIdentityEqual`:

C++

```

Ice::ObjectPrx p1 = ...;           // Get a proxy...
Ice::ObjectPrx p2 = ...;           // Get another proxy...

if (!Ice::proxyIdentityEqual(p1, p2) {
    // p1 and p2 denote different objects           // Correct
} else {
    // p1 and p2 denote the same object             // Correct
}

```

Basic C++ Mapping for Operations

As we saw in the [C++ mapping for interfaces](#), for each [operation](#) on an interface, the proxy class contains a corresponding member function with the same name. To invoke an operation, you call it via the proxy handle. For example, here is part of the definitions for our [file system](#):

Slice

```

module Filesystem {
    interface Node {
        idempotent string name();
    };
    // ...
};

```

The proxy class for the `Node` interface, tidied up to remove irrelevant detail, is as follows:

C++

```

namespace IceProxy {
    namespace Filesystem {
        class Node : virtual public IceProxy::Ice::Object {
        public:
            std::string name();
            // ...
        };
        typedef IceInternal::ProxyHandle<Node> NodePrx;
        // ...
    }
    // ...
}

```

The `name` operation returns a value of type `string`. Given a proxy to an object of type `Node`, the client can invoke the operation as follows:

C++

```
NodePrx node = ...;           // Initialize proxy
string name = node->name();    // Get name via RPC
```

The proxy handle overloads `operator->` to forward method calls to the underlying proxy class instance which, in turn, sends the operation invocation to the server, waits until the operation is complete, and then unmarshals the return value and returns it to the caller.

Because the return value is of type `string`, it is safe to ignore the return value. For example, the following code contains no memory leak:

C++

```
NodePrx node = ...;           // Initialize proxy
node->name();                  // Useless, but no leak
```

This is true for all mapped Slice types: you can safely ignore the return value of an operation, no matter what its type — return values are always returned by value. If you ignore the return value, no memory leak occurs because the destructor of the returned value takes care of deallocating memory as needed.

Normal and idempotent Operations in C++

You can add an `idempotent` qualifier to a Slice operation. As far as the signature for the corresponding proxy methods is concerned, `idempotent` has no effect. For example, consider the following interface:

Slice

```
interface Example {
    string op1();
    idempotent string op2();
    idempotent void op3(string s);
};
```

The proxy class for this interface looks like this:

C++

```

namespace IceProxy {
  class Example : virtual public IceProxy::Ice::Object {
  public:
    std::string op1();
    std::string op2();           // idempotent
    void op3(const std::string&); // idempotent
    // ...
  };
}

```

Because `idempotent` affects an aspect of call dispatch, not interface, it makes sense for the mapping to be unaffected by the `idempotent` keyword.

Passing Parameters in C++***In-Parameters in C++***

The parameter passing rules for the C++ mapping are very simple: parameters are passed either by value (for small values) or by `const` reference (for values that are larger than a machine word). Semantically, the two ways of passing parameters are identical: it is guaranteed that the value of a parameter will not be changed by the invocation.

Here is an interface with operations that pass parameters of various types from client to server:

Slice

```

struct NumberAndString {
  int x;
  string str;
};

sequence<string> StringSeq;

dictionary<long, StringSeq> StringTable;

interface ClientToServer {
  void op1(int i, float f, bool b, string s);
  void op2(NumberAndString ns, StringSeq ss, StringTable st);
  void op3(ClientToServer* proxy);
};

```

The Slice compiler generates the following code for this definition:

C++

```

struct NumberAndString {
    Ice::Int x;
    std::string str;
    // ...
};

typedef std::vector<std::string> StringSeq;

typedef std::map<Ice::Long, StringSeq> StringTable;

namespace IceProxy {
    class ClientToServer : virtual public IceProxy::Ice::Object {
    public:
        void op1(Ice::Int, Ice::Float, bool, const std::string&);
        void op2(const NumberAndString&, const StringSeq&,
const StringTable&);
        void op3(const ClientToServerPrx&);
        // ...
    };
}

```

Given a proxy to a `ClientToServer` interface, the client code can pass parameters as in the following example:

C++

```

ClientToServerPrx p = ...; // Get proxy...

p->op1(42, 3.14, true, "Hello world!"); // Pass simple literals

int i = 42;
float f = 3.14;
bool b = true;
string s = "Hello world!";
p->op1(i, f, b, s); // Pass simple variables

NumberAndString ns = { 42, "The Answer" };
StringSeq ss;
ss.push_back("Hello world!");
StringTable st;
st[0] = ss;
p->op2(ns, ss, st); // Pass complex variables

p->op3(p); // Pass proxy

```

You can pass either literals or variables to the various operations. Because everything is passed by value or `const` reference, there are no memory-management issues to consider.

Out-Parameters in C++

The C++ mapping passes out-parameters by reference. Here is the [Slice definition](#) once more, modified to pass all parameters in the `out` direction:

```

Slice

```

struct NumberAndString {
 int x;
 string str;
};

sequence<string> StringSeq;

dictionary<long, StringSeq> StringTable;

interface ServerToClient {
 void op1(out int i, out float f, out bool b, out string s);
 void op2(out NumberAndString ns, out StringSeq ss,
out StringTable st);
 void op3(out ServerToClient* proxy);
};

```

```

The Slice compiler generates the following code for this definition:

```

C++

```

namespace IceProxy {
 class ServerToClient : virtual public IceProxy::Ice::Object {
 public:
 void op1(Ice::Int&, Ice::Float&, bool&, std::string&);
 void op2(NumberAndString&, StringSeq&, StringTable&);
 void op3(ServerToClientPrx&);
 // ...
 };
}

```

```

Given a proxy to a `ServerToClient` interface, the client code can pass parameters as in the following example:

C++

```

ServerToClientPrx p = ...;      // Get proxy...

int i;
float f;
bool b;
string s;

p->op1(i, f, b, s);
// i, f, b, and s contain updated values now

NumberAndString ns;
StringSeq ss;
StringTable st;

p->op2(ns, ss, st);
// ns, ss, and st contain updated values now

p->op3(p);
// p has changed now!

```

Again, there are no surprises in this code: the caller simply passes variables to an operation; once the operation completes, the values of those variables will be set by the server.

It is worth having another look at the final call:

C++

```

p->op3(p);      // Weird, but well-defined

```

Here, `p` is the proxy that is used to dispatch the call. That same variable `p` is also passed as an out-parameter to the call, meaning that the server will set its value. In general, passing the same parameter as both an input and output parameter is safe: the Ice run time will correctly handle all locking and memory-management activities.

Optional Parameters in C++

The mapping for [optional parameters](#) is the same as for required parameters, except each optional parameter is encapsulated in an `IceUtil::Optional` value. Consider the following operation:

Slice

```

optional(1) int execute(optional(2) string params, out optional(3) float
value);

```

The C++ mapping for this operation is shown below:

C++

```
IceUtil::Optional<Ice::Int>
execute(const IceUtil::Optional<std::string>& params,
IceUtil::Optional<Ice::Float>& value, ...);
```

The constructors provided by the `IceUtil::Optional` template simplify the use of optional parameters:

C++

```
IceUtil::Optional<Ice::Int> i;
IceUtil::Optional<Ice::Float> v;

i = proxy->execute("--file log.txt", v); // string converted to
Optional<string>
i = proxy->execute(IceUtil::None, v);    // params is unset

if(v)
    cout << "value = " << v.get() << endl;
```

For an optional output parameter, the Ice run time resets the client's `Optional` instance if the server does not supply a value for the parameter, therefore it is safe to pass an `Optional` instance that already has a value.

A well-behaved program must not assume that an optional parameter always has a value.

Chained Invocations in C++

Consider the following simple interface containing two operations, one to set a value and one to get it:

Slice

```
interface Name {
    string getName();
    void setName(string name);
};
```

Suppose we have two proxies to interfaces of type `Name`, `p1` and `p2`, and chain invocations as follows:

C++

```
p2->setName(p1->getName());
```

This works exactly as intended: the value returned by `p1` is transferred to `p2`. There are no memory-management or exception safety issues with this code.

Exception Handling in C++

Any operation invocation may throw a [run-time exception](#) and, if the operation has an exception specification, may also throw [user exceptions](#). Suppose we have the following simple interface:

Slice
<pre>exception Tantrum { string reason; }; interface Child { void askToCleanUp() throws Tantrum; };</pre>

Slice exceptions are thrown as C++ exceptions, so you can simply enclose one or more operation invocations in a `try-catch` block:

C++
<pre>ChildPrx child = ...; // Get proxy... try { child->askToCleanUp(); // Give it a try... } catch (const Tantrum& t) { cout << "The child says: " << t.reason << endl; }</pre>

Typically, you will catch only a few exceptions of specific interest around an operation invocation; other exceptions, such as unexpected run-time errors, will typically be dealt with by exception handlers higher in the hierarchy. For example:

C++

```

void run()
{
    ChildPrx child = ...;        // Get proxy...
    try {
        child->askToCleanUp(); // Give it a try...
    } catch (const Tantrum& t) {
        cout << "The child says: " << t.reason << endl;

        child->scold();         // Recover from error...
    }
    child->praise();            // Give positive feedback...
}

int
main(int argc, char* argv[])
{
    int status = 1;
    try {
        // ...
        run();
        // ...
        status = 0;
    } catch (const Ice::Exception& e) {
        cerr << "Unexpected run?time error: " << e << endl;
    }
    // ...
    return status;
}

```

This code handles a specific exception of local interest at the point of call and deals with other exceptions generically. (This is also the strategy we used for our [first simple application](#).)

For efficiency reasons, you should always catch exceptions by `const` reference. This permits the compiler to avoid calling the exception's copy constructor (and, of course, prevents the exception from being sliced to a base type).

Exceptions and Out-Parameters in C++

The Ice run time makes no guarantees about the state of out-parameters when an operation throws an exception: the parameter may have still have its original value or may have been changed by the operation's implementation in the target object. In other words, for out-parameters, Ice provides the weak exception guarantee [1] but does not provide the strong exception guarantee.

This is done for reasons of efficiency: providing the strong exception guarantee would require more overhead than can be justified.

Exceptions and Return Values in C++

For return values, C++ provides the guarantee that a variable receiving the return value of an operation will not be overwritten if an exception is thrown. (Of course, this guarantee holds only if you do not use the same variable as both an out-parameter and to receive the [return value of an invocation](#)).

C++ Mapping for Optional Values

On this page:

- [The IceUtil::Optional Template](#)
- [The IceUtil::None Value](#)

The IceUtil::Optional Template

The C++ mapping uses a template to hold the values of optional [data members](#) and [parameters](#):

C++

```

namespace IceUtil {
template<typename T>
class Optional {
public:
    typedef T element_type;

    Optional();
    Optional(NoneType);
    Optional(const T&);

    template<typename Y>
    Optional(const Optional<Y>&);

    Optional(const Optional& r);

    Optional& operator=(NoneType);
    Optional& operator=(const T&);

    template<typename Y>
    Optional& operator=(const Optional<Y>&);
    Optional& operator=(const Optional&);

    const T& get() const;
    T& get();
    const T* operator->() const;
    T* operator->();
    const T& operator*() const;
    T& operator*();

    operator bool() const;
    bool operator!() const;

    void swap(Optional& other);

    ...
};
}

```

The `IceUtil::Optional` template provides constructors and assignment operators that allow you to initialize an instance using the element type or an existing optional value. The default constructor initializes an instance to an unset condition. The `get` method and dereference operators retrieve the current value held by the instance, or throw `IceUtil::OptionalNotSetException` if no value is currently set. Use the `bool` or `!` operators to test whether the instance has a value prior to dereferencing it. Finally, the `swap` method exchanges the state of two instances.

The `IceUtil::None` Value

The template includes a constructor and assignment operator that accept `NoneType`. Ice defines an instance of this type, `IceUtil::None`, that you can use to initialize (or reset) an `Optional` instance to an unset condition:

C++

```
IceUtil::Optional<int> i = 5;  
i = IceUtil::None;  
assert(!i); // true
```

You can pass `IceUtil::None` anywhere an `IceUtil::Optional` value is expected.

Basic C++ Mapping for Classes

A Slice `class` is mapped to a C++ class with the same name. The generated class contains a public data member for each Slice data member (just as for structures and exceptions), and a virtual member function for each operation. Consider the following class definition:

```

Slice

```
class TimeOfDay {
 short hour; // 0 - 23
 short minute; // 0 - 59
 short second; // 0 - 59
 string format(); // Return time as hh:mm:ss
};
```

```

The Slice compiler generates the following code for this definition:

C++

```

class TimeOfDay;

typedef IceInternal::ProxyHandle<IceProxy::TimeOfDay> TimeOfDayPrx;
typedef IceInternal::Handle<TimeOfDay> TimeOfDayPtr;

class TimeOfDay : virtual public Ice::Object {
public:
    Ice::Short hour;
    Ice::Short minute;
    Ice::Short second;

    virtual std::string format() = 0;

    TimeOfDay() {};
    TimeOfDay(Ice::Short, Ice::Short, Ice::Short);

    virtual bool ice_isA(const std::string&);
    virtual const std::string& ice_id();
    static const std::string& ice_staticId();

    typedef TimeOfDayPrx ProxyType;
    typedef TimeOfDayPtr PointerType;

    // ...
};

```

The [ProxyType](#) and [PointerType](#) definitions are for template programming.

There are a number of things to note about the generated code:

1. The generated class `TimeOfDay` inherits from `Ice::Object`. This means that all classes implicitly inherit from `Ice::Object`, which is the ultimate ancestor of all classes. Note that `Ice::Object` is *not* the same as `IceProxy::Ice::Object`. In other words, you *cannot* pass a class where a proxy is expected and vice versa.
2. The generated class contains a public member for each Slice data member.
3. The generated class has a constructor that takes one argument for each data member, as well as a default constructor.
4. The generated class contains a pure virtual member function for each Slice operation.
5. The generated class contains additional member functions: `ice_isA`, `ice_id`, `ice_staticId`, and `ice_factory`.
6. The compiler generates a type definition `TimeOfDayPtr`. This type implements a smart pointer that wraps dynamically-allocated instances of the class. In general, the name of this type is `<class-name>Ptr`. Do not confuse this with `<class-name>Prx` — that type exists as well, but is the proxy handle for the class, not a smart pointer.

There is quite a bit to discuss here, so we will look at each item in turn.

Inheritance from `Ice::Object` in C++

Like interfaces, classes implicitly inherit from a common base class, `Ice::Object`. However, as shown in the figure below, classes inherited from `Ice::Object` instead of `Ice::ObjectPrx` (which is at the base of the inheritance hierarchy for proxies). As a result, you cannot pass a class where a proxy is expected (and vice versa) because the base types for classes and proxies are not compatible.

Inheritance from Ice::ObjectPrx and Ice::Object.

Ice::Object contains a number of member functions:

C++

```

namespace Ice {
  class Object : public virtual IceInternal::Shared {
  public:
    virtual bool ice_isA(const std::string&,
      const Current& = Current()) const;
    virtual void ice_ping(const Current& = Current()) const;
    virtual std::vector<std::string> ice_ids(const Current& = Current()) const;
    virtual const std::string& ice_id(const Current& = Current()) const;
    static const std::string& ice_staticId();
    virtual ObjectPtr ice_clone() const;

    virtual void ice_preMarshal();
    virtual void ice_postUnmarshal();

    virtual void ice_collectable(bool);

    virtual DispatchStatus ice_dispatch(
      Ice::Request&,
      const DispatcherAsyncCallbackPtr& = 0);

    virtual bool operator==(const Object&) const;
    virtual bool operator!=(const Object&) const;
    virtual bool operator<(const Object&) const;
    virtual bool operator<=(const Object&) const;
    virtual bool operator>(const Object&) const;
    virtual bool operator>=(const Object&) const;
  };
}

```

The member functions of Ice::Object behave as follows:

- ice_isA

This function returns `true` if the object supports the given `type ID`, and `false` otherwise.

- `ice_ping`
As for interfaces, `ice_ping` provides a basic reachability test for the class. Note that `ice_ping` is normally only invoked on the proxy for a class that might be remote because a class instance that is local (in the caller's address space) can always be reached.
- `ice_ids`
This function returns a string sequence representing all of the `type IDs` supported by this object, including `::Ice::Object`.
- `ice_id`
This function returns the actual run-time `type ID` for a class. If you call `ice_id` through a smart pointer to a base instance, the returned type id is the actual (possibly more derived) type ID of the instance.
- `ice_staticId`
This function returns the static type ID of a class.
- `ice_clone`
This function makes a [polymorphic shallow copy of a class](#).
- `ice_preMarshal`
The Ice run time invokes this function prior to marshaling the object's state, providing the opportunity for a subclass to validate its declared data members.
- `ice_postUnmarshal`
The Ice run time invokes this function after unmarshaling an object's state. A subclass typically overrides this function when it needs to perform additional initialization using the values of its declared data members.
- `ice_collectable`
Determines whether this object, and by extension the graph of all objects reachable from this object, are eligible for [garbage collection](#) when all external references to the graph have been released.
- `ice_dispatch`
This function dispatches an incoming request to a servant. It is used in the implementation of [dispatch interceptors](#).
- `operator==`
`operator!=`
`operator<`
`operator<=`
`operator>`
`operator>=`
The comparison operators permit you to use classes as elements of STL sorted containers. Note that sort order, unlike for [structures](#), is based on the memory address of the class, not on the contents of its data members of the class.

Class Data Members in C++

By default, data members of classes are mapped exactly as for structures and exceptions: for each data member in the Slice definition, the generated class contains a corresponding public data member. [Optional data members](#) are mapped to instances of the `IceUtil::Optional` template.

If you wish to restrict access to a data member, you can modify its visibility using the `protected` metadata directive. The presence of this directive causes the Slice compiler to generate the data member with protected visibility. As a result, the member can be accessed only by the class itself or by one of its subclasses. For example, the `TimeOfDay` class shown below has the `protected` metadata directive applied to each of its data members:

```

Slice

class TimeOfDay {
    ["protected"] short hour;    // 0 - 23
    ["protected"] short minute; // 0 - 59
    ["protected"] short second; // 0 - 59
    string format();           // Return time as hh:mm:ss
};
```

The Slice compiler produces the following generated code for this definition:

```
C++
```

```
class TimeOfDay : virtual public Ice::Object {
public:

    virtual std::string format() = 0;

    // ...

protected:

    Ice::Short hour;
    Ice::Short minute;
    Ice::Short second;
};
```

For a class in which all of the data members are protected, the metadata directive can be applied to the class itself rather than to each member individually. For example, we can rewrite the `TimeOfDay` class as follows:

```
Slice
```

```
["protected"] class TimeOfDay {
    short hour;          // 0 - 23
    short minute;       // 0 - 59
    short second;       // 0 - 59
    string format();    // Return time as hh:mm:ss
};
```

Class Constructors in C++

Classes have a default constructor that default-constructs each data member. Members having a complex type, such as strings, sequences, and dictionaries, are initialized by their own default constructor. However, the default constructor performs no initialization for members having one of the simple built-in types boolean, integer, floating point, or enumeration. For such a member, it is not safe to assume that the member has a reasonable default value. This is especially true for enumerated types as the member's default value may be outside the legal range for the enumeration, in which case an exception will occur during marshaling unless the member is explicitly set to a legal value.

To ensure that data members of primitive types are initialized to reasonable values, you can declare default values in your [Slice definition](#). The default constructor initializes each of these data members to its declared value. [Optional data members](#) are unset unless they declare default values.

Classes also have a second constructor that has one parameter for each data member. This allows you to construct and initialize a class instance in a single statement. For each optional data member, its corresponding constructor parameter uses the same mapping as for [operation parameters](#), allowing you to pass its initial value or `IceUtil::None` to indicate an unset value.

For derived classes, the constructor has one parameter for each of the base class's data members, plus one parameter for each of the derived class's data members, in base-to-derived order. For example:

Slice

```
class Base {
    int i;
};

class Derived extends Base {
    string s;
};
```

This generates:

C++

```
class Base : virtual public ::Ice::Object
{
public:
    ::Ice::Int i;

    Base() {};
    explicit Base(::Ice::Int);

    // ...
};

class Derived : public Base
{
public:
    ::std::string s;

    Derived() {};
    Derived(::Ice::Int, const ::std::string&);

    // ...
};
```

Note that single-parameter constructors are defined as `explicit`, to prevent implicit argument conversions.

By default, derived classes derive non-virtually from their base class. If you need virtual inheritance, you can enable it using the `["cpp:virtual"]` metadata directive.

Class Operations in C++

Operations of classes are mapped to pure virtual member functions in the generated class. This means that, if a class contains operations (such as the `format` operation of our `TimeOfDay` class), you must provide an implementation of the operation in a class that is derived from the generated class. For example:

C++

```

class TimeOfDayI : virtual public TimeOfDay {
public:
    virtual std::string format() {
        std::ostringstream s;
        s << setw(2) << setfill('0') << hour << ":";
        s << setw(2) << setfill('0') << minute << ":";
        s << setw(2) << setfill('0') << second;
        return s.c_str();
    }

protected:
    virtual ~TimeOfDayI() {} // Optional
};

```

We discuss the motivation for the protected destructor in [Preventing Stack-Allocation of Class Instances](#).

Class Factories in C++

Having created a class such as `TimeOfDayI`, we have an implementation and we can instantiate the `TimeOfDayI` class, but we cannot receive it as the return value or as an out-parameter from an operation invocation. To see why, consider the following simple interface:

Slice

```

interface Time {
    TimeOfDay get();
};

```

When a client invokes the `get` operation, the Ice run time must instantiate and return an instance of the `TimeOfDay` class. However, `TimeOfDay` is an abstract class that cannot be instantiated. Unless we tell it, the Ice run time cannot magically know that we have created a `TimeOfDayI` class that implements the abstract `format` operation of the `TimeOfDay` abstract class. In other words, we must provide the Ice run time with a factory that knows that the `TimeOfDay` abstract class has a `TimeOfDayI` concrete implementation. The `Ice::CommunicatorI` interface provides us with the necessary operations:

Slice

```

module Ice {
    local interface ObjectFactory {
        Object create(string type);
        void destroy();
    };

    local interface Communicator {
        void addObjectFactory(ObjectFactory factory, string id);
        ObjectFactory findObjectFactory(string id);
        // ...
    };
};

```

To supply the Ice run time with a factory for our `TimeOfDayI` class, we must implement the `ObjectFactory` interface:

Slice

```

module Ice {
    local interface ObjectFactory {
        Object create(string type);
        void destroy();
    };
};

```

The object factory's `create` operation is called by the Ice run time when it needs to instantiate a `TimeOfDay` class. The factory's `destroy` operation is called by the Ice run time when its communicator is destroyed. A possible implementation of our object factory is:

C++

```

class ObjectFactory : public Ice::ObjectFactory {
public:
    virtual Ice::ObjectPtr create(const std::string& type) {
        assert(type == M::TimeOfDay::ice_staticId());
        return new TimeOfDayI;
    }
    virtual void destroy() {}
};

```

The `create` method is passed the `type ID` of the class to instantiate. For our `TimeOfDay` class, the type ID is `"::M::TimeOfDay"`. Our implementation of `create` checks the type ID: if it matches, the method instantiates and returns a `TimeOfDayI` object. For other type IDs, the method asserts because it does not know how to instantiate other types of objects.

Note that we used the `ice_staticId` method to obtain the type ID rather than embedding a literal string. Using a literal type ID string in your code is discouraged because it can lead to errors that are only detected at run time. For example, if a Slice class or one of its enclosing

modules is renamed and the literal string is not changed accordingly, a receiver will fail to unmarshal the object and the Ice run time will raise `NoObjectFactoryException`. By using `ice_staticId` instead, we avoid any risk of a misspelled or obsolete type ID, and we can discover at compile time if a Slice class or module has been renamed.

Given a factory implementation, such as our `ObjectFactory`, we must inform the Ice run time of the existence of the factory:

C++

```
Ice::CommunicatorPtr ic = ...;
ic->addObjectFactory(new ObjectFactory, M::TimeOfDay::ice_staticId());
```

Now, whenever the Ice run time needs to instantiate a class with the type ID `"::M::TimeOfDay"`, it calls the `create` method of the registered `ObjectFactory` instance.

The `destroy` operation of the object factory is invoked by the Ice run time when the communicator is destroyed. This gives you a chance to clean up any resources that may be used by your factory. Do not call `destroy` on the factory while it is registered with the communicator — if you do, the Ice run time has no idea that this has happened and, depending on what your `destroy` implementation is doing, may cause undefined behavior when the Ice run time tries to next use the factory.

The run time guarantees that `destroy` will be the last call made on the factory, that is, `create` will not be called concurrently with `destroy`, and `create` will not be called once `destroy` has been called. However, calls to `create` can be made concurrently.

Note that you cannot register a factory for the same type ID twice: if you call `addObjectFactory` with a type ID for which a factory is registered, the Ice run time throws an `AlreadyRegisteredException`.

Finally, keep in mind that if a class has only data members, but no operations, you need not create and register an object factory to transmit instances of such a class. Only if a class has operations do you have to define and register an object factory.

Automatic Memory Management with Smart Pointers

A recurring theme for C++ programmers is the need to deal with memory allocations and deallocations in their programs. The difficulty of doing so is well known: in the face of exceptions, multiple return paths from functions, and callee-allocated memory that must be deallocated by the caller, it can be extremely difficult to ensure that a program does not leak resources. This is particularly important in multi-threaded programs: if you do not rigorously track ownership of dynamic memory, a thread may delete memory that is still used by another thread, usually with disastrous consequences.

To alleviate this problem, Ice provides smart pointers for classes. These smart pointers use reference counting to keep track of each class instance and, when the last reference to a class instance disappears, automatically delete the instance.

Smart pointer classes are an example of the *RAII (Resource Acquisition Is Initialization)* idiom [1].

Smart pointers are generated by the Slice compiler for each class type. For a Slice class `<class-name>`, the compiler generates a C++ smart pointer called `<class-name>Ptr`. Rather than showing all the details of the generated class, here is the basic usage pattern: whenever you allocate a class instance on the heap, you simply assign the pointer returned from `new` to a smart pointer for the class. Thereafter, memory management is automatic and the class instance is deleted once the last smart pointer for it goes out of scope:

```

C++

{                                     // Open scope
    TimeOfDayPtr tod = new TimeOfDayI; // Allocate instance
    // Initialize...
    tod->hour = 18;
    tod->minute = 11;
    tod->second = 15;
    // ...
}                                     // No memory leak here!
```

As you can see, you use `operator->` to access the members of the class via its smart pointer. When the `tod` smart pointer goes out of scope, its destructor runs and, in turn, the destructor takes care of calling `delete` on the underlying class instance, so no memory is leaked.

A smart pointer performs reference counting of its underlying class instance:

- The constructor of a class sets its reference count to zero.
- Initializing a smart pointer with a dynamically-allocated class instance causes the smart pointer to increment the reference count of the instance by one.
- Copy-constructing a smart pointer increments the reference count of the instance by one.
- Assigning one smart pointer to another increments the target's reference count and decrements the source's reference count. (Self-assignment is safe.)
- The destructor of a smart pointer decrements the reference count by one and calls `delete` on its class instance if the reference count drops to zero.

Suppose that we default-construct a smart pointer as follows:

```
C++
```

```
TimeOfDayPtr tod;
```

This creates a smart pointer with an internal null pointer.

Newly initialized smart pointer.

Constructing a class instance creates that instance with a reference count of zero; the assignment to the smart pointer causes the smart pointer to increment the instance's reference count:

```
C++
```

```
tod = new TimeOfDayI; // Refcount == 1
```

The resulting situation is shown below:

Initialized smart pointer.

Assigning or copy-constructing a smart pointer assigns and copy-constructs the smart pointer (not the underlying instance) and increments the reference count of the instance:

```
C++
```

```
TimeOfDayPtr tod2(tod); // Copy-construct tod2
TimeOfDayPtr tod3;
tod3 = tod;             // Assign to tod3
```

Here is the situation after executing these statements:

Three smart pointers pointing at the same class instance.

Continuing the example, we can construct a second class instance and assign it to one of the original smart pointers, `tod2`:

```

C++

tod2 = new TimeOfDayI;
```

This decrements the reference count of the instance originally denoted by `tod2` and increments the reference count of the instance that is assigned to `tod2`. The resulting situation becomes the following:

Three smart pointers and two instances.

You can clear a smart pointer by assigning zero to it:

```

C++

tod = 0;           // Clear handle
```

As you would expect, this decrements the reference count of the instance, as shown here:

Decrementing reference count after clearing a smart pointer.

If a smart pointer goes out of scope, is cleared, or has a new instance assigned to it, the smart pointer decrements the reference count of its instance; if the reference count drops to zero, the smart pointer calls `delete` to deallocate the instance. The following code snippet deallocates the instance on the right by assigning `tod2` to `tod3`:

```

C++

tod3 = tod2;
```

This results in the following situation:

Deallocation of an instance with a reference count of zero.

Copying and Assignment of Classes

Classes have a default memberwise copy constructor and assignment operator, so you can copy and assign class instances:

```

C++

TimeOfDayPtr tod = new TimeOfDayI(2, 3, 4); // Create instance
TimeOfDayPtr tod2 = new TimeOfDayI(*tod);   // Copy instance

TimeOfDayPtr tod3 = new TimeOfDayI;
*tod3 = *tod;                               // Assign instance
```

Copying and assignment in this manner performs a memberwise shallow copy or assignment, that is, the source members are copied into the target members; if a class contains class members (which are mapped as smart pointers), what is copied or assigned is the smart pointer, not the target of the smart pointer.

To illustrate this, consider the following Slice definitions:

```

Slice

class Node {
    int i;
    Node next;
};
```

Assume that we initialize two instances of type `Node` as follows:

C++

```

NodePtr p1 = new Node(99, new Node(48, 0));
NodePtr p2 = new Node(23, 0);

// ...

*p2 = *p1; // Assignment

```

After executing the first two statements, we have the situation shown below:

Class instances prior to assignment.

After executing the assignment statement, we end up with this result:

Class instances after assignment.

Note that copying and assignment also works for the implementation of abstract classes, such as our `TimeOfDayI` class, for example:

C++

```

class TimeOfDayI;

typedef IceUtil::Handle<TimeOfDayI> TimeOfDayIPtr;

class TimeOfDayI : virtual public TimeOfDay {
    // As before...
};

```

The default copy constructor and assignment operator will perform a memberwise copy or assignment of your implementation class:

C++

```

TimeOfDayIPtr tod1 = new TimeOfDayI;
TimeOfDayIPtr tod2 = new TimeOfDayI(*tod1);    // Make copy

```

Of course, if your implementation class contains raw pointers (for which a memberwise copy would almost certainly be inappropriate), you must implement your own copy constructor and assignment operator that take the appropriate action (and probably call the base copy constructor or assignment operator to take care of the base part).

Note that the preceding code uses `TimeOfDayIPtr` as a typedef for `IceUtil::Handle<TimeOfDayI>`. This class is a template that contains the smart pointer implementation. If you want smart pointers for the implementation of an abstract class, you must define a smart pointer type as illustrated by this type definition.

Copying and assignment of classes also works correctly for derived classes: you can assign a derived class to a base class, but not vice-versa; during such an assignment, the derived part of the source class is sliced, as per the usual C++ assignment semantics.

Polymorphic Copying of Classes

As shown in [Inheritance from `Ice::Object`](#), the C++ mapping generates an `ice_clone` member function for every class:

C++

```

class TimeOfDay : virtual public Ice::Object {
public:
    // ...

    virtual Ice::ObjectPtr ice_clone() const;
};

```

This member function makes a polymorphic shallow copy of a class: members that are not class members are deep copied; all members that are class members are shallow copied. To illustrate, consider the following class definition:

Slice

```
class Node {
    Node n1;
    Node n2;
};
```

Assume that we have an instance of this class, with the `n1` and `n2` members initialized to point at separate instances, as shown below:

A class instance pointing at two other instances.

If we call `ice_clone` on the instance on the left, we end up with this situation:

Resulting graph after calling `ice_clone` on the left-most instance.

As you can see, class members are shallow copied, that is, `ice_clone` makes a copy of the class instance on which it is invoked, but does not copy any class instances that are pointed at by the copied instance.

Note that `ice_clone` returns a value of type `Ice::ObjectPtr`, to avoid problems with compilers that do not support covariant return types. The generated `Ptr` classes contain a `dynamicCast` member that allows you to safely down-cast the return value of `ice_clone`. For example, the code to achieve the situation shown in the illustration above, looks as follows:

C++

```
NodePtr p1 = new Node(new Node, new Node);
NodePtr p2 = NodePtr::dynamicCast(p1->ice_clone());
```

`ice_clone` is generated by the Slice compiler for concrete classes (that is, classes that do not have operations). However, because classes with operations are abstract, the generated `ice_clone` for abstract classes cannot know how to instantiate an instance of the derived concrete class (because the name of the derived class is not known). This means that, for abstract classes, the generated `ice_clone` throws a `CloneNotImplementedException`.

If you want to clone the implementation of an abstract class, you must override the virtual `ice_clone` member in your concrete implementation class. For example:

C++

```
class TimeOfDayI : public TimeOfDay {
public:
    virtual Ice::ObjectPtr ice_clone() const
    {
        return new TimeOfDayI(*this);
    }
};
```

Null Smart Pointers

A null smart pointer contains a null C++ pointer to its underlying instance. This means that if you attempt to dereference a null smart pointer, you get an `IceUtil::NullHandleException`:

C++

```
TimeOfDayPtr tod; // Construct null handle

try {
    tod->minute = 0; // Dereference null handle
    assert(false); // Cannot get here
} catch (const IceUtil::NullHandleException&) {
    ; // OK, expected
} catch (...) {
    assert(false); // Must get NullHandleException
}
```

Preventing Stack-Allocation of Class Instances

The Ice C++ mapping expects class instances to be allocated on the heap. Allocating class instances on the stack or in static variables is pragmatically useless because all the Ice APIs expect parameters that are smart pointers, not class instances. This means that, to do

anything with a stack-allocated class instance, you must initialize a smart pointer for the instance. However, doing so does not work because it inevitably leads to a crash:

```

C++

{
    TimeOfDayI t;           // Stack-allocated class instance
    TimeOfDayPtr todp;     // Handle for a TimeOfDay instance

    todp = &t;             // Legal, but dangerous
    // ...

}                          // Leave scope, looming crash!
```

This goes badly wrong because, when `todp` goes out of scope, it decrements the reference count of the class to zero, which then calls `delete` on itself. However, the instance is stack-allocated and cannot be deleted, and we end up with undefined behavior (typically, a core dump).

The following attempt to fix this is also doomed to failure:

```

C++

{
    TimeOfDayI t;           // Stack-allocated class instance
    TimeOfDayPtr todp;     // Handle for a TimeOfDay instance

    todp = &t;             // Legal, but dangerous
    // ...
    todp = 0;              // Crash imminent!

}
```

This code attempts to circumvent the problem by clearing the smart pointer explicitly. However, doing so also causes the smart pointer to drop the reference count on the class to zero, so this code ends up with the same call to `delete` on the stack-allocated instance as the previous example.

The upshot of all this is: **never allocate a class instance on the stack or in a static variable**. The C++ mapping assumes that all class instances are allocated on the heap and no amount of coding trickery will change this.

You could abuse the `__setNoDelete` member to disable deallocation, but we strongly discourage you from doing this.

You can prevent allocation of class instances on the stack or in static variables by adding a protected destructor to your implementation of the class: if a class has a protected destructor, allocation must be made with `new`, and static or stack allocation causes a compile-time error. In addition, explicit calls to `delete` on a heap-allocated instance also are flagged at compile time.

Tip

You may want to habitually add a protected destructor to your implementation of abstract Slice classes to protect yourself from accidental heap allocation, as shown in [Class Operations](#). (For Slice classes that do not have operations, the Slice compiler automatically adds a protected destructor.)

Smart Pointers and Constructors

Slice classes inherit their reference-counting behavior from the `IceUtil::Shared` class, which ensures that reference counts are managed

in a thread-safe manner. When a stack-allocated smart pointer goes out of scope, the smart pointer invokes the `__decRef` function on the reference-counted object. Ignoring thread-safety issues, `__decRef` is implemented like this:

```
C++
```

```

void
IceUtil::Shared::__decRef()
{
    if (--_ref == 0 && !_noDelete)
        delete this;
}

```

In other words, when the smart pointer calls `__decRef` on the pointed-at instance and the reference count reaches zero (which happens when the last smart pointer for a class instance goes out of scope), the instance self-destructs by calling `delete this`.

However, as you can see, the instance self-destructs only if `_noDelete` is false (which it is by default, because the constructor initializes it to false). You can call `__setNoDelete(true)` to prevent this self-destruction and, later, call `__setNoDelete(false)` to enable it again. This is necessary if, for example, a class in its constructor needs to pass `this` to another function:

```
C++
```

```

void someFunction(const TimeOfDayPtr& t)
{
    // ...
}

TimeOfDayI::TimeOfDayI()
{
    someFunction(this); // Trouble looming here!
}

```

At first glance, this code looks innocuous enough. While `TimeOfDayI` is being constructed, it passes `this` to `someFunction`, which expects a smart pointer. The compiler constructs a temporary smart pointer at the point of call (because the smart pointer template has a single-argument constructor that accepts a pointer to a heap-allocated instance, so the constructor acts as a conversion function). However, this code fails badly. The `TimeOfDayI` instance is constructed with a statement such as:

```
C++
```

```

TimeOfDayPtr tod = new TimeOfDayI;

```

The constructor of `TimeOfDayI` is called by `operator new` and, when the constructor starts executing, the reference count of the instance is zero (because that is what the reference count is initialized to by the `Shared` base class of `TimeOfDayI`). When the constructor calls `someFunction`, the compiler creates a temporary smart pointer, which increments the reference count of the instance and, once `someFunction` completes, the compiler dutifully destroys that temporary smart pointer again. But, of course, that drops the reference count back to zero and causes the `TimeOfDayI` instance to self-destruct by calling `delete this`. The net effect is that the call to `new TimeOfDayI` returns a pointer to an already deleted object, which is likely to cause the program to crash.

To get around the problem, you can call `__setNoDelete`:

C++

```

TimeOfDayI::TimeOfDayI()
{
    __setNoDelete(true);
    someFunction(this);
    __setNoDelete(false);
}

```

The code disables self-destruction while `someFunction` uses its temporary smart pointer by calling `__setNoDelete(true)`. By doing this, the reference count of the instance is incremented before `someFunction` is called and decremented back to zero when `someFunction` completes without causing the object to self-destruct. The constructor then re-enables self-destruction by calling `__setNoDelete(false)` before returning, so the statement

C++

```

TimeOfDayPtr tod = new TimeOfDayI;

```

does the usual thing, namely to increment the reference count of the object to 1, despite the fact that a temporary smart pointer existed while the constructor ran.

In general, whenever a class constructor passes `this` to a function or another class that accepts a smart pointer, you must temporarily disable self-destruction.

Smart Pointers and Exception Safety

Smart pointers are exception safe: if an exception causes the thread of execution to leave a scope containing a stack-allocated smart pointer, the C++ run time ensures that the smart pointer's destructor is called, so no resource leaks can occur:

C++

```

{ // Enter scope...

    TimeOfDayPtr tod = new TimeOfDayI; // Allocate instance

    someFuncThatMightThrow();          // Might throw...

    // ...

} // No leak here, even if an exception is thrown

```

If an exception is thrown, the destructor of `tod` runs and ensures that it deallocates the underlying class instance.

There is one potential pitfall you must be aware of though: if a constructor of a base class throws an exception, and another class instance holds a smart pointer to the instance being constructed, you can end up with a double deallocation. You can use the `__setNoDelete` mechanism to temporarily disable self-destruction in this case, as described [above](#).

Smart Pointers and Cycles

One thing you need to be aware of is the inability of reference counting to deal with cyclic dependencies. For example, consider the following simple self-referential class:

```

class Node {
    int val;
    Node next;
};

```

Intuitively, this class implements a linked list of nodes. As long as there are no cycles in the list of nodes, everything is fine, and our smart pointers will correctly deallocate the class instances. However, if we introduce a cycle, we have a problem:

```

C++

{ // Open scope...

    NodePtr n1 = new Node; // N1 refcount == 1
    NodePtr n2 = new Node; // N2 refcount == 1
    n1->next = n2; // N2 refcount == 2
    n2->next = n1; // N1 refcount == 2

} // Destructors run: // N2 refcount == 1,
                    // N1 refcount == 1, memory leak!

```

The nodes pointed to by `n1` and `n2` do not have names but, for the sake of illustration, let us assume that `n1`'s node is called N1, and `n2`'s node is called N2. When we allocate the N1 instance and assign it to `n1`, the smart pointer `n1` increments N1's reference count to 1. Similarly, N2's reference count is 1 after allocating the node and assigning it to `n2`. The next two statements set up a cyclic dependency between `n1` and `n2` by making their `next` pointers point at each other. This sets the reference count of both N1 and N2 to 2. When the enclosing scope closes, the destructor of `n2` is called first and decrements N2's reference count to 1, followed by the destructor of `n1`, which decrements N1's reference count to 1. The net effect is that neither reference count ever drops to zero, so both N1 and N2 are leaked.

Garbage Collection of Class Instances

The previous example illustrates a problem that is generic to using reference counts for deallocation: if a cyclic dependency exists anywhere in a graph (possibly via many intermediate nodes), all nodes in the cycle are leaked.

To avoid memory leaks due to such cycles, Ice for C++ includes a garbage collection facility. The facility identifies class instances that are part of a cycle but are no longer reachable from the program and deletes such instances. Applications must assist the Ice run time in this process by indicating when a graph is eligible for collection. For eligible graphs, Ice makes a sweep of the graph each time a reference count to one of the graph's objects is decremented.

Two components of the garbage collection facility influence its behavior:

- The `Ice::CollectObjects` property determines whether Ice assumes all object graphs are eligible for collection by default.
- The `Object::ice_collectable(bool)` method allows an application to indicate whether an object (and by extension, the graph of objects reachable via this object) is eligible for collection.

The correct operation of the garbage collection facility relies on the assumption that all eligible object graphs are immutable. If an application needs to make changes that could affect the structure of the graph, it must disable collection for that graph by calling `ice_collectable(false)`.

`ce_collectable(false)` on any root object in the graph. Once the changes are complete, call `ice_collectable(true)` on any root object in the graph to make it eligible again. Modifying the structure of an eligible graph has undefined behavior.

In general, there are two strategies you can use for garbage collection depending on your application's requirements:

1. Set `Ice.CollectObjects=1` so that Ice assumes all object graphs are eligible for collection by default. This is recommended for applications that receive object graphs but rarely modify them. For those situations where an application needs to modify a graph, surround the modification with calls to `ice_collectable` as shown below:

C++

```
NodePtr graph = proxy->getGraph(); // Eligible by default
graph->ice_collectable(false);
// modify graph...
graph->ice_collectable(true);
graph = 0; // Starts a sweep
```

2. Set `Ice.CollectObjects=0` (the default setting) so that Ice does not attempt to collect object graphs except for those explicitly marked by the application. Use this setting for applications that typically modify the structure of the graphs they receive. Call `ice_collectable(true)` to mark a graph as eligible:

C++

```
NodePtr graph = proxy->getGraph(); // Ineligible by default
// modify graph...
graph->ice_collectable(true);
graph = 0; // Starts a sweep
```

As mentioned earlier, an application does not take any action to force a collection; rather, the collection occurs automatically when a reference count is decremented.

To minimize overhead, GC-related behavior is only enabled for those Slice classes whose data members can refer to Ice objects. Furthermore, graph traversal only occurs for those objects that are part of a cycle and marked as collectable.

Smart Pointer Comparison

As for [proxy handles](#), class handles support the comparison operators `==`, `!=`, and `<`. This allows you to use class handles in STL sorted containers. Be aware that, for smart pointers, object identity is not used for the comparison, because class instances do not have identity. Instead, these operators simply compare the memory address of the classes they point to. This means that `operator==` returns true only if two smart pointers point at the same physical class instance:

C++

```

// Create a class instance and initialize
//
TimeOfDayIPtr p1 = new TimeOfDayI;
p1->hour = 23;
p1->minute = 10;
p1->second = 18;

// Create another class instance with
// the same member values
//
TimeOfDayIPtr p2 = new TimeOfDayI;
p2->hour = 23;
p2->minute = 10;
p2->second = 18;

assert(p1 != p2);          // The two do not compare equal

TimeOfDayIPtr p3 = p1;    // Point at first class again

assert(p1 == p3);        // Now they compare equal

```

Asynchronous Method Invocation (AMI) in C++

Asynchronous Method Invocation (AMI) is the term used to describe the client-side support for the asynchronous programming model. AMI supports both oneway and twoway requests, but unlike their synchronous counterparts, AMI requests never block the calling thread. When a client issues an AMI request, the Ice run time hands the message off to the local transport buffer or, if the buffer is currently full, queues the request for later delivery. The application can then continue its activities and poll or wait for completion of the invocation, or receive a callback when the invocation completes.

AMI is transparent to the server: there is no way for the server to tell whether a client sent a request synchronously or asynchronously.

Basic Asynchronous API in C++

Consider the following simple Slice definition:

Slice
<pre> module Demo { interface Employees { string getName(int number); }; }; </pre>

Asynchronous Proxy Methods in C++

Besides the synchronous proxy methods, `slice2cpp` generates the following asynchronous proxy methods:

C++
<pre> Ice::AsyncResultPtr begin_getName(Ice::Int number); Ice::AsyncResultPtr begin_getName(Ice::Int number, const Ice::Context& __ctx) std::string end_getName(const Ice::AsyncResultPtr&); </pre>

Four additional overloads of `begin_getName` are generated for use with [generic callbacks](#) and [type-safe callbacks](#).

As you can see, the single `getName` operation results in `begin_getName` and `end_getName` methods. (The `begin_` method is overloaded so you can pass a [per-invocation context](#).)

- The `begin_getName` method sends (or queues) an invocation of `getName`. This method does not block the calling thread.
- The `end_getName` method collects the result of the asynchronous invocation. If, at the time the calling thread calls `end_getName`, the result is not yet available, the calling thread blocks until the invocation completes. Otherwise, if the invocation completed some time before the call to `end_getName`, the method returns immediately with the result.

A client could call these methods as follows:

```
C++
```

```

EmployeesPrx e = ...;
Ice::AsyncResultPtr r = e->begin_getName(99);

// Continue to do other things here...

string name = e->end_getName(r);

```

Because `begin_getName` does not block, the calling thread can do other things while the operation is in progress.

Note that `begin_getName` returns a value of type `AsyncResultPtr`. The `AsyncResult` associated with this smart pointer contains the state that the Ice run time requires to keep track of the asynchronous invocation. You must pass the `AsyncResultPtr` that is returned by the `begin_` method to the corresponding `end_` method.

The `begin_` method has one parameter for each in-parameter of the corresponding Slice operation. Similarly, the `end_` method has one out-parameter for each out-parameter of the corresponding Slice operation (plus the `AsyncResultPtr` parameter). For example, consider the following operation:

```
Slice
```

```

double op(int inp1, string inp2, out bool outp1, out long outp2);

```

The `begin_op` and `end_op` methods have the following signature:

```
C++
```

```

Ice::AsyncResultPtr begin_op(Ice::Int inp1, const ::std::string& inp2)

Ice::Double end_op(bool& outp1, Ice::Long& outp2,
const Ice::AsyncResultPtr&);

```

Asynchronous Exception Semantics in C++

If an invocation raises an exception, the exception is thrown by the `end_` method, even if the actual error condition for the exception was encountered during the `begin_` method ("on the way out"). The advantage of this behavior is that all exception handling is located with the code that calls the `end_` method (instead of being present twice, once where the `begin_` method is called, and again where the `end_` method is called).

There is one exception to the above rule: if you destroy the communicator and then make an asynchronous invocation, the `begin_` method throws `CommunicatorDestroyedException`. This is necessary because, once the run time is finalized, it can no longer throw an exception from the `end_` method.

The only other exception that is thrown by the `begin_` and `end_` methods is `IceUtil::IllegalArgumentException`. This exception indicates that you have used the API incorrectly. For example, the `begin_` method throws this exception if you call an operation that has a return value or out-parameters on a oneway proxy. Similarly, the `end_` method throws this exception if you use a different proxy to call the `end_` method than the proxy you used to call the `begin_` method, or if the `AsyncResult` you pass to the `end_` method was obtained by calling the `begin_` method for a different operation.

AsyncResult Class in C++

The `AsyncResult` that is returned by the `begin_` method encapsulates the state of the asynchronous invocation:

```

C++

class AsyncResult : public Ice::LocalObject,
private IceUtil::noncopyable {
public:
    bool operator==(const AsyncResult&) const;
    bool operator<(const AsyncResult&) const;

    Int getHash() const;

    void cancel();

    CommunicatorPtr getCommunicator() const;
    ConnectionPtr getConnection() const;
    ObjectPrx getProxy() const;
    const string& getOperation() const;
    LocalObjectPtr getCookie() const;

    bool isCompleted() const;
    void waitForCompleted();

    bool isSent() const;
    void waitForSent();

    void throwLocalException() const;

    bool sentSynchronously() const;
};
```

The methods have the following semantics:

- `bool operator==(const AsyncResult&) const`
`bool operator<(const AsyncResult&) const`
`Int getHash() const`
 These methods allow you to create ordered or hashed collections of pending asynchronous invocations. This is useful, for example, if you can have a number of outstanding requests, and need to pass state between the `begin_` and the `end_` methods. In this case, you can use the returned `AsyncResult` objects as keys into a map that stores the state for each call.
- `void cancel()`
 This method prevents a queued invocation from being sent or, if the invocation has already been sent, ignores a reply if the server sends one. `cancel` is a local operation and has no effect on the server. A canceled invocation is considered to be completed, meaning `isCompleted` returns true, and the result of the invocation is an `Ice::InvocationCanceledException`.
- `CommunicatorPtr getCommunicator() const`
 This method returns the communicator that sent the invocation.
- `virtual ConnectionPtr getConnection() const`
 This method returns the connection that was used for the invocation. Note that, for typical asynchronous proxy invocations, this method returns a nil value because the possibility of automatic retries means the connection that is currently in use could change unexpectedly. The `getConnection` method only returns a non-nil value when the `AsyncResult` object is obtained by calling `begin_flushBatchRequests` on a `Connection` object.

- `virtual ObjectPrx getProxy() const`
This method returns the proxy that was used to call the `begin_` method, or nil if the `AsyncResult` object was not obtained via an asynchronous proxy invocation.
- `const string& getOperation() const`
This method returns the name of the operation.
- `LocalObjectPtr getCookie() const`
This method returns the `cookie` that was passed to the `begin_` method. If you did not pass a cookie to the `begin_` method, the return value is null.
- `bool isCompleted() const`
This method returns true if, at the time it is called, the result of an invocation is available, indicating that a call to the `end_` method will not block the caller. Otherwise, if the result is not yet available, the method returns false.
- `void waitForCompleted()`
This method blocks the caller until the result of an invocation becomes available.
- `bool isSent() const`
When you call the `begin_` method, the Ice run time attempts to write the corresponding request to the client-side transport. If the transport cannot accept the request, the Ice run time queues the request for later transmission. `isSent` returns true if, at the time it is called, the request has been written to the local transport (whether it was initially queued or not). Otherwise, if the request is still queued or an exception occurred before the request could be sent, `isSent` returns false.
- `void waitForSent()`
This method blocks the calling thread until a request has been written to the client-side transport, or an exception occurs. After `waitForSent` returns, `isSent` returns true if the request was successfully written to the client-side transport, or false if an exception occurred. In the case of a failure, you can call the corresponding `end_` method or `throwLocalException` to obtain the exception.
- `void throwLocalException() const`
This method throws the local exception that caused the invocation to fail. If no exception has occurred yet, `throwLocalException` does nothing.
- `bool sentSynchronously() const`
This method returns true if a request was written to the client-side transport without first being queued. If the request was initially queued, `sentSynchronously` returns false (independent of whether the request is still in the queue or has since been written to the client-side transport).

Polling for Completion in C++

The `AsyncResult` methods allow you to poll for call completion. Polling is useful in a variety of cases. As an example, consider the following simple interface to transfer files from client to server:

Slice

```
interface FileTransfer
{
    void send(int offset, ByteSeq bytes);
};
```

The client repeatedly calls `send` to send a chunk of the file, indicating at which offset in the file the chunk belongs. A naïve way to transmit a file would be along the following lines:

C++

```
FileHandle file = open(...);
FileTransferPrx ft = ...;
const int chunkSize = ...;

Ice::Int offset = 0;
while (!file.eof()) {
    ByteSeq bs;
    bs = file.read(chunkSize); // Read a chunk
    ft->send(offset, bs);      // Send the chunk
    offset += bs.size();
}
```

This works, but not very well: because the client makes synchronous calls, it writes each chunk on the wire and then waits for the server to receive the data, process it, and return a reply before writing the next chunk. This means that both client and server spend much of their time doing nothing — the client does nothing while the server processes the data, and the server does nothing while it waits for the client to send the next chunk.

Using asynchronous calls, we can improve on this considerably:

C++

```

FileHandle file = open(...);
FileTransferPrx ft = ...;
const int chunkSize = ...;
Ice::Int offset = 0;

list<Ice::AsyncResultPtr> results;
const int numRequests = 5;

while (!file.eof()) {
    ByteSeq bs;
    bs = file.read(chunkSize);

    // Send up to numRequests + 1 chunks asynchronously.
    Ice::AsyncResultPtr r = ft->begin_send(offset, bs);
    offset += bs.size();

    // Wait until this request has been passed to the transport.
    r->waitForSent();
    results.push_back(r);

    // Once there are more than numRequests, wait for the least
    // recent one to complete.
    while (results.size() > numRequests) {
        Ice::AsyncResultPtr r = results.front();
        results.pop_front();
        r->waitForCompleted();
    }
}

// Wait for any remaining requests to complete.
while (!results.empty()) {
    Ice::AsyncResultPtr r = results.front();
    results.pop_front();
    r->waitForCompleted();
}

```

With this code, the client sends up to `numRequests + 1` chunks before it waits for the least recent one of these requests to complete. In other words, the client sends the next request without waiting for the preceding request to complete, up to the limit set by `numRequests`. In effect, this allows the client to "keep the pipe to the server full of data": the client keeps sending data, so both client and server continuously do work.

Obviously, the correct chunk size and value of `numRequests` depend on the bandwidth of the network as well as the amount of time taken by the server to process each request. However, with a little testing, you can quickly zoom in on the point where making the requests larger or queuing more requests no longer improves performance. With this technique, you can realize the full bandwidth of the link to within a percent or two of the theoretical bandwidth limit of a native socket connection.

Generic Completion Callbacks in C++

The `begin_` method is overloaded to allow you to provide completion callbacks. Here are the corresponding methods for the `getName` operation:

```
C++
```

```
Ice::AsyncResultPtr begin_getName(
    Ice::Int number,
    const Ice::CallbackPtr& __del,
    const Ice::LocalObjectPtr& __cookie = 0);

Ice::AsyncResultPtr begin_getName(
    Ice::Int number,
    const Ice::Context& __ctx,
    const Ice::CallbackPtr& __del,
    const Ice::LocalObjectPtr& __cookie = 0);
```

The second version of `begin_getName` lets you override the default context. (We discuss the purpose of the `cookie` parameter in the next section.) Following the in-parameters, the `begin_` method accepts a parameter of type `Ice::CallbackPtr`. This is a smart pointer to a callback class that is provided by the Ice run time. This class stores an instance of a callback class that you implement. The Ice run time invokes a method on your callback instance when an asynchronous operation completes. Your callback class must provide a method that returns `void` and accepts a single parameter of type `const AsyncResultPtr&`, for example:

```
C++
```

```
class MyCallback : public IceUtil::Shared {
public:
    void finished(const Ice::AsyncResultPtr& r) {
        EmployeesPrx e = EmployeesPrx::uncheckedCast(r->getProxy());
        try {
            string name = e->end_getName(r);
            cout << "Name is: " << name << endl;
        } catch (const Ice::Exception& ex) {
            cerr << "Exception is: " << ex << endl;
        }
    }
};

typedef IceUtil::Handle<MyCallback> MyCallbackPtr;
```

Note that your callback class must derive from `IceUtil::Shared`. The callback method can have any name you prefer but its signature must match the preceding example.

The implementation of your callback method must call the `end_` method. The proxy for the call is available via the `getProxy` method on the `AsyncResult` that is passed by the Ice run time. The return type of `getProxy` is `Ice::ObjectPrx`, so you must down-cast the proxy to its correct type. (You should always use an `uncheckedCast` to do this, otherwise you will send an additional message to the server to verify the proxy type.)

Your callback method should catch and handle any exceptions that may be thrown by the `end_` method. If you allow an exception to escape from the callback method, the Ice run time produces a log entry by default and ignores the exception. (You can disable the log message by setting the property `Ice.Warn.AMICallback` to zero.)

To inform the Ice run time that you want to receive a callback for the completion of the asynchronous call, you pass the callback instance to the `begin_` method:

C++

```

EmployeesPrx e = ...;

MyCallbackPtr cb = new MyCallback;
Ice::CallbackPtr d = Ice::newCallback(cb, &MyCallback::finished);

e->begin_getName(99, d);

```

Note the call to `Ice::newCallback` in this example. This helper function expects a smart pointer to your callback instance and a member function pointer that specifies your callback method.

Using Cookies for Generic Completion Callbacks in C++

It is common for the `end_` method to require access to some state that is established by the code that calls the `begin_` method. As an example, consider an application that asynchronously starts a number of operations and, as each operation completes, needs to update different user interface elements with the results. In this case, the `begin_` method knows which user interface element should receive the update, and the `end_` method needs access to that element.

The API allows you to pass such state by providing a cookie. A cookie is an instance of a class that you write; the class can contain whatever data you want to pass, as well as any methods you may want to add to manipulate that data.

The only requirement on the cookie class is that it must derive from `Ice::LocalObject`. Here is an example implementation that stores a `WidgetHandle`. (We assume that this class provides whatever methods are needed by the `end_` method to update the display.)

C++

```

class Cookie : public Ice::LocalObject
{
public:
    Cookie(WidgetHandle h) : _h(h) {}
    WidgetHandle getWidget() { return _h; }

private:
    WidgetHandle _h;
};
typedef IceUtil::Handle<Cookie> CookiePtr;

```

When you call the `begin_` method, you pass the appropriate cookie instance to inform the `end_` method how to update the display:

C++

```
// Make cookie for call to getName(99).
CookiePtr cookie1 = new Cookie(widgetHandle1);

// Make cookie for call to getName(42);
CookiePtr cookie2 = new Cookie(widgetHandle2);

// Invoke the getName operation with different cookies.
e->begin_getName(99, getNameCB, cookie1);
e->begin_getName(24, getNameCB, cookie2);
```

The `end_` method can retrieve the cookie from the `AsyncResult` by calling `getCookie`. For this example, we assume that widgets have a `writeString` method that updates the relevant UI element:

C++

```
void
MyCallback::getName(const Ice::AsyncResultPtr& r)
{
    EmployeesPrx e = EmployeesPrx::uncheckedCast(r->getProxy());
    CookiePtr cookie = CookiePtr::dynamicCast(r->getCookie());
    try {
        string name = e->end_getName(r);
        cookie->getWidget()->writeString(name);
    } catch (const Ice::Exception& ex) {
        handleException(ex);
    }
}
```

The cookie provides a simple and effective way for you to pass state between the point where an operation is invoked and the point where its results are processed. Moreover, if you have a number of operations that share common state, you can pass the same cookie instance to multiple invocations.

Type-Safe Completion Callbacks in C++

The [generic callback API](#) is not entirely type-safe:

- You must down-cast the return value of `getProxy` to the correct proxy type before you can call the `end_` method.
- You must call the correct `end_` method to match the operation called by the `begin_` method.
- If you use a cookie, you must down-cast the cookie to the correct type before you can access the data inside the cookie.
- You must remember to catch exceptions when you call the `end_` method; if you forget to do this, you will not know that the operation failed.

`slice2cpp` generates an additional type-safe API that takes care of these chores for you. The type-safe API is provided as a template that works much like the `Ice::Callback` class of the generic API, but requires strongly-typed method signatures.

To use type-safe callbacks, you must implement a callback class that provides two callback methods:

- A success callback that is called if the operation succeeds
- A failure callback that is called if the operation raises an exception

As for the generic API, your callback class must derive from `IceUtil::Shared`. Here is a callback class for an invocation of the `getName` operation:

```
C++
```

```
class MyCallback : public IceUtil::Shared
{
public:
    void getNameCB(const string& name) {
        cout << "Name is: " << name << endl;
    }

    void failureCB(const Ice::Exception& ex) {
        cerr << "Exception is: " << ex << endl;
    }
};
```

The callback methods can have any name you prefer and must have `void` return type. The failure callback always has a single parameter of type `const Ice::Exception&`. The success callback parameters depend on the operation signature. If the operation has non-void return type, the first parameter of the success callback is the return value. The return value (if any) is followed by a parameter for each out-parameter of the corresponding Slice operation, in the order of declaration.

To receive these callbacks, you instantiate your callback instance and specify the methods you have defined before passing a smart pointer to a callback wrapper instance to the `begin_` method:

```
C++
```

```
MyCallbackPtr cb = new MyCallback;

Callback_Employees_getNamePtr getNameCB =
    newCallback_Employees_getName(cb, &MyCallback::getNameCB, &MyCallback::failureCB);

Callback_Employees_getNumberPtr getNumberCB =
    newCallback_Employees_getNumber(cb, &MyCallback::getNumberCB, &MyCallback::failureCB);

e->begin_getName(99, getNameCB);
e->begin_getNumber("Fred", getNumberCB);
```

Note how this code creates instances of two smart pointer types generated by `slice2cpp` named `Callback_Employees_getNamePtr` and `Callback_Employees_getNumberPtr`. Each smart pointer points to a template instance that encapsulates your callback instance and two member function pointers for the callback methods. The name of this smart pointer type is formed as follows:

```
<module>::Callback_<interface>_<operation>Ptr
```

Also note that the code uses helper functions to initialize the smart pointers. The first argument to the helper function is your callback instance, and the two following arguments are the success and failure member function pointers, respectively. The name of this helper function is formed as follows:

```
<module>::newCallback_<interface>_<operation>
```

It is legal to pass a null pointer as the success or failure callback. For the success callback, this is legal only for operations that have `void` return type and no out-parameters. This is useful if you do not care when the operation completes but want to know if the call failed. If you pass a null exception callback, the Ice run time will ignore any exception that is raised by the invocation.

The type of the success and exception member function pointers is provided as `Response` and `Exception` typedefs by the callback template. For example, you can ignore exceptions for an invocation of `getName` as follows:

```
C++
```

```

Callback_Employees_getName::Exception nullException = 0;

MyCallbackPtr cb = new MyCallback;

Callback_Employees_getNamePtr getNameCB =
    newCallback_Employees_getName(cb, &MyCallback::getNameCB, nullExcep
tion);

e->begin_getName(99, getNameCB); // Ignores exceptions

```

Using Cookies for Type-Safe Completion Callbacks in C++

The `begin_` method optionally accepts a cookie as a trailing parameter. As for the generic API, you can use the cookie to share state between the `begin_` and `end_` methods. However, with the type-safe API, there is no need to down-cast the cookie. Instead, the cookie parameter that is passed to the `end_` method is strongly typed. Assuming that you have defined a `Cookie` class and `CookiePtr` smart pointer, you can pass a cookie to the `begin_` method as follows:

```
C++
```

```

MyCallbackPtr cb = new MyCallback;

Callback_Employees_getNamePtr getNameCB =
    newCallback_Employees_getName(cb, &MyCallback::getNameCB, &MyCallba
ck::failureCB);

CookiePtr cookie = new Cookie(widgetHandle);
e->begin_getName(99, getNameCB, cookie);

```

The callback methods of your callback class simply add the cookie parameter:

```
C++
```

```

class MyCallback : public IceUtil::Shared
{
public:
    void getNameCB(const string& name, const CookiePtr& cookie) {
        cookie->getWidget()->writeString(name);
    }

    void failureCB(const Ice::Exception& ex, const CookiePtr& cookie) {
        cookie->getWidget()->writeError(ex.what());
    }
};

```

Lambda Completion Callbacks in C++

`slice2cpp` generates overloaded versions of the `begin_` methods that accept lambda functions, eliminating the need to create a separate callback object. The Slice compiler generates the following methods for the `getName` operation:

C++
<pre>Ice::AsyncResultPtr begin_getName(Ice::Int number, const Function<void (const std::string*)>& response, const Function<void (const Ice::Exception*)>& exception = ... const Function<void (bool)>& sent = ...); Ice::AsyncResultPtr begin_getName(Ice::Int number, const Ice::Context& ctx, const Function<void (const std::string*)>& response, const Function<void (const Ice::Exception*)>& exception = ... const Function<void (bool)>& sent = ...); Ice::AsyncResultPtr begin_getName(Ice::Int number, const Function<void (const Ice::AsyncResultPtr*)>& completed, const Function<void (const Ice::AsyncResultPtr*)>& sent = ...); Ice::AsyncResultPtr begin_getName(Ice::Int number, const Ice::Context& ctx, const Function<void (const Ice::AsyncResultPtr*)>& completed, const Function<void (const Ice::AsyncResultPtr*)>& sent = ...);</pre>

The overloaded versions of `begin_getName` allow you to use the type-safe and generic styles, with and without a context argument. Notice that default values are provided for the `exception` and `sent` arguments, meaning you can omit these arguments if you wish to ignore their events. The first two functions above correspond to the type-safe API and the second two have generic API semantics.

These `begin_` methods are generated by default, but can only be used with a compiler that supports C++11 lambda functions, and with an Ice installation that was built with C++11 features enabled.

We can invoke `begin_getName` as shown below:

C++

```

EmployeesPrx e = ...;

// Type-safe
e->begin_getName(42, [](const std::string& name) { cout << "name = " <<
name << endl; });

// Generic
e->begin_getName(42, [=](const Ice::AsyncResultPtr& r) {
    cout << "name = " << e->end_getName(r) << endl;
});

```

For the sake of brevity we have omitted the error handling that would normally be necessary.

Asynchronous Oneway Invocations in C++

You can invoke operations via oneway proxies asynchronously, provided the operation has `void` return type, does not have any out-parameters, and does not raise user exceptions. If you call the `begin_` method on a oneway proxy for an operation that returns values or raises a user exception, the `begin_` method throws an `IceUtil::IllegalArgumentException`.

For the generic API, the callback method looks exactly as for a twoway invocation. However, for oneway invocations, the Ice run time does not call the callback method unless the invocation raised an exception during the `begin_` method ("on the way out").

For the type-safe API, the `newCallback` helper for `void` operations is overloaded so you can omit the success callback. For example, here is how you could call `ice_ping` asynchronously:

C++

```

MyCallbackPtr cb = new MyCallback;

Ice::Callback_Object_ice_pingPtr callback =
    Ice::newCallback_Object_ice_ping(cb, &MyCallback::failureCB);

p->begin_opVoid(callback);

```

Flow Control in C++

Asynchronous method invocations never block the thread that calls the `begin_` method: the Ice run time checks to see whether it can write the request to the local transport. If it can, it does so immediately in the caller's thread. (In that case, `AsyncResult::sentSynchronously` returns true.) Alternatively, if the local transport does not have sufficient buffer space to accept the request, the Ice run time queues the request internally for later transmission in the background. (In that case, `AsyncResult::sentSynchronously` returns false.)

This creates a potential problem: if a client sends many asynchronous requests at the time the server is too busy to keep up with them, the requests pile up in the client-side run time until, eventually, the client runs out of memory.

The API provides a way for you to implement flow control by counting the number of requests that are queued so, if that number exceeds some threshold, the client stops invoking more operations until some of the queued operations have drained out of the local transport.

For the generic API, you can create an additional callback method:

C++

```
class MyCallback : public IceUtil::Shared {
public:
    void finished(const Ice::AsyncResultPtr&);
    void sent(const Ice::AsyncResultPtr&);
};
typedef IceUtil::Handle<MyCallback> MyCallbackPtr;
```

As with any other callback method, you are free to choose any name you like. For this example, the name of the callback method is `sent`. You inform the Ice run time that you want to be informed when a call has been passed to the local transport by specifying the `sent` method as an additional parameter when you create the `Ice::Callback`:

C++

```
EmployeesPrx e = ...;

MyCallbackPtr cb = new MyCallback;
Ice::CallbackPtr d = Ice::newCallback(cb, &MyCallback::finished,
&MyCallback::sent);

e->begin_getName(99, d);
```

If the Ice run time can immediately pass the request to the local transport, it does so and invokes the `sent` method from the thread that calls the `begin_` method. On the other hand, if the run time has to queue the request, it calls the `sent` method from a different thread once it has written the request to the local transport. In addition, you can find out from the `AsyncResult` that is returned by the `begin_` method whether the request was sent synchronously or was queued, by calling `sentSynchronously`.

For the generic API, the `sent` method has the following signature:

C++

```
void sent(const Ice::AsyncResult&);
```

For the type-safe API, there are two versions, one without and one with a cookie:

C++

```
void sent(bool sentSynchronously);
void sent(bool sentSynchronously, const <CookiePtr>& cookie);
```

For the version with a cookie, `<CookiePtr>` is replaced with the actual type of the cookie smart pointer you passed to the `begin_` method.

The `sent` methods allow you to limit the number of queued requests by counting the number of requests that are queued and decrementing the count when the Ice run time passes a request to the local transport.

Asynchronous Batch Requests in C++

Applications that send [batched requests](#) can either flush a batch explicitly or allow the Ice run time to flush automatically. The proxy method `ice_flushBatchRequests` performs an immediate flush using the synchronous invocation model and may block the calling thread until the entire message can be sent. Ice also provides asynchronous versions of this method so you can flush batch requests asynchronously.

`begin_ice_flushBatchRequests` and `end_ice_flushBatchRequests` are proxy methods that flush any batch requests queued by that proxy.

In addition, similar methods are available on the communicator and the `Connection` object that is returned by `AsyncResult::getConnection`. These methods flush batch requests sent via the same communicator and via the same connection, respectively.

Concurrency Semantics for AMI in C++

The Ice run time always invokes your callback methods from a separate thread. This means that you can safely use a non-recursive mutex without risking deadlock. There is one exception to this rule: the run time calls the `sent` callback from the thread calling the `begin_` method if the request could be sent synchronously. In the `sent` callback, you know which thread is calling the callback by looking at the `sentSynchronously` member or parameter, so you can take appropriate action to avoid a self-deadlock.

Using Slice Checksums in C++

The Slice compilers can optionally generate [checksums](#) of Slice definitions. For `slice2cpp`, the `--checksum` option causes the compiler to generate code in each C++ source file that accumulates checksums in a global map. A copy of this map can be obtained by calling a function defined in the header file `Ice/SliceChecksums.h`:

```

C++

namespace Ice {
    Ice::SliceChecksumDict sliceChecksums();
}

```

In order to verify a server's checksums, a client could simply compare the dictionaries using the equality operator. However, this is not feasible if it is possible that the server might be linked with more Slice definitions than the client. A more general solution is to iterate over the local checksums as demonstrated below:

```

C++

Ice::SliceChecksumDict serverChecksums = ...
Ice::SliceChecksumDict localChecksums = Ice::sliceChecksums();

for (Ice::SliceChecksumDict::const_iterator p = localChecksums.begin();
     p != localChecksums.end(); ++p) {

    Ice::SliceChecksumDict::const_iterator q
= serverChecksums.find(p->first);
    if (q == serverChecksums.end()) {
        // No match found for type id!
    } else if (p->second != q->second) {
        // Checksum mismatch!
    }
}
}

```

In this example, the client first verifies that the server's dictionary contains an entry for each Slice type ID, and then it proceeds to compare the checksums.

Example of a File System Client in C++

This page presents a very simple client to access a server that implements the file system we developed in [Slice for a Simple File System](#). The C++ code shown here hardly differs from the code you would write for an ordinary C++ program. This is one of the biggest advantages of using Ice: accessing a remote object is as easy as accessing an ordinary, local C++ object. This allows you to put your effort where you should, namely, into developing your application logic instead of having to struggle with arcane networking APIs. This is true for the [server side](#) as well, meaning that you can develop distributed applications easily and efficiently.

We now have seen enough of the client-side C++ mapping to develop a complete client to access our remote file system. For reference, here is the Slice definition once more:

```

Slice

module Filesystem {
    interface Node {
        idempotent string name();
    };

    exception GenericError {
        string reason;
    };

    sequence<string> Lines;

    interface File extends Node {
        idempotent Lines read();
        idempotent void write(Lines text) throws GenericError;
    };

    sequence<Node*> NodeSeq;

    interface Directory extends Node {
        idempotent NodeSeq list();
    };
};
```

To exercise the file system, the client does a recursive listing of the file system, starting at the root directory. For each node in the file system, the client shows the name of the node and whether that node is a file or directory. If the node is a file, the client retrieves the contents of the file and prints them.

The body of the client code looks as follows:

```

C++

#include <Ice/Ice.h>
#include <Filesystem.h>
#include <iostream>
#include <iterator>

using namespace std;
using namespace Filesystem;

static void
```

```

listRecursive(const DirectoryPrx& dir, int depth = 0)
{
    // ...
}

int
main(int argc, char* argv[])
{
    int status = 0;
    Ice::CommunicatorPtr ic;
    try {
        // Create a communicator
        //
        ic = Ice::initialize(argc, argv);

        // Create a proxy for the root directory
        //
        Ice::ObjectPrx base
= ic->stringToProxy("RootDir:default -p 10000");
        if (!base)
            throw "Could not create proxy";

        // Down-cast the proxy to a Directory proxy
        //
        DirectoryPrx rootDir = DirectoryPrx::checkedCast(base);
        if (!rootDir)
            throw "Invalid proxy";

        // Recursively list the contents of the root directory
        //
        cout << "Contents of root directory:" << endl;
        listRecursive(rootDir);
    } catch (const Ice::Exception& ex) {
        cerr << ex << endl;
        status = 1;
    } catch (const char* msg) {
        cerr << msg << endl;
        status = 1;
    }

    // Clean up
    //
    if (ic)
        ic->destroy();
}

```

```

    return status;
}

```

1. The code includes a few header files:

- `Ice/Ice.h`:
Always included in both client and server source files, provides definitions that are necessary for accessing the Ice run time.
- `Filesystem.h`:
The header that is generated by the Slice compiler from the Slice definitions in `Filesystem.ice`.
- `iostream`:
The client uses the `iostream` library to produce its output.
- `iterator`:
The implementation of `listRecursive` uses an STL iterator.

2. The code adds `using` declarations for the `std` and `Filesystem` namespaces.

3. The structure of the code in `main` follows what we saw in [Hello World Application](#). After initializing the run time, the client creates a proxy to the root directory of the file system. For this example, we assume that the server runs on the local host and listens using the default protocol (TCP/IP) at port 10000. The object identity of the root directory is known to be `RootDir`.

4. The client down-casts the proxy to `DirectoryPrx` and passes that proxy to `listRecursive`, which prints the contents of the file system.

Most of the work happens in `listRecursive`:

C++

```

// Recursively print the contents of directory "dir" in
// tree fashion. For files, show the contents of each file.
// The "depth" parameter is the current nesting level
// (for indentation).

static void
listRecursive(const DirectoryPrx& dir, int depth = 0)
{
    string indent(++depth, '\t');

    NodeSeq contents = dir->list();

    for (NodeSeq::const_iterator i = contents.begin();
         i != contents.end(); ++i) {
        DirectoryPrx dir = DirectoryPrx::checkedCast(*i);
        FilePrx file = FilePrx::uncheckedCast(*i);
        cout << indent << (*i)->name()
        << (dir ? " (directory):" : " (file):") << endl;
        if (dir) {
            listRecursive(dir, depth);
        } else {
            Lines text = file->read();
            for (Lines::const_iterator j = text.begin();
                 j != text.end(); ++j) {
                cout << indent << "\t" << *j << endl;
            }
        }
    }
}

```

The function is passed a proxy to a directory to list, and an indent level. (The indent level increments with each recursive call and allows the code to print the name of each node at an indent level that corresponds to the depth of the tree at that node.) `listRecursive` calls the `list` operation on the directory and iterates over the returned sequence of nodes:

1. The code does a `checkedCast` to narrow the `Node` proxy to a `Directory` proxy, as well as an `uncheckedCast` to narrow the `Node` proxy to a `File` proxy. Exactly one of those casts will succeed, so there is no need to call `checkedCast` twice: if the `Node` is-a `Directory`, the code uses the `DirectoryPrx` returned by the `checkedCast`; if the `checkedCast` fails, we *know* that the `Node` is-a `File` and, therefore, an `uncheckedCast` is sufficient to get a `FilePrx`. In general, if you know that a down-cast to a specific type will succeed, it is preferable to use an `uncheckedCast` instead of a `checkedCast` because an `uncheckedCast` does not incur any network traffic.
2. The code prints the name of the file or directory and then, depending on which cast succeeded, prints "(directory)" or "(file)" following the name.
3. The code checks the type of the node:
 - If it is a directory, the code recurses, incrementing the indent level.
 - If it is a file, the code calls the `read` operation on the file to retrieve the file contents and then iterates over the returned sequence of lines, printing each line.

Assume that we have a small file system consisting of two files and a directory as follows:

A small file system.

The output produced by the client for this file system is:

```

Contents of root directory:
  README (file):
    This file system contains a collection of poetry.
  Coleridge (directory):
    Kubla_Khan (file):
      In Xanadu did Kubla Khan
      A stately pleasure-dome decree:
      Where Alph, the sacred river, ran
      Through caverns measureless to man
      Down to a sunless sea.
  
```

Note that, so far, our client (and server) are not very sophisticated:

- The protocol and address information are hard-wired into the code.
- The client makes more remote procedure calls than strictly necessary; with minor redesign of the Slice definitions, many of these calls can be avoided.

We will see how to address these shortcomings in our discussions of [IceGrid](#) and [object life cycle](#).

Server-Side Slice-to-C++ Mapping

The mapping for Slice data types to C++ is identical on the client side and server side. This means that everything in [Client-Side Slice-to-C++ Mapping](#) also applies to the server side. However, for the server side, there are a few additional things you need to know — specifically how to:

- Initialize and finalize the server-side run time
- Implement servants
- Pass parameters and throw exceptions
- Create servants and register them with the Ice run time.

Because the mapping for Slice data types is identical for clients and servers, the server-side mapping only adds a few additional mechanisms to the client side: a small API to initialize and finalize the run time, plus a few rules for how to derive servant classes from skeletons and how to register servants with the server-side run time.

Although the examples we present are very simple, they accurately reflect the basics of writing an Ice server. Of course, for more sophisticated servers, you will be using [additional APIs](#), for example, to improve performance or scalability. However, these APIs are all described in Slice, so, to use these APIs, you need not learn any C++ mapping rules beyond those we describe here.

A Basic main Function in C++

The main entry point to the Ice run time is represented by the local Slice interface `Ice::Communicator`. As for the client side, you must initialize the Ice run time by calling `Ice::initialize` before you can do anything else in your server. `Ice::initialize` returns a smart pointer to an instance of an `Ice::Communicator`:

C++

```

int
main(int argc, char* argv[])
{
    Ice::CommunicatorPtr ic = Ice::initialize(argc, argv);
    // ...
}

```

`Ice::initialize` accepts a C++ reference to `argc` and `argv`. The function scans the argument vector for any [command-line options](#) that are relevant to the Ice run time; any such options are removed from the argument vector so, when `Ice::initialize` returns, the only options and arguments remaining are those that concern your application. If anything goes wrong during initialization, `initialize` throws an exception.

`Ice::initialize` has [additional overloads](#) to permit other information to be passed to the Ice run time.

Before leaving your `main` function, you must call `Communicator::destroy`. The `destroy` operation is responsible for finalizing the Ice run time. In particular, `destroy` waits for any operation implementations that are still executing in the server to complete. In addition, `destroy` ensures that any outstanding threads are joined with and reclaims a number of operating system resources, such as file descriptors and memory. Never allow your `main` function to terminate without calling `destroy` first; doing so has undefined behavior.

The general shape of our server-side `main` function is therefore as follows:

C++

```

#include <Ice/Ice.h>

int
main(int argc, char* argv[])
{
    int status = 0;
    Ice::CommunicatorPtr ic;
    try {
        ic = Ice::initialize(argc, argv);

        // Server code here...

    } catch (const Ice::Exception& e) {
        cerr << e << endl;
        status = 1;
    } catch (const std::string& msg) {
        cerr << msg << endl;
        status = 1;
    } catch (const char* msg) {
        cerr << msg << endl;
        status = 1;
    }
    if (ic) {
        try {
            ic->destroy();
        } catch (const Ice::Exception& e) {
            cerr << e << endl;
            status = 1;
        }
    }
    return status;
}

```

Note that the code places the call to `Ice::initialize` in to a `try` block and takes care to return the correct exit status to the operating system. Also note that an attempt to destroy the communicator is made only if the initialization succeeded.

The catch handlers for `const std::string &` and `const char *` are in place as a convenience feature: if we encounter a fatal error condition anywhere in the server code, we can simply throw a string or a string literal containing an error message; this causes the stack to be unwound back to `main`, at which point the error message is printed and, after destroying the communicator, `main` terminates with non-zero exit status.

The `Ice::Application` Class

The preceding structure for the `main` function is so common that `Ice` offers a class, `Ice::Application`, that encapsulates all the correct initialization and finalization activities. The definition of the class is as follows (with some detail omitted for now):

C++

```

namespace Ice {
    enum SignalPolicy { HandleSignals, NoSignalHandling };

    class Application /* ... */ {
    public:
        Application(SignalPolicy = HandleSignals);
        virtual ~Application();

        int main(int argc, char*[] argv);
        int main(int argc, char*[] argv, const char* config);
        int main(int argc, char*[] argv,
const Ice::InitializationData& id);
        int main(int argc, char* const [] argv);
        int main(int argc, char* const [] argv, const char* config);
        int main(int argc, char* const [] argv,
const Ice::InitializationData& id);
        int main(const Ice::StringSeq&);
        int main(const Ice::StringSeq&, const char* config);
        int main(const Ice::StringSeq&,
const Ice::InitializationData& id);

#ifdef _WIN32
        int main(int argc, wchar_t*[] argv);
        int main(int argc, wchar_t*[] argv, const char* config);
        int main(int argc, wchar_t*[] argv,
const Ice::InitializationData& id);
#endif

        virtual int run(int, char*[]) = 0;

        static const char* appName();
        static CommunicatorPtr communicator();
        // ...
    };
}

```

The intent of this class is that you specialize `Ice::Application` and implement the pure virtual `run` method in your derived class. Whatever code you would normally place in `main` goes into the `run` method instead. Using `Ice::Application`, our program looks as follows:

C++

```

#include <Ice/Ice.h>

class MyApplication : virtual public Ice::Application {
public:
    virtual int run(int, char*[]) {

        // Server code here...

        return 0;
    }
};

int
main(int argc, char* argv[])
{
    MyApplication app;
    return app.main(argc, argv);
}

```

Note that `Application::main` is overloaded: you can pass a string sequence instead of an `argc/argv` pair. This is useful if you need to [parse application-specific property settings](#) on the command line. You also can call `main` with an optional file name or an `InitializationData` structure.

If you pass a [configuration file name](#) to `main`, the property settings in this file are overridden by settings in a file identified by the `ICE_CONFIG` environment variable (if defined). Property settings supplied on the [command line](#) take precedence over all other settings.

The `Application::main` function does the following:

1. It installs an exception handler for `Ice::Exception`. If your code fails to handle an Ice exception, `Application::main` prints the exception details on `stderr` before returning with a non-zero return value.
2. It installs exception handlers for `const std::string &` and `const char*`. This allows you to terminate your server in response to a fatal error condition by throwing a `std::string` or a string literal. `Application::main` prints the string on `stderr` before returning a non-zero return value.
3. It initializes (by calling `Ice::initialize`) and finalizes (by calling `Communicator::destroy`) a communicator. You can get access to the communicator for your server by calling the static `communicator()` member function.
4. It scans the argument vector for options that are relevant to the Ice run time and removes any such options. The argument vector that is passed to your `run` method therefore is free of Ice-related options and only contains options and arguments that are specific to your application.
5. It provides the name of your application via the static `appName` member function. The return value from this call is `argv[0]`, so you can get at `argv[0]` from anywhere in your code by calling `Ice::Application::appName` (which is often necessary for error messages).
6. It installs a [signal handler](#) that properly destroys the communicator.
7. It installs a [per-process logger](#) if the application has not already configured one. The per-process logger uses the value of the `Ice::ProgramName` property as a prefix for its messages and sends its output to the standard error channel. An application can also specify an [alternate logger](#).

Using `Ice::Application` ensures that your program properly finalizes the Ice run time, whether your server terminates normally or in response to an exception or signal. We recommend that all your programs use this class; doing so makes your life easier. In addition, `Ice::Application` also provides features for signal handling and configuration that you do not have to implement yourself when you use this class.

Using Ice::Application on the Client Side

You can use `Ice::Application` for your clients as well: simply implement a class that derives from `Ice::Application` and place the client code into its `run` method. The advantage of this approach is the same as for the server side: `Ice::Application` ensures that the

communicator is destroyed correctly even in the presence of exceptions.

Catching Signals in C++

The simple server we developed in [Hello World Application](#) had no way to shut down cleanly: we simply interrupted the server from the command line to force it to exit. Terminating a server in this fashion is unacceptable for many real-life server applications: typically, the server has to perform some cleanup work before terminating, such as flushing database buffers or closing network connections. This is particularly important on receipt of a signal or keyboard interrupt to prevent possible corruption of database files or other persistent data.

To make it easier to deal with signals, `Ice::Application` encapsulates the platform-independent [signal handling capabilities](#) provided by the class `IceUtil::CtrlCHandler`. This allows you to cleanly shut down on receipt of a signal and to use the same source code regardless of the underlying operating system and threading package:

```

C++

namespace Ice {
    class Application : /* ... */ {
    public:
        // ...
        static void destroyOnInterrupt();
        static void shutdownOnInterrupt();
        static void ignoreInterrupt();
        static void callbackOnInterrupt();
        static void holdInterrupt();
        static void releaseInterrupt();
        static bool interrupted();

        virtual void interruptCallback(int);
    };
}

```

You can use `Ice::Application` under both Windows and Unix: for Unix, the member functions control the behavior of your application for `SIGINT`, `SIGHUP`, and `SIGTERM`; for Windows, the member functions control the behavior of your application for `CTRL_C_EVENT`, `CTRL_BREAK_EVENT`, `CTRL_CLOSE_EVENT`, `CTRL_LOGOFF_EVENT`, and `CTRL_SHUTDOWN_EVENT`.

The functions behave as follows:

- `destroyOnInterrupt`
This function creates an `IceUtil::CtrlCHandler` that destroys the communicator when one of the monitored signals is raised. This is the default behavior.
- `shutdownOnInterrupt`
This function creates an `IceUtil::CtrlCHandler` that shuts down the communicator when one of the monitored signals is raised.
- `ignoreInterrupt`
This function causes signals to be ignored.
- `callbackOnInterrupt`
This function configures `Ice::Application` to invoke `interruptCallback` when a signal occurs, thereby giving the subclass responsibility for handling the signal. Note that if the signal handler needs to terminate the program, you must call `_exit` (instead of `exit`). This prevents global destructors from running which, depending on the activities of other threads in the program, could cause deadlock or assertion failures.
- `holdInterrupt`
This function causes signals to be held.
- `releaseInterrupt`
This function restores signal delivery to the previous disposition. Any signal that arrives after `holdInterrupt` was called is delivered when you call `releaseInterrupt`.

- `interrupted`
This function returns `true` if a signal caused the communicator to shut down, `false` otherwise. This allows us to distinguish intentional shutdown from a forced shutdown that was caused by a signal. This is useful, for example, for logging purposes.
- `interruptCallback`
A subclass overrides this function to respond to signals. The Ice run time may call this function concurrently with any other thread. If the function raises an exception, the Ice run time prints a warning on `cerr` and ignores the exception.

By default, `Ice::Application` behaves as if `destroyOnInterrupt` was invoked, therefore our server `main` function requires no change to ensure that the program terminates cleanly on receipt of a signal. (You can disable the signal-handling functionality of `Ice::Application` by passing the enumerator `NoSignalHandling` to the constructor. In that case, signals retain their default behavior, that is, terminate the process.) However, we add a diagnostic to report the occurrence of a signal, so our `main` function now looks like:

```

C++

#include <Ice/Ice.h>

class MyApplication : virtual public Ice::Application {
public:
    virtual int run(int, char*[]) {

        // Server code here...

        if (interrupted())
            cerr << appName() << ": terminating" << endl;

        return 0;
    }
};

int
main(int argc, char* argv[])
{
    MyApplication app;
    return app.main(argc, argv);
}

```

Note that, if your server is interrupted by a signal, the Ice run time waits for all currently executing operations to finish. This means that an operation that updates persistent state cannot be interrupted in the middle of what it was doing and cause partial update problems.

Under Unix, if you handle signals with your own handler (by deriving a subclass from `Ice::Application` and calling `callbackOnInterrupt`), the handler is invoked synchronously from a separate thread. This means that the handler can safely call into the Ice run time or make system calls that are not `async-signal-safe` without fear of deadlock or data corruption. Note that `Ice::Application` blocks delivery of `SIGINT`, `SIGHUP`, and `SIGTERM`. If your application calls `exec`, this means that the child process will also ignore these signals; if you need the default behavior of these signals in the `exec'd` process, you must explicitly reset them to `SIG_DFL` before calling `exec`.

Ice::Application and Properties

Apart from the functionality shown in this section, `Ice::Application` also takes care of initializing the Ice run time with property values. [Properties](#) allow you to configure the run time in various ways. For example, you can use properties to control things such as the thread pool size or port number for a server.

Limitations of Ice::Application

`Ice::Application` is a singleton class that creates a single communicator. If you are using multiple communicators, you cannot use `Ice::Application`. Instead, you must structure your code as we saw in [Hello World Application](#) (taking care to always destroy the communicators).

The `Ice::Service` Class

The `Ice::Application` class is very convenient for general use by Ice client and server applications. In some cases, however, an application may need to run at the system level as a Unix daemon or Windows service. For these situations, Ice includes `Ice::Service`, a singleton class that is comparable to `Ice::Application` but also encapsulates the low-level, platform-specific initialization and shutdown procedures common to system services. The `Ice::Service` class is defined as follows:

```

C++

namespace Ice {
  class Service {
  public:
    Service();

    virtual bool shutdown();
    virtual void interrupt();

    int main(int& argc, char* argv[],
             const Ice::InitializationData& =
Ice::InitializationData());
    int main(Ice::StringSeq& args,
             const Ice::InitializationData& =
Ice::InitializationData());

    Ice::CommunicatorPtr communicator() const;

    static Service* instance();

    bool service() const;
    std::string name() const;
    bool checkSystem() const;

    int run(int& argc, char* argv[],
const Ice::InitializationData&);

#ifdef _WIN32
    int main(int& argc, wchar_t* argv[], const InitializationData& =
InitializationData());

    void configureService(const std::string& name);
#else
    void configureDaemon(bool changeDir, bool closeFiles,
const std::string& pidFile);
#endif

    virtual void handleInterrupt(int);

  protected:
    virtual bool start(int argc, char* argv[], int& status) = 0;
    virtual void waitForShutdown();

```

```
virtual bool stop();
virtual Ice::CommunicatorPtr initializeCommunicator(
    int& argc, char* argv[],
    const Ice::InitializationData&);

virtual void syserror(const std::string& msg);
virtual void error(const std::string& msg);
virtual void warning(const std::string& msg);
virtual void trace(const std::string& msg);
virtual void print(const std::string& msg);

void enableInterrupt();
void disableInterrupt();

// ...
```

```

    };
}

```

At a minimum, an Ice application that uses the `Ice::Service` class must define a subclass and override the `start` member function, which is where the service must perform its startup activities, such as processing command-line arguments, creating an object adapter, and registering servants. The application's `main` function must instantiate the subclass and typically invokes its `main` member function, passing the program's argument vector as parameters. The example below illustrates a minimal `Ice::Service` subclass:

C++

```

#include <Ice/Ice.h>

class MyService : public Ice::Service {
protected:
    virtual bool start(int, char*[], int&);
private:
    Ice::ObjectAdapterPtr _adapter;
};

bool
MyService::start(int argc, char* argv[], int& status)
{
    _adapter = communicator()->createObjectAdapter("MyAdapter");
    _adapter->addWithUUID(new MyServantI);
    _adapter->activate();
    status = EXIT_SUCCESS;
    return true;
}

int
main(int argc, char* argv[])
{
    MyService svc;
    return svc.main(argc, argv);
}

```

The `Service::main` member function performs the following sequence of tasks:

1. Scans the argument vector for reserved options that indicate whether the program should run as a system service and removes these options from the argument vector (`argc` is adjusted accordingly). Additional reserved options are supported for administrative tasks.
2. Configures the program for running as a system service (if necessary) by invoking `configureService` or `configureDaemon`, as appropriate for the platform.
3. Invokes the `run` member function and returns its result.

Note that, as for `Application::main`, `Service::main` is overloaded to accept a string sequence instead of an `argc/argv` pair. This is useful if you need to [parse application-specific property settings](#) on the command line.

For maximum portability, we strongly recommend that all initialization tasks be performed in the `start` member function and not in the global `main` function. For example, allocating resources in `main` can cause program instability for [Unix daemons](#).

The `Service::run` member function executes the service in the steps shown below:

1. Installs a [signal handler](#).
2. Invokes the `initializeCommunicator` member function to obtain a communicator. The communicator instance can be accessed using the `communicator` member function.
3. Invokes the `start` member function. If `start` returns `false` to indicate failure, `run` destroys the communicator and returns immediately using the exit status provided in `status`.
4. Invokes the `waitForShutdown` member function, which should block until `shutdown` is invoked.
5. Invokes the `stop` member function. If `stop` returns `true`, `run` considers the application to have terminated successfully.
6. Destroys the communicator.
7. Gracefully terminates the system service (if necessary).

If an unhandled exception is caught by `Service::run`, a descriptive message is logged, the communicator is destroyed and the service is terminated.

Ice::Service Member Functions

The virtual member functions in `Ice::Service` represent the points at which a subclass can intercept the service activities. All of the virtual member functions (except `start`) have default implementations.

- `void handleInterrupt(int sig)`
Invoked by the `CtrlCHandler` when a signal occurs. The default implementation ignores the signal if it represents a logoff event and the `Ice.NoHup` property is set to a value larger than zero, otherwise it invokes the `interrupt` member function.
- `Ice::CommunicatorPtr initializeCommunicator(int & argc, char * argv[], const Ice::InitializationData & data)`
Initializes a communicator. The default implementation invokes `Ice::initialize` and passes the given arguments.
- `void interrupt()`
Invoked by the signal handler to indicate a signal was received. The default implementation invokes the `shutdown` member function.
- `bool shutdown()`
Causes the service to begin the shutdown process. The default implementation invokes `shutdown` on the communicator. The subclass must return `true` if shutdown was started successfully, and `false` otherwise.
- `bool start(int argc, char * argv[], int & status)`
Allows the subclass to perform its startup activities, such as scanning the provided argument vector for recognized command-line options, creating an object adapter, and registering servants. The subclass must return `true` if startup was successful, and `false` otherwise. The subclass can set an exit status via the `status` parameter. This status is returned by `main`.
- `bool stop()`
Allows the subclass to clean up prior to termination. The default implementation does nothing but return `true`. The subclass must return `true` if the service has stopped successfully, and `false` otherwise.
- `void syserror(const std::string & msg)`
`void error(const std::string & msg)`
`void warning(const std::string & msg)`
`void trace(const std::string & msg)`
`void print(const std::string & msg)`
Convenience functions for logging messages to the communicator's [logger](#). The `syserror` member function includes a description of the system's current error code. You can also log messages to these functions using utility classes similar to the [C++ Logger Utility Classes](#): these classes are `ServiceSysError`, `ServiceError`, `ServiceWarning`, `ServiceTrace` and `ServicePrint`, all nested in the `Service` class.
- `void waitForShutdown()`
Waits indefinitely for the service to shut down. The default implementation invokes `waitForShutdown` on the communicator.

The non-virtual member functions shown in the class definition are described below:

- `bool checkSystem() const`
Returns true if the operating system supports Windows services or Unix daemons.
- `Ice::CommunicatorPtr communicator() const`
Returns the communicator used by the service, as created by `initializeCommunicator`.
- `void configureDaemon(bool chdir, bool close, const std::string & pidFile)`
Configures the program to run as a Unix daemon. The `chdir` parameter determines whether the daemon changes its working

directory to the root directory. The `close` parameter determines whether the daemon closes unnecessary file descriptors (i.e., `stdin`, `stdout`, etc.). If a non-empty string is provided in the `pidFile` parameter, the daemon writes its process ID to the given file.

- `void configureService(const std::string & name)`
Configures the program to run as a Windows service with the given name.
- `void disableInterrupt()`
Disables the signal handling behavior in `Ice::Service`. When disabled, signals are ignored.
- `void enableInterrupt()`
Enables the signal handling behavior in `Ice::Service`. When enabled, the occurrence of a signal causes the `handleInterrupt` member function to be invoked.
- `static Service * instance()`
Returns the singleton `Ice::Service` instance.
- `int main(int & argc, char * argv[], const Ice::InitializationData & data = Ice::InitializationData())`
`int main(Ice::StringSeq& args, const Ice::InitializationData& = Ice::InitializationData());`
`int main(int & argc, wchar_t * argv[], const Ice::InitializationData & data = Ice::InitializationData())`
The primary entry point of the `Ice::Service` class. The tasks performed by this function are described earlier in this section. The function returns `EXIT_SUCCESS` for success, `EXIT_FAILURE` for failure. For Windows, this function is overloaded to allow you to pass a `wchar_t` argument vector.
- `std::string name() const`
Returns the name of the service. If the program is running as a Windows service, the return value is the Windows service name, otherwise it returns the value of `argv[0]`.
- `int run(int & argc, char * argv[], const Ice::InitializationData & data)`
Alternative entry point for applications that prefer a different style of service configuration. The program must invoke `configureService` (Windows) or `configureDaemon` (Unix) in order to run as a service. The tasks performed by this function were described earlier. The function normally returns `EXIT_SUCCESS` or `EXIT_FAILURE`, but the `start` method can also supply a different value via its `status` argument.
- `bool service() const`
Returns true if the program is running as a Windows service or Unix daemon, or false otherwise.

Unix Daemons

On Unix platforms, passing `--daemon` causes your program to run as a daemon. When this option is present, `Ice::Service` performs the following additional actions:

- Creates a background child process in which `Service::main` performs its tasks. The foreground process does not terminate until the child process has successfully invoked the `start` member function. This behavior avoids the uncertainty often associated with starting a daemon from a shell script by ensuring that the command invocation does not complete until the daemon is ready to receive requests.
- Changes the current working directory of the child process to the root directory, unless `--nochdir` is specified.
- Closes all file descriptors, unless `--noclose` is specified. The standard input (`stdin`) channel is closed and reopened to `/dev/null`. Likewise, the standard output (`stdout`) and standard error (`stderr`) channels are also closed and reopened to `/dev/null` unless `Ice.Stdout` or `Ice.Stderr` are defined, respectively, in which case those channels use the designated log files.

The file descriptors are not closed until after the communicator is initialized, meaning standard input, standard output, and standard error are available for use during this time. For example, the `IceSSL` plug-in may need to prompt for a passphrase on standard input, or `Ice` may print the child's process id on standard output if the property `Ice.PrintProcessId` is set.

The following additional command-line options can be specified in conjunction with the `--daemon` option:

- `--pidfile FILE`
This option writes the process ID of the service into the specified `FILE`.
- `--noclose`

Prevents `Ice::Service` from closing unnecessary file descriptors. This can be useful during debugging and diagnosis because it provides access to the output from the daemon's standard output and standard error.

- `--nochdir`
Prevents `Ice::Service` from changing the current working directory.

All of these options are removed from the argument vector that is passed to the `start` member function.

We strongly recommend that you perform all initialization tasks in your service's `start` member function, and not in the global `main` function. This is especially important for process-specific resources such as file descriptors, threads, and mutexes, which can be affected by the use of the `fork` system call in `Ice::Service`. For example, any files opened in `main` are automatically closed by `Ice::Service` and therefore unusable in your service, unless the daemon is started with the `--noclose` option.

Windows Services

On Windows, `Ice::Service` recognizes the following command-line options:

- `--service NAME`
Run as a Windows service named `NAME`, which must already be installed. This option is removed from the argument vector that is passed to the `start` member function.

Installing and configuring a Windows service is outside the scope of the `Ice::Service` class. Ice includes a [utility](#) for installing its services which you can use as a model for your own applications.

The `Ice::Service` class supports the Windows service control codes `SERVICE_CONTROL_INTERROGATE` and `SERVICE_CONTROL_STOP`. Upon receipt of `SERVICE_CONTROL_STOP`, `Ice::Service` invokes the `shutdown` member function.

Ice::Service Logging Considerations

A service that uses a [custom logger](#) has several ways of configuring it:

- as a [process-wide logger](#),
- in the `InitializationData` argument that is passed to `main`,
- by overriding the `initializeCommunicator` member function.

On Windows, `Ice::Service` installs its own logger that uses the Windows `Application` event log if no custom logger is defined. The source name for the event log is the service's name unless a different value is specified using the property `Ice.EventLog.Source`.

On Unix, the default Ice logger (which logs to the standard error output) is used when no other logger is configured. For daemons, this is not appropriate because the output will be lost. To change this, you can either implement a custom logger or set the `Ice.UseSyslog` property, which selects a logger implementation that logs to the `syslog` facility. Alternatively, you can set the `Ice.LogFile` property to write log messages to a file.

Note that `Ice::Service` may encounter errors before the communicator is initialized. In this situation, `Ice::Service` uses its default logger unless a process-wide logger is configured. Therefore, even if a failing service is configured to use a different logger implementation, you may find useful diagnostic information in the `Application` event log (on Windows) or sent to standard error (on Unix).

Server-Side C++ Mapping for Interfaces

The server-side mapping for interfaces provides an up-call API for the Ice run time: by implementing virtual functions in a servant class, you provide the hook that gets the thread of control from the Ice server-side run time into your application code.

On this page:

- [Skeleton Classes in C++](#)
- [Servant Classes in C++](#)
 - [Normal and idempotent Operations in C++](#)

Skeleton Classes in C++

On the client side, interfaces map to [proxy classes](#). On the server side, interfaces map to *skeleton* classes. A skeleton is a class that has a pure virtual member function for each operation on the corresponding interface. For example, consider our [Slice definition](#) for the `Node` interface:

Slice
<pre> module Filesystem { interface Node { idempotent string name(); }; // ... }; </pre>

The Slice compiler generates the following definition for this interface:

C++
<pre> namespace Filesystem { class Node : public virtual Ice::Object { public: virtual std::string name(const Ice::Current& = Ice::Current()) = 0; // ... }; // ... } </pre>

For the moment, we will ignore a number of other member functions of this class. The important points to note are:

- As for the client side, Slice modules are mapped to C++ namespaces with the same name, so the skeleton class definition is nested in the namespace `Filesystem`.
- The name of the skeleton class is the same as the name of the Slice interface (`Node`).
- The skeleton class contains a pure virtual member function for each operation in the Slice interface.
- The skeleton class is an abstract base class because its member functions are pure virtual.
- The skeleton class inherits from `Ice::Object` (which forms the root of the Ice object hierarchy).

Servant Classes in C++

In order to provide an implementation for an Ice object, you must create a servant class that inherits from the corresponding skeleton class.

For example, to create a servant for the `Node` interface, you could write:

```
C++
```

```
#include <Filesystem.h> // Slice-generated header

class NodeI : public virtual Filesystem::Node {
public:
    NodeI(const std::string&);
    virtual std::string name(const Ice::Current&);
private:
    std::string _name;
};
```

By convention, servant classes have the name of their interface with an `I`-suffix, so the servant class for the `Node` interface is called `NodeI`. (This is a convention only: as far as the Ice run time is concerned, you can choose any name you prefer for your servant classes.)

Note that `NodeI` inherits from `Filesystem::Node`, that is, it derives from its skeleton class. It is a good idea to always use virtual inheritance when defining servant classes. Strictly speaking, virtual inheritance is necessary only for servants that implement interfaces that use multiple inheritance; however, the `virtual` keyword does no harm and, if you add multiple inheritance to an interface hierarchy half-way through development, you do not have to go back and add a `virtual` keyword to all your servant classes.

As far as Ice is concerned, the `NodeI` class must implement only a single member function: the pure virtual `name` function that it inherits from its skeleton. This makes the servant class a concrete class that can be instantiated. You can add other member functions and data members as you see fit to support your implementation. For example, in the preceding definition, we added a `_name` member and a constructor. Obviously, the constructor initializes the `_name` member and the `name` function returns its value:

```
C++
```

```
NodeI::NodeI(const std::string& name) : _name(name)
{
}

std::string
NodeI::name(const Ice::Current&) const
{
    return _name;
}
```

Normal and idempotent Operations in C++

The `name` member function of the `NodeI` skeleton is not a `const` member function. However, given that the operation does not modify the state of its object, it really should be a `const` member function. We can achieve this by adding the `["cpp:const"]` metadata directive. For example:

Slice

```
interface Example {
    void normalOp();

    idempotent void idempotentOp();

    ["cpp:const"]
    idempotent void readonlyOp();
};
```

The skeleton class for this interface looks like this:

C++

```
class Example : public virtual Ice::Object {
public:
    virtual void normalOp(const Ice::Current& = Ice::Current()) = 0;
    virtual void idempotentOp(const Ice::Current& = Ice::Current()) = 0;
    virtual void readonlyOp(const Ice::Current&
= Ice::Current()) const = 0;
    // ...
};
```

Note that `readonlyOp` is mapped as a `const` member function due to the `["cpp:const"]` metadata directive; `normal` and `idempotent` operations (without the metadata directive) are mapped as ordinary, non-`const` member functions.

- [C++ Mapping for Interfaces](#)
- [Parameter Passing in C++](#)
- [Raising Exceptions in C++](#)

Parameter Passing in C++

For each parameter of a Slice operation, the C++ mapping generates a corresponding parameter for the virtual member function in the skeleton. In addition, every operation has a trailing parameter of type `Ice::Current`. For example, the `name` operation of the `Node` interface has no parameters, but the `name` member function of the `Node` skeleton class has a single parameter of type `Ice::Current`. We will ignore this parameter for now.

Parameter passing on the server side follows the rules for the client side:

- in-parameters are passed by value or `const` reference
- out-parameters are passed by reference
- return values are passed by value
- optional parameters are enclosed in `IceUtil::Optional` values

To illustrate the rules, consider the following interface that passes string parameters in all possible directions:

Slice

```

module M {
    interface Example {
        string op(string sin, out string sout);
    };
};

```

The generated skeleton class for this interface looks as follows:

C++

```

namespace M {
    class Example : virtual public ::Ice::Object {
    public:
        virtual std::string op(const std::string&, std::string&,
const Ice::Current& = Ice::Current()) = 0;
        // ...
    };
}

```

As you can see, there are no surprises here. For example, we could implement `op` as follows:

C++

```
std::string
ExampleI::op(const std::string& sin, std::string& sout,
const Ice::Current&)
{
    cout << sin << endl;           // In parameters are initialized
    sout = "Hello World!";        // Assign out parameter
    return "Done";                // Return a string
}
```

This code is in no way different from what you would normally write if you were to pass strings to and from a function; the fact that remote procedure calls are involved does not impact on your code in any way. The same is true for parameters of other types, such as proxies, classes, or dictionaries: the parameter passing conventions follow normal C++ rules and do not require special-purpose API calls or memory management.

- [C++ Mapping for Operations](#)
- [C++ Mapping for Optional Values](#)
- [Raising Exceptions in C++](#)
- [The Current Object](#)

Raising Exceptions in C++

To throw an exception from an operation implementation, you simply instantiate the exception, initialize it, and throw it. For example:

```

C++

void
Filesystem::FileI::write(const Filesystem::Lines& text,
const Ice::Current&)
{
    // Try to write the file contents here...
    // Assume we are out of space...
    if (error) {
        Filesystem::GenericError e;
        e.reason = "file too large";
        throw e;
    }
};

```

No memory management issues arise in the presence of exceptions.

Note that the Slice compiler never generates exception specifications for operations, regardless of whether the corresponding Slice operation definition has an exception specification or not. This is deliberate: C++ exception specifications do not add any value and are therefore not used by the Ice C++ mapping [1].

If you throw an arbitrary C++ exception (such as an `int` or other unexpected type), the Ice run time catches the exception and then returns an `UnknownException` to the client. Similarly, if you throw an "impossible" user exception (a user exception that is not listed in the exception specification of the operation), the client receives an `UnknownUserException`.

If you throw a run-time exception, such as `MemoryLimitException`, the client receives an `UnknownLocalException`. For that reason, you should never throw system exceptions from operation implementations. If you do, all the client will see is an `UnknownLocalException`, which does not tell the client anything useful.

Three run-time exceptions are [treated specially](#) and not changed to `UnknownLocalException` when returned to the client: `ObjectNotExistException`, `OperationNotExistException`, and `FacetNotExistException`.

Object Incarnation in C++

Having created a servant class such as the rudimentary `NodeI` class, you can instantiate the class to create a concrete servant that can receive invocations from a client. However, merely instantiating a servant class is insufficient to incarnate an object. Specifically, to provide an implementation of an Ice object, you must follow the following steps:

1. Instantiate a servant class.
2. Create an identity for the Ice object incarnated by the servant.
3. Inform the Ice run time of the existence of the servant.
4. Pass a proxy for the object to a client so the client can reach it.

On this page:

- [Instantiating a C++ Servant](#)
- [Creating an Identity in C++](#)
- [Activating a C++ Servant](#)

- [UUIDs as Identities in C++](#)
- [Creating Proxies in C++](#)
 - [Proxies and Servant Activation in C++](#)
 - [Direct Proxy Creation in C++](#)

Instantiating a C++ Servant

Instantiating a servant means to allocate an instance on the heap:

```

C++

NodePtr servant = new NodeI("Fred");
```

This code creates a new `NodeI` instance [on the heap](#) and assigns its address to a smart pointer of type `NodePtr`. This works because `NodeI` is derived from `Node`, so a smart pointer of type `NodePtr` can also look after an instance of type `NodeI`. However, if we want to invoke a member function of the derived `NodeI` class at this point, we have a problem: we cannot access member functions of the derived `NodeI` class through a `NodePtr` smart pointer, only member functions of `Node` base class. (The C++ type rules prevent us from accessing a member of a derived class through a pointer to a base class.) To get around this, we can modify the code as follows:

```

C++

typedef IceUtil::Handle<NodeI> NodeIPtr;
NodeIPtr servant = new NodeI("Fred");
```

This code makes use of the [smart pointer template](#) by defining `NodeIPtr` as a smart pointer to `NodeI` instances. Whether you use a smart pointer of type `NodePtr` or `NodeIPtr` depends solely on whether you want to invoke a member function of the `NodeI` derived class; if you only want to invoke member functions that are defined in the `Node` skeleton base class, it is sufficient to use a `NodePtr` and you need not define the `NodeIPtr` type.

Whether you use `NodePtr` or `NodeIPtr`, the advantages of using a smart pointer class should be obvious from the [smart pointer discussion](#): they make it impossible to accidentally leak memory.

Creating an Identity in C++

Each Ice object requires an identity. That identity must be unique for all servants using the same object adapter.

The Ice object model assumes that all objects (regardless of their adapter) have a [globally unique identity](#).

An Ice object identity is a structure with the following Slice definition:

```
Slice
```

```

module Ice {
    struct Identity {
        string name;
        string category;
    };
    // ...
};

```

The full identity of an object is the combination of both the `name` and `category` fields of the `Identity` structure. For now, we will leave the `category` field as the empty string and simply use the `name` field. (The `category` field is most often used in conjunction with [servant locators](#).)

To create an identity, we simply assign a key that identifies the servant to the `name` field of the `Identity` structure:

```
C++
```

```

Ice::Identity id;
id.name = "Fred"; // Not unique, but good enough for now

```

Activating a C++ Servant

Merely creating a servant instance does nothing: the Ice run time becomes aware of the existence of a servant only once you explicitly tell the object adapter about the servant. To activate a servant, you invoke the `add` operation on the object adapter. Assuming that we have access to the object adapter in the `_adapter` variable, we can write:

```
C++
```

```

_adapter->add(servant, id);

```

Note the two arguments to `add`: the smart pointer to the servant and the object identity. Calling `add` on the object adapter adds the servant pointer and the servant's identity to the adapter's servant map and links the proxy for an Ice object to the correct servant instance in the server's memory as follows:

1. The proxy for an Ice object, apart from addressing information, contains the identity of the Ice object. When a client invokes an operation, the object identity is sent with the request to the server.
2. The object adapter receives the request, retrieves the identity, and uses the identity as an index into the servant map.
3. If a servant with that identity is active, the object adapter retrieves the servant pointer from the servant map and dispatches the incoming request into the correct member function on the servant.

Assuming that the object adapter is in the [active state](#), client requests are dispatched to the servant as soon as you call `add`.

Servant Life Time and Reference Counts

Putting the preceding points together, we can write a simple function that instantiates and activates one of our `NodeI` servants. For this example, we use a simple helper function called `activateServant` that creates and activates a servant with a given identity:

C++

```

void
activateServant(const string& name)
{
    NodePtr servant = new NodeI(name);           // Refcount == 1
    Ice::Identity id;
    id.name = name;
    _adapter->add(servant, id);                  // Refcount == 2
}                                               // Refcount == 1

```

Note that we create the servant on the heap and that, once `activateServant` returns, we lose the last remaining handle to the servant (because the `servant` variable goes out of scope). The question is, what happens to the heap-allocated servant instance? The answer lies in the smart pointer semantics:

- When the new servant is instantiated, its reference count is initialized to 0.
- Assigning the servant's address to the `servant` smart pointer increments the servant's reference count to 1.
- Calling `add` passes the `servant` smart pointer to the object adapter which keeps a copy of the handle internally. This increments the reference count of the servant to 2.
- When `activateServant` returns, the destructor of the `servant` variable decrements the reference count of the servant to 1.

The net effect is that the servant is retained on the heap with a reference count of 1 for as long as the servant is in the servant map of its object adapter. (If we deactivate the servant, that is, remove it from the servant map, the reference count drops to zero and the memory occupied by the servant is reclaimed; we discuss these life cycle issues in [Object Life Cycle](#).)

UUIDs as Identities in C++

The Ice object model assumes that object identities are globally unique. One way of ensuring that uniqueness is to use UUIDs (Universally Unique Identifiers) as identities. The `IceUtil` namespace contains a [helper function](#) to create such identities:

C++

```

#include <IceUtil/UUID.h>
#include <iostream>

using namespace std;

int
main()
{
    cout << IceUtil::generateUUID() << endl;
}

```

When executed, this program prints a unique string such as `5029a22c-e333-4f87-86b1-cd5e0fcce509`. Each call to `generateUUID` creates a string that differs from all previous ones.

You can use a UUID such as this to create object identities. For convenience, the object adapter has an operation `addWithUUID` that generates a UUID and adds a servant to the servant map in a single step. Using this operation, we can rewrite the code shown [earlier](#) like this:

C++

```

void
activateServant(const string& name)
{
    NodePtr servant = new NodeI(name);
    _adapter->addWithUUID(servant);
}

```

Creating Proxies in C++

Once we have activated a servant for an Ice object, the server can process incoming client requests for that object. However, clients can only access the object once they hold a proxy for the object. If a client knows the server's address details and the object identity, it can create a proxy from a string, as we saw in our first example in [Hello World Application](#). However, creation of proxies by the client in this manner is usually only done to allow the client access to initial objects for bootstrapping. Once the client has an initial proxy, it typically obtains further proxies by invoking operations.

The object adapter contains all the details that make up the information in a proxy: the addressing and protocol information, and the object identity. The Ice run time offers a number of ways to create proxies. Once created, you can pass a proxy to the client as the return value or as an out-parameter of an operation invocation.

Proxies and Servant Activation in C++

The `add` and `addWithUUID` servant activation operations on the object adapter return a proxy for the corresponding Ice object. This means we can write:

C++

```

typedef IceUtil::Handle<NodeI> NodeIPtr;
NodeIPtr servant = new NodeI(name);
NodePrx proxy = NodePrx::uncheckedCast(_adapter->addWithUUID(servant));

// Pass proxy to client...

```

Here, `addWithUUID` both activates the servant and returns a proxy for the Ice object incarnated by that servant in a single step.

Note that we need to use an `uncheckedCast` here because `addWithUUID` returns a proxy of type `Ice::ObjectPrx`.

Direct Proxy Creation in C++

The object adapter offers an operation to create a proxy for a given identity:

Slice

```

module Ice {
    local interface ObjectAdapter {
        Object* createProxy(Identity id);
        // ...
    };
};

```

Note that `createProxy` creates a proxy for a given identity whether a servant is activated with that identity or not. In other words, proxies have a life cycle that is quite independent from the life cycle of servants:

C++

```

Ice::Identity id;
id.name = IceUtil::generateUUID();
ObjectPrx o = _adapter->createProxy(id);

```

This creates a proxy for an Ice object with the identity returned by `generateUUID`. Obviously, no servant yet exists for that object so, if we return the proxy to a client and the client invokes an operation on the proxy, the client will receive an `ObjectNotExistException`. (We examine these life cycle issues in more detail in [Object Life Cycle](#).)

Asynchronous Method Dispatch (AMD) in C++

The number of simultaneous synchronous requests a server is capable of supporting is determined by the number of threads in the server's [thread pool](#). If all of the threads are busy dispatching long-running operations, then no threads are available to process new requests and therefore clients may experience an unacceptable lack of responsiveness.

Asynchronous Method Dispatch (AMD), the server-side equivalent of [AMI](#), addresses this scalability issue. Using AMD, a server can receive a request but then suspend its processing in order to release the dispatch thread as soon as possible. When processing resumes and the results are available, the server sends a response explicitly using a callback object provided by the Ice run time.

AMD is transparent to the client, that is, there is no way for a client to distinguish a request that, in the server, is processed synchronously from a request that is processed asynchronously.

In practical terms, an AMD operation typically queues the request data (i.e., the callback object and operation arguments) for later processing by an application thread (or thread pool). In this way, the server minimizes the use of dispatch threads and becomes capable of efficiently supporting thousands of simultaneous clients.

An alternate use case for AMD is an operation that requires further processing after completing the client's request. In order to minimize the client's delay, the operation returns the results while still in the dispatch thread, and then continues using the dispatch thread for additional work.

On this page:

- [Enabling AMD with Metadata in C++](#)
- [AMD Mapping in C++](#)
- [AMD Exceptions in C++](#)
- [AMD Example in C++](#)

Enabling AMD with Metadata in C++

To enable asynchronous dispatch, you must add an ["amd"] metadata directive to your Slice definitions. The directive applies at the interface and the operation level. If you specify ["amd"] at the interface level, all operations in that interface use asynchronous dispatch; if you specify ["amd"] for an individual operation, only that operation uses asynchronous dispatch. In either case, the metadata directive *replaces* synchronous dispatch, that is, a particular operation implementation must use synchronous or asynchronous dispatch and cannot use both.

Consider the following Slice definitions:

Slice
<pre>["amd"] interface I { bool isValid(); float computeRate(); }; interface J { ["amd"] void startProcess(); int endProcess(); };</pre>

In this example, both operations of interface `I` use asynchronous dispatch, whereas, for interface `J`, `startProcess` uses asynchronous dispatch and `endProcess` uses synchronous dispatch.

Specifying metadata at the operation level (rather than at the interface or class level) minimizes the amount of generated code and, more importantly, minimizes complexity: although the asynchronous model is more flexible, it is also more complicated to use. It is therefore in your best interest to limit the use of the asynchronous model to those operations that need it, while using the simpler synchronous model for the rest.

AMD Mapping in C++

The C++ mapping emits the following code for each AMD operation:

1. A callback class used by the implementation to notify the Ice run time about the completion of an operation. The name of this class is formed using the pattern `AMD_class_op`. For example, an operation named `foo` defined in interface `I` results in a class named `AMD_I_foo`. The class is generated in the same scope as the interface or class containing the operation. Several methods are provided:
 - `void ice_response(<params>);`
The `ice_response` method allows the server to report the successful completion of the operation. If the operation has a non-void return type, the first parameter to `ice_response` is the return value. Parameters corresponding to the operation's `out` parameters follow the return value, in the order of declaration.
 - `void ice_exception(const std::exception &);`
This version of `ice_exception` allows the server to raise any standard exception, Ice run-time exception, or Ice user exception.
 - `void ice_exception();`
This version of `ice_exception` allows the server to report an `UnknownException`.

Neither `ice_response` nor `ice_exception` throw any exceptions to the caller.
2. The dispatch method, whose name has the suffix `_async`. This method has a `void` return type. The first parameter is a smart pointer to an instance of the callback class described above. The remaining parameters comprise the in-parameters of the operation, in the order of declaration.

For example, suppose we have defined the following operation:

```
Slice
```

```
interface I {
    ["amd"] int foo(short s, out long l);
};
```

The callback class generated for operation `foo` is shown below:

```
C++
```

```
class AMD_I_foo : public ... {
public:
    void ice_response(Ice::Int, Ice::Long);
    void ice_exception(const std::exception&);
    void ice_exception();
};
```

The dispatch method for asynchronous invocation of operation `foo` is generated as follows:

```
C++
```

```
void foo_async(const AMD_I_fooPtr&, Ice::Short);
```

AMD Exceptions in C++

There are two processing contexts in which the logical implementation of an AMD operation may need to report an exception: the dispatch thread (the thread that receives the invocation), and the response thread (the thread that sends the response).

These are not necessarily two different threads: it is legal to send the response from the dispatch thread.

Although we recommend that the callback object be used to report all exceptions to the client, it is legal for the implementation to raise an exception instead, but only from the dispatch thread.

As you would expect, an exception raised from a response thread cannot be caught by the Ice run time; the application's run-time environment determines how such an exception is handled. Therefore, a response thread must ensure that it traps all exceptions and sends the appropriate response using the callback object. Otherwise, if a response thread is terminated by an uncaught exception, the request may never be completed and the client might wait indefinitely for a response.

Whether raised in a dispatch thread or reported via the callback object, user exceptions are [validated](#) and local exceptions may undergo [translation](#).

AMD Example in C++

To demonstrate the use of AMD in Ice, let us define the Slice interface for a simple computational engine:

```
Slice
```

```

module Demo {
    sequence<float> Row;
    sequence<Row> Grid;

    exception RangeError {};

    interface Model {
        ["amd"] Grid interpolate(Grid data, float factor)
            throws RangeError;
    };
};

```

Given a two-dimensional grid of floating point values and a factor, the `interpolate` operation returns a new grid of the same size with the values interpolated in some interesting (but unspecified) way.

Our servant class derives from `Demo::Model` and supplies a definition for the `interpolate_async` method:

```
C++
```

```

class ModelI : virtual public Demo::Model,
virtual public IceUtil::Mutex {
public:
    virtual void interpolate_async(
        const Demo::AMD_Model_interpolatePtr&,
        const Demo::Grid&,
        Ice::Float,
        const Ice::Current&);

private:
    std::list<JobPtr> _jobs;
};

```

The implementation of `interpolate_async` uses synchronization to safely record the callback object and arguments in a `Job` that is added to a queue:

```
C++
```

```

void ModelI::interpolate_async(
    const Demo::AMD_Model_interpolatePtr& cb,
    const Demo::Grid& data,
    Ice::Float factor,
    const Ice::Current& current)
{
    IceUtil::Mutex::Lock sync(*this);
    JobPtr job = new Job(cb, data, factor);
    _jobs.push_back(job);
}

```

After queuing the information, the operation returns control to the Ice run time, making the dispatch thread available to process another request. An application thread removes the next `Job` from the queue and invokes `execute` to perform the interpolation. `Job` is defined as follows:

```
C++
```

```

class Job : public IceUtil::Shared {
public:
    Job(const Demo::AMD_Model_interpolatePtr&, const Demo::Grid&,
        Ice::Float);
    void execute();

private:
    bool interpolateGrid();

    Demo::AMD_Model_interpolatePtr _cb;
    Demo::Grid _grid;
    Ice::Float _factor;
};
typedef IceUtil::Handle<Job> JobPtr;

```

The implementation of `execute` uses `interpolateGrid` (not shown) to perform the computational work:

C++

```

Job::Job(const Demo::AMD_Model_interpolatePtr& cb,
const Demo::Grid& grid, Ice::Float factor) :
    _cb(cb), _grid(grid), _factor(factor)
{
}

void Job::execute()
{
    if (!interpolateGrid()) {
        _cb->ice_exception(Demo::RangeError());
        return;
    }
    _cb->ice_response(_grid);
}

```

If `interpolateGrid` returns `false`, then `ice_exception` is invoked to indicate that a range error has occurred. The `return` statement following the call to `ice_exception` is necessary because `ice_exception` does not throw an exception; it only marshals the exception argument and sends it to the client.

If interpolation was successful, `ice_response` is called to send the modified grid back to the client.

Example of a File System Server in C++

This page presents the source code for a C++ server that implements our [file system](#) and communicates with the [client](#) we wrote earlier. The code is fully functional, apart from the required [interlocking for threads](#).

The server is remarkably free of code that relates to distribution: most of the server code is simply application logic that would be present just the same for a non-distributed version. Again, this is one of the major advantages of Ice: distribution concerns are kept away from application code so that you can concentrate on developing application logic instead of networking infrastructure.

The server code shown here is not quite correct as it stands: if two clients access the same file in parallel, each via a different thread, one thread may read the `_lines` data member while another thread updates it. Obviously, if that happens, we may write or return garbage or, worse, crash the server. However, it is trivial to make the `read` and `write` operations thread-safe: a single data member and two lines of source code are sufficient to achieve this. We discuss how to write thread-safe servant implementations in [Threads and Concurrency with C++](#).

On this page:

- [Implementing a File System Server in C++](#)

Implementing a File System Server in C++

We have now seen enough of the server-side C++ mapping to implement a server for our [file system](#). (You may find it useful to review these [Slice definitions](#) before studying the source code.)

Our server is composed of two source files:

- `Server.cpp`
This file contains the server main program.
- `FilesystemI.cpp`
This file contains the implementation for the file system servants.

Server main Program in C++

Our server main program, in the file `Server.cpp`, uses the `Ice::Application` class. The `run` method installs a signal handler, creates an object adapter, instantiates a few servants for the directories and files in the file system, and then activates the adapter. This leads to a `main` program as follows:

C++

```
#include <Ice/Ice.h>
#include <FilesystemI.h>

using namespace std;
using namespace Filesystem;

class FilesystemApp : virtual public Ice::Application {
public:
    virtual int run(int, char*[]) {
        // Terminate cleanly on receipt of a signal
        //
        shutdownOnInterrupt();
    }
};
```

```

// Create an object adapter.
//
Ice::ObjectAdapterPtr adapter =
communicator()->createObjectAdapterWithEndpoints(
    "SimpleFilesystem", "default -p 10000");

// Create the root directory (with name "/" and no parent)
//
DirectoryIPtr root = new DirectoryI(communicator(), "/", 0);
root->activate(adapter);

// Create a file called "README" in the root directory
//
FileIPtr file = new FileI(communicator(), "README", root);
Lines text;
text.push_back("This file system contains a collection of poetry.");
file->write(text);
file->activate(adapter);

// Create a directory called "Coleridge"
// in the root directory
//
DirectoryIPtr coleridge =
new DirectoryI(communicator(), "Coleridge", root);
coleridge->activate(adapter);

// Create a file called "Kubla_Khan"
// in the Coleridge directory
//
file = new FileI(communicator(), "Kubla_Khan", coleridge);
text.erase(text.begin(), text.end());
text.push_back("In Xanadu did Kubla Khan");
text.push_back("A stately pleasure-dome decree:");
text.push_back("Where Alph, the sacred river, ran");
text.push_back("Through caverns measureless to man");
text.push_back("Down to a sunless sea.");
file->write(text);
file->activate(adapter);

// All objects are created, allow client requests now
//
adapter->activate();

// Wait until we are done
//
communicator()->waitForShutdown();
if (interrupted()) {
    cerr << appName()
<< ": received signal, shutting down" << endl;

```

```
        }  
        return 0;  
    };  
};  
  
int  
main(int argc, char* argv[])  
{  
    FilesystemApp app;
```

```

    return app.main(argc, argv);
}

```

There is quite a bit of code here, so let us examine each section in detail:

C++

```

#include <FilesystemI.h>

using namespace std;
using namespace Filesystem;

```

The code includes the header file `FilesystemI.h`. That file includes `Ice/Ice.h` as well as the header file that is generated by the Slice compiler, `Filesystem.h`.

Two using declarations, for the namespaces `std` and `Filesystem`, permit us to be a little less verbose in the source code.

The next part of the source code is the definition of `FilesystemApp`, which derives from `Ice::Application` and contains the main application logic in its `run` method:

C++

```

class FilesystemApp : virtual public Ice::Application {
public:
    virtual int run(int, char*[]) {
        // Terminate cleanly on receipt of a signal
        //
        shutdownOnInterrupt();

        // Create an object adapter.
        //
        Ice::ObjectAdapterPtr adapter =
communicator()->createObjectAdapterWithEndpoints(
        "SimpleFilesystem", "default -p 10000");

        // Create the root directory (with name "/" and no parent)
        //
        DirectoryIPtr root = new DirectoryI(communicator(), "/", 0);
        root->activate(adapter);

        // Create a file called "README" in the root directory
        //
        FileIPtr file = new FileI(communicator(), "README", root);
        Lines text;
        text.push_back("This file system contains a collection of poetr
y.");
        file->write(text);
        file->activate(adapter);

        // Create a directory called "Coleridge"

```

```

    // in the root directory
    //
    DirectoryIPtr coleridge =
new DirectoryI(communicator(), "Coleridge", root);
    coleridge->activate(adapter);

    // Create a file called "Kubla_Khan"
    // in the Coleridge directory
    //
    file = new FileI(communicator(), "Kubla_Khan", coleridge);
    text.erase(text.begin(), text.end());
    text.push_back("In Xanadu did Kubla Khan");
    text.push_back("A stately pleasure-dome decree:");
    text.push_back("Where Alph, the sacred river, ran");
    text.push_back("Through caverns measureless to man");
    text.push_back("Down to a sunless sea.");
    file->write(text);
    file->activate(adapter);

    // All objects are created, allow client requests now
    //
    adapter->activate();

    // Wait until we are done
    //
    communicator()->waitForShutdown();
    if (interrupted()) {
        cerr << appName()
<< ": received signal, shutting down" << endl;
    }

    return 0;

```

```

    };
};

```

Much of this code is boiler plate that we saw previously: we create an object adapter, and, towards the end, activate the object adapter and call `waitForShutdown`.

The interesting part of the code follows the adapter creation: here, the server instantiates a few nodes for our file system to create the structure shown below:

A small file system.

As we will see shortly, the servants for our directories and files are of type `DirectoryI` and `FileI`, respectively. The constructor for either type of servant accepts three parameters: the communicator, the name of the directory or file to be created, and a handle to the servant for the parent directory. (For the root directory, which has no parent, we pass a null parent handle.) Thus, the statement

```

C++
DirectoryIPtr root = new DirectoryI(communicator(), "/", 0);

```

creates the root directory, with the name `" / "` and no parent directory. Note that we use the [smart pointer class](#) to hold the return value from `new`; that way, we avoid any memory management issues. The types `DirectoryIPtr` and `FileIPtr` are defined as follows in a header file `FilesystemI.h`:

```

C++
typedef IceUtil::Handle<DirectoryI> DirectoryIPtr;
typedef IceUtil::Handle<FileI> FileIPtr;

```

Here is the code that establishes the structure in the illustration above.

C++

```

// Create the root directory (with name "/" and no parent)
//
DirectoryIPtr root = new DirectoryI(communicator(), "/", 0);
root->activate(adapter);

// Create a file called "README" in the root directory
//
FileIPtr file = new FileI(communicator(), "README", root);
Lines text;
text.push_back("This file system contains a collection of poetry.");
file->write(text);
file->activate(adapter);

// Create a directory called "Coleridge"
// in the root directory
//
DirectoryIPtr coleridge =
new DirectoryI(communicator(), "Coleridge", root);
coleridge->activate(adapter);

// Create a file called "Kubla_Khan"
// in the Coleridge directory
//
file = new FileI(communicator(), "Kubla_Khan", coleridge);
text.erase(text.begin(), text.end());
text.push_back("In Xanadu did Kubla Khan");
text.push_back("A stately pleasure-dome decree:");
text.push_back("Where Alph, the sacred river, ran");
text.push_back("Through caverns measureless to man");
text.push_back("Down to a sunless sea.");
file->write(text);
file->activate(adapter);

```

We first create the root directory and a file `README` within the root directory. (Note that we pass the handle to the root directory as the parent pointer when we create the new node of type `FileI`.)

After creating each servant, the code calls `activate` on the servant. (We will see the definition of this member function shortly.) The `activate` member function adds the servant to the ASM.

The next step is to fill the file with text:

C++

```
FileIPtr file = new FileI(communicator(), "README", root);
Lines text;
text.push_back("This file system contains a collection of poetry.");
file->write(text);
file->activate(adapter);
```

Recall that [Slice sequences](#) map to STL vectors. The Slice type `Lines` is a sequence of strings, so the C++ type `Lines` is a vector of strings; we add a line of text to our `README` file by calling `push_back` on that vector.

Finally, we call the Slice `write` operation on our `FileI` servant by simply writing:

C++

```
file->write(text);
```

This statement is interesting: the server code invokes an operation on one of its own servants. Because the call happens via a smart class pointer (of type `FilePtr`) and not via a proxy (of type `FilePrx`), the Ice run time does not know that this call is even taking place — such a direct call into a servant is not mediated by the Ice run time in any way and is dispatched as an ordinary C++ function call.

In similar fashion, the remainder of the code creates a subdirectory called `Coleridge` and, within that directory, a file called `Kubla_Khan` to complete the structure in the above illustration.

Servant Class Definitions in C++

We must provide servants for the concrete interfaces in our Slice specification, that is, we must provide servants for the `File` and `Directory` interfaces in the C++ classes `FileI` and `DirectoryI`. This means that our servant classes might look as follows:

C++

```
namespace Filesystem {
    class FileI : virtual public File {
        // ...
    };

    class DirectoryI : virtual public Directory {
        // ...
    };
}
```

This leads to the C++ class structure as shown:

File system servants using interface inheritance.

The shaded classes in the illustration above are skeleton classes and the unshaded classes are our servant implementations. If we implement our servants like this, `FileI` must implement the pure virtual operations it inherits from the `File` skeleton (`read` and `write`), as well as the operation it inherits from the `Node` skeleton (`name`). Similarly, `DirectoryI` must implement the pure virtual function it inherits from the `Directory` skeleton (`list`), as well as the operation it inherits from the `Node` skeleton (`name`). Implementing the servants in this way uses interface inheritance from `Node` because no implementation code is inherited from that class.

Alternatively, we can implement our servants using the following definitions:

```

C++
namespace Filesystem {
  class NodeI : virtual public Node {
    // ...
  };

  class FileI : virtual public File, virtual public NodeI {
    // ...
  };

  class DirectoryI : virtual public Directory, virtual public NodeI {
    // ...
  };
}

```

This leads to the C++ class structure shown:

File system servants using implementation inheritance.

In this implementation, `NodeI` is a concrete base class that implements the name operation it inherits from the `Node` skeleton. `FileI` and `DirectoryI` use multiple inheritance from `NodeI` and their respective skeletons, that is, `FileI` and `DirectoryI` use implementation inheritance from their `NodeI` base class.

Either implementation approach is equally valid. Which one to choose simply depends on whether we want to re-use common code provided by `NodeI`. For the implementation that follows, we have chosen the second approach, using implementation inheritance.

Given the structure in the above illustration and the operations we have defined in the Slice definition for our file system, we can add these operations to the class definition for our servants:

```

C++
namespace Filesystem {
  class NodeI : virtual public Node {
  public:
    virtual std::string name(const Ice::Current&);
  };

  class FileI : virtual public File, virtual public NodeI {
  public:
    virtual Lines read(const Ice::Current&);
    virtual void write(const Lines&, const Ice::Current&);
  };

  class DirectoryI : virtual public Directory, virtual public NodeI {
  public:
    virtual NodeSeq list(const Ice::Current&);
  };
}

```

This simply adds signatures for the operation implementations to each class. Note that the signatures must exactly match the operation signatures in the generated skeleton classes — if they do not match exactly, you end up overloading the pure virtual function in the base class instead of overriding it, meaning that the servant class cannot be instantiated because it will still be abstract. To avoid signature mismatches, you can copy the signatures from the generated header file (`Filesystem.h`), or you can use the `--impl` option with `slice2cpp` to generate header and implementation files that you can add your application code to.

Now that we have the basic structure in place, we need to think about other methods and data members we need to support our servant implementation. Typically, each servant class hides the copy constructor and assignment operator, and has a constructor to provide initial

state for its data members. Given that all nodes in our file system have both a name and a parent directory, this suggests that the `NodeI` class should implement the functionality relating to tracking the name of each node, as well as the parent-child relationships:

```
C++
```

```

namespace Filesystem {
    class DirectoryI;
    typedef IceUtil::Handle<DirectoryI> DirectoryIPtr;

    class NodeI : virtual public Node {
    public:
        virtual std::string name(const Ice::Current&);
        NodeI(const Ice::CommunicatorPtr&, const std::string&,
const DirectoryIPtr&);
        void activate(const Ice::ObjectAdapterPtr&);
    private:
        std::string _name;
        Ice::Identity _id;
        DirectoryIPtr _parent;
        NodeI(const NodeI&); // Copy forbidden
        void operator=(const NodeI&); // Assignment forbidden
    };
}

```

The `NodeI` class has a private data member to store its name (of type `std::string`) and its parent directory (of type `DirectoryIPtr`). The constructor accepts parameters that set the value of these data members. For the root directory, by convention, we pass a null handle to the constructor to indicate that the root directory has no parent. The constructor also requires the communicator to be passed to it. This is necessary because the constructor creates the identity for the servant, which requires access to the communicator. The `activate` member function adds the servant to the ASM (which requires access to the object adapter) and connects the child to its parent.

The `FileI` servant class must store the contents of its file, so it requires a data member for this. We can conveniently use the generated `Lines` type (which is a `std::vector<std::string>`) to hold the file contents, one string for each line. Because `FileI` inherits from `NodeI`, it also requires a constructor that accepts the communicator, file name, and parent directory, leading to the following class definition:

```
C++
```

```

namespace Filesystem {
    class FileI : virtual public File, virtual public NodeI {
    public:
        virtual Lines read(const Ice::Current&);
        virtual void write(const Lines&, const Ice::Current&);
        FileI(const Ice::CommunicatorPtr&, const std::string&,
const DirectoryIPtr&);
    private:
        Lines _lines;
    };
}

```

For directories, each directory must store its list of child nodes. We can conveniently use the generated `NodeSeq` type (which is a `vector<NodePrx>`) to do this. Because `DirectoryI` inherits from `NodeI`, we need to add a constructor to initialize the directory name and its parent directory. As we will see shortly, we also need a private helper function, `addChild`, to make it easier to connect a newly created directory to its parent. This leads to the following class definition:

C++

```
namespace Filesystem {
    class DirectoryI : virtual public Directory, virtual public NodeI {
    public:
        virtual NodeSeq list(const Ice::Current&) const;
        DirectoryI(const Ice::CommunicatorPtr&, const std::string&,
const DirectoryIPtr&);
        void addChild(NodePrx child);
    private:
        NodeSeq _contents;
    };
}
```

Servant Header File Example

Putting all this together, we end up with a servant header file, `FilesystemI.h`, as follows:

C++

```

#include <Ice/Ice.h>
#include <Filesystem.h>

namespace Filesystem {
    class DirectoryI;
    typedef IceUtil::Handle<DirectoryI> DirectoryIPtr;

    class NodeI : virtual public Node {
    public:
        virtual std::string name(const Ice::Current&);
        NodeI(const Ice::CommunicatorPtr&, const std::string&,
const DirectoryIPtr&);
        void activate(const Ice::ObjectAdapterPtr&);
    private:
        std::string _name;
        Ice::Identity _id;
        DirectoryIPtr _parent;
        NodeI(const NodeI&);           // Copy forbidden
        void operator=(const NodeI&); // Assignment forbidden
    };

    typedef IceUtil::Handle<NodeI> NodeIPtr;

    class FileI : virtual public File, virtual public NodeI {
    public:
        virtual Lines read(const Ice::Current&);
        virtual void write(const Lines&,
const Ice::Current& = Ice::Current());
        FileI(const Ice::CommunicatorPtr&, const std::string&,
const DirectoryIPtr&);
    private:
        Lines _lines;
    };

    typedef IceUtil::Handle<FileI> FileIPtr;

    class DirectoryI : virtual public Directory, virtual public NodeI {
    public:
        virtual NodeSeq list(const Ice::Current&);
        DirectoryI(const Ice::CommunicatorPtr&, const std::string&,
const DirectoryIPtr&);
        void addChild(const Filesystem::NodePrx&);
    private:
        Filesystem::NodeSeq _contents;
    };
}

```

The Servant Implementation in C++

The implementation of our servants is mostly trivial, following from the class definitions in our `FilesystemI.h` header file.

Implementing `FileI`

The implementation of the `read` and `write` operations for files is trivial: we simply store the passed file contents in the `_lines` data member. The constructor is equally trivial, simply passing its arguments through to the `NodeI` base class constructor:

```

C++

Filesystem::Lines
Filesystem::FileI::read(const Ice::Current&)
{
    return _lines;
}

void
Filesystem::FileI::write(const Filesystem::Lines& text,
const Ice::Current&)
{
    _lines = text;
}

Filesystem::FileI::FileI(const Ice::CommunicatorPtr& communicator,
                        const string& name,
                        const DirectoryIPtr& parent)
    : NodeI(communicator, name, parent)
{
}

```

Implementing `DirectoryI`

The implementation of `DirectoryI` is equally trivial: the `list` operation simply returns the `_contents` data member and the constructor passes its arguments through to the `NodeI` base class constructor:

C++

```

Filesystem::NodeSeq
Filesystem::DirectoryI::list(const Ice::Current&)
{
    return _contents;
}

Filesystem::DirectoryI::DirectoryI(const
Ice::CommunicatorPtr& communicator,
                                   const string& name,
                                   const DirectoryIPtr& parent)
    : NodeI(name, parent)
{
}

void
Filesystem::DirectoryI::addChild(const NodePrx child)
{
    _contents.push_back(child);
}

```

The only noteworthy thing is the implementation of `addChild`: when a new directory or file is created, the constructor of the `NodeI` base class calls `addChild` on its own parent, passing it the proxy to the newly-created child. The implementation of `addChild` appends the passed reference to the contents list of the directory it is invoked on (which is the parent directory).

Implementing `NodeI`

The name operation of our `NodeI` class is again trivial: it simply returns the `_name` data member:

C++

```

std::string
Filesystem::NodeI::name(const Ice::Current&)
{
    return _name;
}

```

The `NodeI` constructor creates an identity for the servant:

C++

```

Filesystem::NodeI::NodeI(const Ice::CommunicatorPtr& communicator,
                        const string& name,
                        const DirectoryIPtr& parent)
    : _name(name), _parent(parent)
{
    _id.name = parent ? IceUtil::generateUUID() : "RootDir";
}

```

For the root directory, we use the fixed identity "RootDir". This allows the `client` to create a proxy for the root directory. For directories other than the root directory, we use a `UUID` as the identity.

Finally, `NodeI` provides the `activate` member function that adds the servant to the ASM and connects the child node to its parent directory:

C++

```

void
Filesystem::NodeI::activate(const Ice::ObjectAdapterPtr& a)
{
    NodePrx thisNode = NodePrx::uncheckedCast(a->add(this, _id));
    if(_parent)
    {
        _parent->addChild(thisNode);
    }
}

```

This completes our servant implementation. The complete source code is shown here once more:

C++

```

#include <IceUtil/IceUtil.h>
#include <FilesystemI.h>

using namespace std;

// Slice Node::name() operation

std::string
Filesystem::NodeI::name(const Ice::Current&)
{
    return _name;
}

// NodeI constructor

Filesystem::NodeI::NodeI(const Ice::CommunicatorPtr& communicator,
                        const string& name,

```

```

        const DirectoryIPtr& parent)
    : _name(name), _parent(parent)
    {
        // Create an identity. The root directory has the fixed identity "RootDir"
        //
        _id.name = parent ? IceUtil::generateUUID() : "RootDir";
    }

// NodeI activate() member function

void
Filesystem::NodeI::activate(const Ice::ObjectAdapterPtr& a)
{
    NodePrx thisNode = NodePrx::uncheckedCast(a->add(this, _id));
    if(_parent)
    {
        _parent->addChild(thisNode);
    }
}

// Slice File::read() operation

Filesystem::Lines
Filesystem::FileI::read(const Ice::Current&)
{
    return _lines;
}

// Slice File::write() operation

void
Filesystem::FileI::write(const Filesystem::Lines& text, const Ice::Current&)
{
    _lines = text;
}

// FileI constructor

Filesystem::FileI::FileI(const Ice::CommunicatorPtr& communicator,
                        const string& name,
                        const DirectoryIPtr& parent)
    : NodeI(communicator, name, parent)
    {
    }

// Slice Directory::list() operation

Filesystem::NodeSeq

```

```
Filesystem::DirectoryI::list(const Ice::Current& c)
{
    return _contents;
}

// DirectoryI constructor

Filesystem::DirectoryI::DirectoryI(const Ice::CommunicatorPtr& communic
ator,
                                   const string& name,
                                   const DirectoryIPtr& parent)
    : NodeI(communicator, name, parent)
{
}

// addChild is called by the child in order to add
// itself to the _contents member of the parent

void
Filesystem::DirectoryI::addChild(const NodePrx& child)
{
```

```
    _contents.push_back(child);  
}
```

Customizing the C++ Mapping

Ice for C++ allows you to map Slice strings, sequences and dictionaries to your own C++ types, through the `cpp:type` and `cpp:view-type` metadata directives.

When you map a Slice type to a C++ type from the standard library type, Ice is able to [marshal and unmarshal](#) this type without your help. For example, if you map a `sequence<string>` to a `std::list<std::wstring>`, Ice knows exactly what to do. However, if you select a class or template outside the standard C++ library, such as your own C++ template, you usually need to tell Ice how to marshal and unmarshal this type.

The following pages describe the set of classes and templates that Ice uses for marshaling and unmarshaling, and how to plug-in your own C++ types into this framework.

Topics

- [The C++ Stream Helpers](#)
- [The `cpp:type` and `cpp:view-type` Metadata Directives](#)

The C++ Stream Helpers

Ice for C++ uses a set of C++ templates and specializations of these templates to marshal and unmarshal C++ types. A type that can be marshaled and/or unmarshaled using this framework is known as a *Streamable*.

On this page:

- [Marshaling and Unmarshaling C++ Objects](#)
- [StreamableTraits](#)
- [Marshaling and Unmarshaling Optional Values](#)

Marshaling and Unmarshaling C++ Objects

Ice for C++ marshals C++ objects into streams of bytes, and unmarshals these C++ objects from streams of bytes. Ice for C++ has an internal implementation for these streams, and a [publicly available implementation](#), and both implementations have mostly the same API.

To marshal a C++ object into a stream, you (or the generated code) can simply call `write(obj)` on that stream. For basic types, such as `int` or `string`, there is a corresponding [write function](#) on the stream. For other types, `write` is an inline template function that delegates to a specialization of the `StreamHelper` template class:

```

C++

namespace Ice {
class OutputStream : public IceUtil::Shared {
public:
...
    template<typename T> inline void write(const T& v) {
        StreamHelper<T, StreamableTraits<T>::helper>::write(this, v);
    }
};
}
```

Likewise, when unmarshaling a C++ object from a stream, you (or the generated code) can simply call `read(obj)` on that stream, and the reading of most types delegates to a specialization of this `StreamHelper` template class:

```

C++

namespace Ice {
class InputStream : public IceUtil::Shared {
public:
...
    template<typename T> inline void read(T& v) {
        StreamHelper<T, StreamableTraits<T>::helper>::read(this, v);
    }
};
}
```

Ice looks for the `StreamHelper` specializations in namespace `Ice`, so they must all be in namespace `Ice`.

Each `StreamHelper` specialization typically provides a static `write` function to write the C++ object into the stream, and a static `read` function

ion to read the C++ object from the stream. The stream object in these `StreamHelper` static functions is represented by a template parameter type, which allows a `StreamHelper` specialization to work with any stream implementation:

```
C++
```

```

// Typical StreamHelper specialization
namespace Ice {
template<>
struct StreamHelper<SomeType, StreamHelperCategoryXXX> {
    template<class S> static inline void
    write(S* stream, const SomeType& v) {
        ... marshal v...
    }
    template<class S> static inline void
    read(S* stream, SomeType& v) {
        ... unmarshal v ...
    }
};
}

```

The base `StreamHelper` template class is not defined, since there is no default way to read a C++ object from a stream or write this object into a stream:

```
C++
```

```

namespace Ice {
template<typename T, StreamHelperCategory st> struct StreamHelper;
}

```

For most types, Ice for C++ provides or generates the corresponding `StreamHelper` specialization (or partial specialization), for example all Slice sequences mapped to a C++ vector, C++ list or similar type use this specialization:

C++

```

namespace Ice {
template<typename T>
struct StreamHelper<T, StreamHelperCategorySequence> {
    template<class S> static inline void
    write(S* stream, const T& v) {
        stream->writeSize(static_cast<Int>(v.size()));
        for(typename T::const_iterator p = v.begin(); p != v.end(); ++p)
        {
            stream->write(*p);
        }
    }
    template<class S> static inline void
    read(S* stream, T& v) {
        Int sz = stream->readAndCheckSeqSize(StreamableTraits<typename
T::value_type>::minWireSize);
        T(sz).swap(v);
        for(typename T::iterator p = v.begin(); p != v.end(); ++p) {
            stream->read(*p);
        }
    }
};
}

```

StreamableTraits

The `StreamHelper` specializations use specializations of the `StreamableTraits` template class to retrieve some characteristics (or traits) of the C++ type it operates on:

C++

```

namespace Ice {

typedef int StreamHelperCategory;
const StreamHelperCategory StreamHelperCategoryUnknown = 0;
const StreamHelperCategory StreamHelperCategoryBuiltin = 1;
const StreamHelperCategory StreamHelperCategoryStruct = 2;
const StreamHelperCategory StreamHelperCategoryStructClass = 3;
const StreamHelperCategory StreamHelperCategoryEnum = 4;
const StreamHelperCategory StreamHelperCategorySequence = 5;
const StreamHelperCategory StreamHelperCategoryDictionary = 6;
const StreamHelperCategory StreamHelperCategoryProxy = 7;
const StreamHelperCategory StreamHelperCategoryClass = 8;
const StreamHelperCategory StreamHelperCategoryUserException = 9;

template<typename T, typename Enabler = void>
struct StreamableTraits {
    static const StreamHelperCategory helper = ...;
    static const int minWireSize = 1;
    static const bool fixedLength = false;
};
}

```

In particular, `StreamHelper` specializations are divided in various categories, to allow a single partial specialization of `StreamHelper` to handle several similar C++ types. For example, Ice for C++ provides a single `StreamHelper` partial specialization for all enum types, with category `StreamHelperCategoryEnum`:

C++

```

template<typename T>
struct StreamHelper<T, StreamHelperCategoryEnum> {
    template<class S> static inline void
    write(S* stream, const T& v) {
        ...sanity check...
        stream->writeEnum(static_cast<Int>(v),
StreamableTraits<T>::maxValue);
    }
    template<class S> static inline void
    read(S* stream, T& v) {
        Int value = stream->readEnum(StreamableTraits<T>::maxValue);
        ..sanity check...
        v = static_cast<T>(value);
    }
};

```

`StreamHelperCategory` is an integer (`int`). Values between 0 and 20 are reserved for Ice; you can use other values for your own `StreamHelper` specializations.

A `StreamableTraits` is always defined in namespace `Ice` and provides three `static const` data members:

- `helper`
The category of `StreamHelper` associated with this C++ type (see above). The base `StreamableTraits` template class computes `helper` automatically for maps, lists, vectors and similar types.
- `minWireSize`
The minimum size (in bytes) of the corresponding `Slice` type when marshaled using the [Ice Encoding](#). The base `StreamableTraits` template class provides the default value, 1 byte. This value should be one for sequences and dictionaries, since an empty sequence or dictionary is marshaled as a single byte (`size = 0`).
- `fixedLength`
`true` when the corresponding `Slice` type is marshaled on a fixed number of bytes, and `false` when it is marshaled on a variable number of bytes. The default, provided by the base `StreamableTraits` template class, is `false`.

Ice provides `StreamableTraits` specializations for all the C++ types it uses when mapping `Slice` types to C++. For example, Ice provides a `StreamTraits<Ice::Long>` (for 64-bit signed integers) and a `StreamableTraits<::std::string>`:

C++

```

namespace Ice {
template<>
struct StreamableTraits<Long> {
    static const StreamHelperCategory helper =
StreamHelperCategoryBuiltin;
    static const int minWireSize = 8;
    static const bool fixedLength = true;
};

template<>
struct StreamableTraits<::std::string> {
    static const StreamHelperCategory helper =
StreamHelperCategoryBuiltin;
    static const int minWireSize = 1;
    static const bool fixedLength = false;
};
}

```

For each constructed type, such as `Slice` structs, the `Slice` to C++ translator generates the corresponding `StreamableTraits` specialization. For example:

C++

```
// Generated C++ code
namespace Ice {
template<>
struct StreamableTraits< ::Ice::Identity> {
    static const StreamHelperCategory helper =
StreamHelperCategoryStruct;
    static const int minWireSize = 2;
    static const bool fixedLength = false;
};
```

Marshaling and Unmarshaling Optional Values

As described in [Data Encoding for Optional Values](#), the encoding or wire representation of an optional data member or parameter consists of:

- An optional format (a 3-bits value) that depends on the associated Slice type. For example, the optional format for a `sequence<string>` is `FSize (or 6)`.
- The tag associated with this optional data member or parameter (this tag is a positive integer)
- The actual value of this optional data member or parameter

To marshal an optional value into a stream, you (or the generated code) call `write(tag, obj)` on that stream, where `tag` is the optional's tag (an int), and `obj` is the optional value. `write` is a template function that uses a specialization of the `StreamOptionalHelper` template class when this optional value is set:

C++

```
namespace Ice {
class OutputStream : public IceUtil::Shared {
public:
...
    template<typename T> inline void write(Int tag, const
IceUtil::Optional<T>& v) {
        if(v) {
            writeOptional(tag, StreamOptionalHelper<T,
StreamableTraits<T>::helper,
StreamableTraits<T>::fixedLength>::optionalFormat);
            StreamOptionalHelper<T, StreamableTraits<T>::helper,
StreamableTraits<T>::fixedLength>::write(this, *v);
        }
    }
};
}
```

Likewise, when unmarshaling an optional value from a stream, you (or the generated code) call `read(tag, obj)` on that stream, which

delegates to a specialization of the same `StreamOptionalHelper` template class when the stream holds a value for this optional data member or parameter:

C++

```
namespace Ice {
class InputStream : public IceUtil::Shared {
public:
...
    template<typename T> inline void read(Int tag, IceUtil::Optional<T>&
v) {
        if(readOptional(tag, StreamOptionalHelper<T,
StreamableTraits<T>::helper,
StreamableTraits<T>::fixedLength>::optionalFormat)) {
            v.__setIsSet();
            StreamOptionalHelper<T, StreamableTraits<T>::helper,
StreamableTraits<T>::fixedLength>::read(this, *v);
        }
        else {
            v = IceUtil::None;
        }
    }
};
}
```

Each `StreamOptionalHelper` specialization usually provides static `read` and `write` functions, just like `StreamHelper` specializations, and also an `optionalFormat` static data member that provides the optional format of the corresponding `Slice` type.

For many types, the `StreamOptionalHelper` specialization simply delegates to this type's `StreamHelper` specialization, and computes `optionalFormat` with the `GetOptionalFormat` template:

C++

```

// GetOptionalFormat is declared but never defined
template<StreamHelperCategory st, int minWireSize, bool fixedLength>
struct GetOptionalFormat;

// Base StreamOptionalHelper template class
namespace Ice {
template<typename T, StreamHelperCategory st, bool fixedLength>
struct StreamOptionalHelper {
    typedef StreamableTraits<T> Traits;

    static const OptionalFormat optionalFormat = GetOptionalFormat<st,
Traits::minWireSize, fixedLength>::value;

    template<class S> static inline void
write(S* stream, const T& v) {
    stream->write(v);
}
    template<class S> static inline void
read(S* stream, T& v) {
    stream->read(v);
}
};
}

```

For example, the optional format for an `Ice::Long` (64-bit signed integer, encoded on exactly 8 bytes) is provided by this specialization of `GetOptionalFormat`:

C++

```

namespace Ice {
template<>
struct GetOptionalFormat<StreamHelperCategoryBuiltin, 8, true> {
    static const OptionalFormat value = OptionalFormatF8;
};
}

```

The `cpp:type` and `cpp:view-type` Metadata Directives

Ice for C++ provides two [metadata directives](#) that allow you to map Slice types to arbitrary C++ types: `cpp:type` and `cpp:view-type`. These metadata directives currently apply only to the following Slice types:

- `string`
- `sequence`
- `dictionary`

On this page:

- [Customizing the sequence mapping with `cpp:type`](#)
- [Customizing the dictionary mapping with `cpp:type`](#)
- [`cpp:type` with custom C++ types](#)
- [`cpp:type:string` and `cpp:type:wstring`](#)
- [Avoiding copies with `cpp:view-type`](#)
- [Using both `cpp:type` and `cpp:view-type`](#)

Customizing the sequence mapping with `cpp:type`

The `cpp:type:c++-type` metadata directive allows you to map a given Slice type, data member or parameter to the C++ type of your choice.

For example, you can override the default mapping of a Slice sequence type:

Slice
<pre>[["cpp:include:list"]] module Food { enum Fruit { Apple, Pear, Orange }; ["cpp:type:std::list< ::Food::Fruit>"] sequence<Fruit> FruitPlatter; };</pre>

With this metadata directive, the Slice sequence now maps to a C++ `std::list` instead of the default `std::vector`:

C++
<pre>#include <list> namespace Food { typedef std::list< Food::Fruit> FruitPlatter; // ... }</pre>

The Slice to C++ compiler takes the string following the `cpp:type:` prefix as the name of the mapped C++ type. For example, we could use `["cpp:type::std::list< ::Food::Fruit>"]`. In that case, the compiler would use a fully-qualified name to define the type:

C++

```
typedef ::std::list< ::Food::Fruit> FruitPlatter;
```

Note that the code generator inserts whatever string you specify following the `cpp:type:` prefix literally into the generated code. We recommend you use fully qualified names to avoid C++ compilation failures due to unknown symbols.

Also note that, to avoid compilation errors in the generated code, you must instruct the compiler to generate an appropriate include directive with the `cpp:include` global metadata directive. This causes the compiler to add the line

C++

```
#include <list>
```

to the generated header file.

In addition to modifying the type of a sequence itself, you can also modify the mapping for particular [return values](#) or [parameters](#). For example:

Slice

```
[["cpp:include:list"]]
[["cpp:include:deque"]]

module Food {
    enum Fruit { Apple, Pear, Orange };

    sequence<Fruit> FruitPlatter;

    interface Market {
        ["cpp:type:list< ::Food::Fruit>"]
        FruitPlatter
        barter(["cpp:type:deque< ::Food::Fruit>"] FruitPlatter offer);
    };
};
```

With this definition, the default mapping of `FruitPlatter` to a C++ vector still applies but the return value of `barter` is mapped as a `list`, and the `offer` parameter is mapped as a `deque`.

Instead of `std::list` or `std::deque`, you can specify a type of your own as the sequence type, for example:

Slice

```
[[ "cpp:include:FruitBowl.h" ]]

module Food {
    enum Fruit { Apple, Pear, Orange };

    [ "cpp:type:FruitBowl" ]
    sequence<Fruit> FruitPlatter;
};
```

With these metadata directives, the compiler will use a C++ type `FruitBowl` as the sequence type, and add an `include` directive for the header file `FruitBowl.h` to the generated code.

The class or template class you provide must meet the following requirements:

- The class must have a default constructor.
- The class must have a copy constructor.

If you use a class that also meets the following requirements

- The class has a single-argument constructor that takes the size of the sequence as an argument of unsigned integral type.
- The class has a member function `size` that returns the number of elements in the sequence as an unsigned integral type.
- The class provides a member function `swap` that swaps the contents of the sequence with another sequence of the same type.
- The class defines `iterator` and `const_iterator` types and provides `begin` and `end` member functions with the usual semantics; its iterators are comparable for equality and inequality.

then you do not need to provide code to marshal and unmarshal your custom sequence – Ice will do it automatically.

Less formally, this means that if the provided class looks like a `vector`, `list`, or `deque` with respect to these points, you can use it as a custom sequence implementation without any additional coding.

Customizing the dictionary mapping with `cpp:type`

You can override the default mapping of Slice dictionaries to C++ maps with a `cpp:type` metadata directive, for example:

Slice

```
[[ "cpp:include:unordered_map" ]]

[ "cpp:type:std::unordered_map<Ice::Long, Employee>" ] dictionary<long,
Employee> EmployeeMap;
```

With this metadata directive, the dictionary now maps to a C++ `std::unordered_map`:

C++

```
#include <unordered_map>

typedef std::unordered_map<Ice::Long, Employee> EmployeeMap;
```

Like with sequences, anything following the `cpp:type:` prefix is taken to be the name of the type. For example, we could use `["cpp:type::std::unordered_map<int, std::string>"]`. In that case, the compiler would use a fully-qualified name to define the type:

C++

```
typedef ::std::unordered_map<int, std::string> IntStringDict;
```

To avoid compilation errors in the generated code, you must instruct the compiler to generate an appropriate include directive with the `cpp:include` global metadata directive. This causes the compiler to add the line

C++

```
#include <unordered_map>
```

to the generated header file.

Instead of `std::unordered_map`, you can specify a type of your own as the dictionary type, for example:

Slice

```
[ [ "cpp:include:CustomMap.h" ] ]

[ "cpp:type:MyCustomMap<Ice::Long, Employee>" ] dictionary<long, Employee>
EmployeeMap;
```

With these metadata directives, the compiler will use a C++ type `MyCustomMap` as the dictionary type, and add an include directive for the header file `CustomMap.h` to the generated code.

The class or template class you provide must meet the following requirements:

- The class must have a default constructor.
- The class must have a copy constructor.
- The class must provide nested types named `key_type`, `mapped_type` and `value_type`.
- The class must provide `iterator` and `const_iterator` types and provide `begin` and `end` member functions with the usual semantics; these iterators must be comparable for equality and inequality.
- The class must provide a `clear` function.
- The class must provide an `insert` function that takes an `iterator` (as location hint) plus a `value_type` parameter, and returns an `iterator` to the new entry or to the existing entry with the given key.

Less formally, this means you can use any class or template class that looks like a standard `map` or `unordered_map` as your custom dictionary type.

In addition to modifying the type of a dictionary itself, you can also modify the mapping for particular [return values](#) or [parameters](#). For example:

Slice

```

[["cpp:include:unordered_map"]]

module HR {

    struct Employee {
        long    number;
        string  firstName;
        string  lastName;
    };
    dictionary<long, Employee> EmployeeMap;

    interface Office {
        ["cpp:type:std::unordered_map<Ice::Long, Employee>"] EmployeeMap
        getAllEmployees();
    };
};

```

With this definition, `getAllEmployees` returns an `unordered_map`, while other unqualified parameters of type `EmployeeMap` would use the default mapping (to a `std::map`).

cpp:type with custom C++ types

If your C++ type does not look like a standard C++ container, you need to tell Ice how to marshal and unmarshal this type by providing your own `StreamHelper` specialization for this type.

For example, you can map a Slice `sequence<byte>` to a [Google Protocol Buffer](#) C++ class, `tutorial::Person`, with the following metadata directive:

Slice

```

module Demo {
    ["cpp:type:tutorial::Person"] sequence<byte> Person;
};

```

Since `tutorial::Person` does not look like a `vector<Ice::Byte>` or a `list<Ice::Byte>`, you need a `StreamHelper` specialization for `tutorial::Person`.

The simplest is to create a `StreamHelper` specialization that handles only this specific class:

C++

```

namespace Ice {

template<>
struct StreamHelper<tutorial::Person, StreamHelperCategoryUnknown> {
    template<class S> static inline void
    write(S* stream, const tutorial::Person& v) {
        // ... marshal v into a sequence of bytes...
    }

    template<class S> static inline void
    read(S* stream, tutorial::Person& v) {
        //... unmarshal bytes from stream into v...
    }
};
}

```

You should also provide the corresponding `StreamTraits` specialization:

C++

```

namespace Ice {
template<>
struct StreamableTraits<tutorial::Person> {
    static const StreamHelperCategory helper =
StreamHelperCategoryUnknown;
    static const int minWireSize = 1;
    static const bool fixedLength = false;
};
}

```

This `StreamTraits` specialization is actually optional for `tutorial::Person`, and more generally for any mapping of `sequence<byte>`, since these are the values provided by the base `StreamableTraits` template.

Finally, remember to insert the header for these `StreamHelper` and `StreamTraits` specializations with a `cpp:include` global metadata directive:

Slice

```

[["cpp:include:Person.pb.h"]]
[["cpp:include:PersonStreaming.h"]]
module Demo {
["cpp:type:tutorial::Person"] sequence<byte> Person;

```

Now, if your application maps several `Slice sequence<byte>` to different Google Protocol Buffers, you could provide a `StreamHelper` specialization for each of these Google Protocol Buffer classes, but it would be more judicious to provide a single partial specialization capable of marshaling and unmarshaling any Google Protocol Buffer C++ class as a `Slice sequence<byte>` in a stream:

C++

```

namespace Ice {

// A new helper category for all Google Protocol Buffers
const StreamHelperCategory StreamHelperCategoryProtobuf = 100;

// All classes derived from ::google::protobuf::MessageLite will use
// this StreamableTraits
template<typename T>
struct StreamableTraits<T, typename std::enable_if<std::is_base_of<
::google::protobuf::MessageLite, T>::value >::type> {
    static const StreamHelperCategory helper =
StreamHelperCategoryProtobuf;
    static const int minWireSize = 1;
    static const bool fixedLength = false;
};
// T can be any Google Protocol Buffer C++ class
template<typename T>
struct StreamHelper<T, StreamHelperCategoryProtobuf> {
    template<class S> static inline void
write(S* stream, const T& v) {
    std::vector<Byte> data(v.ByteSize());
    // ... marshal v into a sequence of bytes...
    stream->write(&data[0], &data[0] + data.size());
}

    template<class S> static inline void
read(S* stream, T& v) {
    std::pair<const Byte*, const Byte*> data;
    stream->read(data);
    //... unmarshal data into v...
}
};
}

```

If you use any of these `sequence<byte>` mapped to Google Protocol Buffers for optional data members or optional parameters, you also need to tell Ice which optional format to use:

C++

```
namespace Ice {

// Optional format for Slice sequence<byte> mapped to Google Protocol
// Buffer
// The template parameters correspond to the data members of the
// corresponding StreamTraits specialization.
template<>
struct GetOptionalFormat<StreamHelperCategoryProtobuf, 1, false> {
    static const OptionalFormat value = OptionalFormatVSize;
};
}
```

The `OptionalFormat` provided by `GetOptionalFormat` for `StreamHelperCategoryUnknown` and its default `StreamableTraits` is `OptionalFormatVSize`, like in the example above. This way, if your application needs a single `sequence<byte>` mapped to a custom C++ type, you can provide just a `StreamHelper` specialization for this type and rely on the default `StreamTraits` and `GetOptionalFormat` templates.

cpp:type:string and cpp:type:wstring

The metadata directives `cpp:type:string` and `cpp:type:wstring` are used map Slice strings to `std::string` or `std::wstring`, as described in [Alternative String Mapping for C++](#). The Slice to C++ compiler recognize `string` and `wstring` as special tokens and does not treat them like C++ types with these names.

For example, you can map a `sequence<string>` to a `std::vector<std::wstring>` with either of the following directives:

Slice

```
// Special cpp:type:wstring metadata directive: it maps the sequence to
// a std::vector<std::wstring>, not to a wstring!
["cpp:type:wstring"] sequence<string>;
```

or

Slice

```
// Maps the sequence to a std::vector<std::wstring> using a regular
// cpp:type metadata directive
["cpp:type:std::vector<std::wstring>"] sequence<string>;
```

Avoiding copies with cpp:view-type

The main drawback of using standard C++ library classes to represent strings, sequences and dictionaries (as Ice does by default) is copying. For example, if we transfer an array of characters with Ice:

Slice

```
void sendChars(string s);
```

with the default mapping, our C++ code would look like:

C++

```
// client side
const char* cstring = ... null terminated array of chars;
proxy->sendChars(string(cstring));

// server side
void sendChars(const string& s, ...) {
    // use s;
}
```

Each invocation triggers a number of copies:

- (client) the creation of the string on the client side makes a copy of the array of characters
- (client) `sendChars` copies the characters of the string into the client-side marshaling buffer
- (server) the unmarshaling code creates a string from the bytes in the server-side marshaling buffer

If instead of `std::string`, Ice could use a string-type with view semantics—its instances point to memory owned by some other objects—we could avoid these copies. This is exactly what the `cpp:view-type` metadata directive allows us to do: select a custom mapping for Slice strings, sequences and dictionaries.

For example, we can map our Slice string parameter in the example above to a `std::experimental::string_view`, that has such view semantics:

Slice

```
void sendChars(["cpp:view-type:std::experimental::string_view"] string s);
```

Our C++ code pretty much the same, but we avoid several copies:

C++

```
// client side
const char* cstring = ... null terminated array of chars;
proxy->sendChars(string_view(cstring)); // string_view points to the
characters cstring, without copy

// server side
void sendChars(const string_view& s, ...) { // string_view points to
bytes in the server-side unmarshaling buffer
    // use s;
}
```

With this metadata directive, the only remaining copy during each invocation is:

- (client) `sendChars` copies the characters into the client-side marshaling buffer

This `cpp:view-type` metadata is very much like the `cpp:type` metadata directive [described earlier](#), and just like for `cpp:type`, the Slice to C++ compiler uses the string provided after the `cpp:view-type:` prefix literally in the generated code. The compiler does not (and cannot) check that this string represents a valid C++ type, or a C++ type with view semantics.

There are however two significant differences between `cpp:view-type` and `cpp:type`:

- `cpp:view-type` can be applied only to operation parameters, while `cpp:type` can be applied to the definition of sequence and dictionary types, to operation parameters and to data members
- `cpp:view-type` changes the mapping of a parameter to the specified C++ type only when it is safe to use a view object (an object that does not own memory), while `cpp:type` changes the mapping all the time.

For example, if instead of sending an array of characters from a client to a server, we return an array of character from the server to the client, without using [AMI](#) or [AMD](#) (the default):

Slice
<pre>string getChars();</pre>

With the default mapping, we get a `std::string` back, and each invocation makes a few copies:

C++
<pre>// client-side string s = prx->getChars(); // server side string getChars(...) { const char* cstring = ... null terminated array of chars; return cstring; // the conversion to string makes a copy }</pre>

Now, if we map the returned string to a `string_view` with the `cpp:type` metadata directive:

Slice
<pre>["cpp:type:std::experimental::string_view"] string getChars(); // Don't do this</pre>

we avoid some copies but our `string_view` now points to deallocated memory and our program will crash!

C++

```
// client-side
string_view s = prx->getChars(); // string_view points to the
client-side marshaling buffer, which is deallocated as soon as
getChars() returns

// server side
string_view getChars(...) {
    const char* cstring = ... null terminated array of chars;
    return cstring; // string_view points to (or may point to)
stack-allocated memory, reclaimed when getChars() returns
}
```

Never use the `cpp:type` metadata directive with a view type (a type that does not manage its memory); you should only use `cpp:view-type` with view types.

With `cpp:view-type`, the compiler changes the mapping only when it's safe to use a view-type, namely for:

- Input parameters, on the client-side and on the server-side
- Out and return parameters provided by the Ice run-time to [AMI type-safe callbacks](#) and [AMI lambdas](#)
- Out and return parameters provided to [AMD](#) callbacks

The `cpp:array` and `cpp:range` metadata directives for sequences follow the same rules.

With our `getChars` example:

Slice

```
[ "cpp:view-type:std::experimental::string_view" ] string getChars();
```

it is not safe the change the client-side mapping or the server-side mapping (unless we use [AMD](#)), so the returned C++ type remains a `std::string`.

Like with the `cpp:type` metadata directive, if the C++ type specified with `cpp:view-type` is a standard library type (such as `std::list`) or looks like one, Ice will automatically marshal and unmarshal it for you. You just need to include the corresponding header with the `cpp:include global metadata` directive:

Slice

```
[ [ "cpp:include:MyContainer.h" ] ]
module Sample {
    ...
};
```

For other C++ types, you need to tell Ice how to marshal and unmarshal these types, as described above in [cpp:type with custom C++ types](#).

In particular, Ice does not know how to marshal and unmarshal the experimental `string_view` type. If you want to map some string parameters to `string_view`, you need to provide a `StreamHelper` for `string_view`, such as:

C++

```

namespace Ice {

template<>
struct StreamableTraits<std::experimental::string_view> {
    static const StreamHelperCategory helper =
StreamHelperCategoryBuiltin;
    static const int minWireSize = 1;
    static const bool fixedLength = false;
};

template<>
struct StreamHelper<std::experimental::string_view,
StreamHelperCategoryBuiltin> {
    template<class S> static inline void
    write(S* stream, const std::experimental::string_view& v) {
#ifdef STRING_VIEW_IGNORE_STRING_CONVERTER
        stream->write(v.data(), v.size(), false);
#else
        stream->write(v.data(), v.size(), true);
#endif
    }
    template<class S> static inline void
    read(S* stream, std::experimental::string_view& v) {
        const char* vdata = 0;
        size_t vsize = 0;
#ifdef STRING_VIEW_IGNORE_STRING_CONVERTER
        stream->read(vdata, vsize);
#else
        std::string holder;
        stream->read(vdata, vsize, holder);

        // If holder is not empty, a string conversion occurred, and we
        can't return a
        // string_view since it does not hold the memory
        if(!holder.empty()) {
            throw Ice::MarshalException(__FILE__, __LINE__, "string
conversion not supported");
        }
#endif
        if(vsize > 0) {
            v = std::experimental::string_view(vdata, vsize);
        }
        else {
            v.clear();
        }
    }
};
}

```

This `StreamHelper` specialization will take care of plain `string` parameters, and also sequence or dictionary parameters that contain strings mapped to `string_view` (when it's safe to do so), such as:

Slice

```
[ "amd", "cpp:view-type:std::vector<std::experimental::string_view>" ]
StringSeq
  echoStringSeq( [ "cpp:view-type:std::vector<std::experimental::string_view>" ] StringSeq seq);
```

The `Ice/throughput` demo illustrates the use of `cpp:view-type` with sequences of strings.

Using both `cpp:type` and `cpp:view-type`

If you specify both `cpp:type` and `cpp:view-type` for the same parameter, `cpp:view-type` applies to mapped parameters safe for view types, and `cpp:type` applies to all other mapped parameters.

With the following somewhat contrived example:

Slice

```
[ "amd", "cpp:view-type:std::vector<std::experimental::string_view>",
  "cpp:type:std::list<std::wstring>" ] StringSeq getStringSeq();
```

calling `getStringSeq()` on a proxy returns a `std::list<std::wstring>`, while the `StringSeq` is passed to the [AMD callback](#) as a `std::vector<string_view>`.

Version Information in C++

The header file `IceUtil/Config.h` defines two macros that expand to the version of the Ice run time:

```

C++

#define ICE_STRING_VERSION "3.6.2" // "<major>.<minor>.<patch>"  
#define ICE_INT_VERSION 30602     // AABCC, with AA=major,  
                                 // BB=minor, CC=patch
```

`ICE_STRING_VERSION` is a string literal in the form `<major>.<minor>.<patch>`, for example, `3.6.2`. For beta releases, the version is `<major>.<minor>b`, for example, `3.6b`.

`INT_VERSION` is an integer literal in the form `AABCC`, where `AA` is the major version number, `BB` is the minor version number, and `CC` is the patch level, for example, `30602` for version `3.6.2`. For beta releases, the patch level is set to `51` so, for example, for version `3.6b`, the value is `30651`.

slice2cpp Command-Line Options

On this page:

- [slice2cpp Command-Line Options](#)
 - `--header-ext EXT`
 - `--source-ext EXT`

 - `--include-dir DIR`
 - `--impl`
 - `--dll-export MACRO`
 - `--checksum`
 - `--stream`
- [Include Directives](#)
 - [Header Files](#)
 - [Source Files](#)

slice2cpp Command-Line Options

The Slice-to-C++ compiler, `slice2cpp`, offers the following command-line options in addition to the [standard options](#).

`--header-ext EXT`

Changes the file extension for the generated header files from the default `h` to the extension specified by `EXT`.

You can also change the header file extension with a global metadata directive:

Slice
<pre>[["cpp:header-ext:hpp"]]</pre> <pre>// ...</pre>

Only one such directive can appear in each source file. If you specify a header extension on both the command line and with a metadata directive, the metadata directive takes precedence. This ensures that included Slice files that were compiled separately get the correct header extension (provided that the included Slice files contain a corresponding metadata directive). For example:

Slice
<pre>// File example.ice</pre> <pre>#include <Ice/BuiltinSequences.ice></pre> <pre>// ...</pre>

Compiling this file with

<pre>\$ slice2cpp --header-ext=hpp -I/opt/Ice/include example.ice</pre>

generates `example.hpp`, but the `#include` directive in that file is for `Ice/BuiltinSequences.h` (not `Ice/BuiltinSequences.hpp`) because `BuiltinSequences.ice` contains the metadata directive `[["cpp:header-ext:h"]]`.

You normally will not need to use this metadata directive. The directive is necessary only if:

- You `#include` a Slice file in one of your own Slice files.

- The included Slice file is part of a library you link against.
- The library ships with the included Slice file's header.
- The library header uses a different header extension than your own code.

For example, if the library uses `.hpp` as the header extension, but your own code uses `.h`, the library's Slice file should contain a `[["cpp:header?ext:hpp"]]` directive. (If the directive is missing, you can add it to the library's Slice file.)

`--source-ext EXT`

Changes the file extension for the generated source files from the default `cpp` to the extension specified by `EXT`.

`--add-header HDR[,GUARD]`

This option adds an include directive for the specified header at the beginning of the generated source file (preceding any other include directives). If `GUARD` is specified, the include directive is protected by the specified guard. For example, `--add-header precompiled.h, __PRECOMPILED_H__` results in the following directives at the beginning of the generated source file:

```

C++

#include <precompiled.h>

```

The option can be repeated to create include directives for several files.

As suggested by the preceding example, this option is useful mainly to integrate the generated code with a compiler's precompiled header mechanism.

`--include-dir DIR`

Modifies `#include` directives in source files to prepend the path name of each header file with the directory `DIR`.

`--impl`

Generate sample implementation files. This option will not overwrite an existing file.

`--dll-export MACRO`

Use `MACRO` to control the export and import of symbols from DLLs on Windows and dynamic shared libraries on other platforms. This option allows you to export symbols from the generated code, and place such generated code in a DLL (on Windows) or shared library (on other platforms). As an example, compiling a Slice definition with:

```

$ slice2cpp --dll-export WIDGET_API x.ice

```

results in the following additional code being generated into `x.h`:

C++

```

#ifndef WIDGET_API
#   ifdef WIDGET_API_EXPORTS
#       define WIDGET_API ICE_DECLSPEC_EXPORT
#   else
#       define WIDGET_API ICE_DECLSPEC_IMPORT
#   endif
#endif

```

The generated code also includes the provided `MACRO` name (`WIDGET_API` in our example) in the declaration of classes and functions that need to be exported (when building a DLL or dynamic library) or imported (when using such library).

`ICE_DECLSPEC_EXPORT` and `ICE_DECLSPEC_IMPORT` are macros that expand to compiler-specific attributes. For example, for Visual Studio, they are defined as:

C++

```

#if defined(_WIN32) && !defined(ICE_STATIC_LIBS)
#   define ICE_DECLSPEC_EXPORT __declspec(dllexport)
#   define ICE_DECLSPEC_IMPORT __declspec(dllimport)
...

```

With GCC and clang, they are defined as:

C++

```

#elif defined(__GNUC__)
#   define ICE_DECLSPEC_EXPORT __attribute__((visibility ("default")))
#   define ICE_DECLSPEC_IMPORT __attribute__((visibility ("default")))
...

```

The net effect is that, if you are using Visual Studio to create a DLL that includes `x.cpp`, and you want to be able to use `x.cpp`'s definitions from code outside this DLL, you need to export `x.cpp`'s symbols by compiling `x.cpp` with `-DWIDGET_API_EXPORTS`. If you use GCC or clang, you can likewise compile `x.cpp` with `-DWIDGET_API_EXPORTS`; this is however optional since GCC and clang's definitions for `ICE_DECLSPEC_IMPORT` and `ICE_DECLSPEC_EXPORT` are identical.

Similar definitions exist for other platforms. For platforms that do not have any concept of explicit export or import of shared library symbols, both macros are empty.

--checksum

Generate [checksums](#) for Slice definitions.

--stream

Generate [streaming helper functions](#) for Slice classes and exceptions. For other Slice types, streaming support is always generated.

Include Directives

The `#include` directives generated by the Slice-to-C++ compiler can be a source of confusion if the semantics governing their generation are not well-understood. The generation of `#include` directives is influenced by the command-line options `-I` and `--include-dir`; these options are discussed in more detail below. The `--output-dir` option directs the translator to place all generated files in a particular directory, but has no impact on the contents of the generated code.

Given that the `#include` directives in header files and source files are generated using different semantics, we describe them in separate sections.

Header Files

In most cases, the compiler generates the appropriate `#include` directives by default. As an example, suppose file `A.ice` includes `B.ice` using the following statement:

```

Slice

// A.ice
#include <B.ice>
```

Assuming both files are in the current working directory, we run the compiler as shown below:

```
$ slice2cpp -I. A.ice
```

The generated file `A.h` contains this `#include` directive:

```

C++

// A.h
#include <B.h>
```

If the proper include paths are specified to the C++ compiler, everything should compile correctly.

Similarly, consider the common case where `A.ice` includes `B.ice` from a subdirectory:

```

Slice

// A.ice
#include <inc/B.ice>
```

Assuming both files are in the `inc` subdirectory, we run the compiler as shown below:

```
$ slice2cpp -I. inc/A.ice
```

The default output of the compiler produces this `#include` directive in `A.h`:

C++

```
// A.h
#include <inc/B.h>
```

Again, it is the user's responsibility to ensure that the C++ compiler is configured to find `inc/B.h` during compilation.

Now let us consider a more complex example, in which we do not want the `#include` directive in the header file to match that of the Slice file. This can be necessary when the organizational structure of the Slice files does not match the application's C++ code. In such a case, the user may need to relocate the generated files from the directory in which they were created, and the `#include` directives must be aligned with the new structure.

For example, let us assume that `B.ice` is located in the subdirectory `slice/inc`:

Slice

```
// A.ice
#include <slice/inc/B.ice>
```

However, we do not want the `slice` subdirectory to appear in the `#include` directive generated in the header file, therefore we specify the additional compiler option `-Islice`:

```
$ slice2cpp -I. -Islice slice/inc/A.ice
```

The generated code demonstrates the impact of this extra option:

C++

```
// A.h
#include <inc/B.h>
```

As you can see, the `#include` directives generated in header files are affected by the include paths that you specify when running the compiler. Specifically, the include paths are used to abbreviate the path name in generated `#include` directives.

When translating an `#include` directive from a Slice file to a header file, the compiler compares each of the include paths against the path of the included file. If an include path matches the leading portion of the included file, the compiler removes that leading portion when generating the `#include` directive in the header file. If more than one include path matches, the compiler selects the one that results in the shortest path for the included file.

For example, suppose we had used the following options when compiling `A.ice`:

```
$ slice2cpp -I. -Islice -Islice/inc slice/inc/A.ice
```

In this case, the compiler compares all of the include paths against the included file `slice/inc/B.ice` and generates the following directive:

C++

```
// A.h
#include <B.h>
```

The option `-Islice/inc` produces the shortest result, therefore the default path for the included file (`slice/inc/B.h`) is replaced with `B.h`.

In general, the `-I` option plays two roles: it enables the preprocessor to locate included Slice files, and it provides you with a certain amount of control over the generated `#include` directives. In the last example above, the preprocessor locates `slice/inc/B.ice` using the include path specified by the `-I.` option. The remaining `-I` options do not help the preprocessor locate included files; they are simply hints to the compiler.

Finally, we recommend using caution when specifying include paths. If the preprocessor is able to locate an included file via multiple include paths, it always uses the first include path that successfully locates the file. If you intend to modify the generated `#include` directives by specifying extra `-I` options, you must ensure that your include path hints match the include path selected by the preprocessor to locate the included file. As a general rule, you should avoid specifying include paths that enable the preprocessor to locate a file in multiple ways.

Source Files

By default, the compiler generates `#include` directives in source files using only the base name of the included file. This behavior is usually appropriate when the source file and header file reside in the same directory.

For example, suppose `A.ice` includes `B.ice` from a subdirectory, as shown in the following snippet of `A.ice`:

Slice

```
// A.ice
#include <inc/B.ice>
```

We generate the source file using this command:

```
$ slice2cpp -I. inc/A.ice
```

Upon examination, we see that the source file contains the following `#include` directive:

C++

```
// A.cpp
#include <B.h>
```

However, suppose that we wish to enforce a particular standard for generated `#include` directives so that they are compatible with our C++ compiler's existing include path settings. In this case, we use the `--include-dir` option to modify the generated code. For example, consider the compiler command shown below:

```
$ slice2cpp --include-dir src -I. inc/A.ice
```

The source file now contains the following `#include` directive:

C++

```
// A.cpp  
#include <src/B.h>
```

Any leading path in the included file is discarded as usual, and the value of the `--include-dir` option is prepended.

C++ Strings and Character Encoding

On the wire, Ice [transmits](#) all strings as Unicode strings in UTF-8 encoding. For languages other than C++, Ice uses strings in their language-native Unicode representation and converts automatically to and from UTF-8 for transmission, so applications can transparently use characters from non-English alphabets.

However, for C++, how strings are represented inside a process depends on the platform as well as the mapping that is chosen for a particular string: the default mapping to `std::string`, or the [alternative mapping](#) to `std::wstring`.

This discussion is only relevant for C++. For scripting language mappings based on Ice for C++, it is possible to use [Ice's default string converter plug-in](#) and to [install your own string converter plug-in](#).

We will explore how strings are encoded by the Ice for C++ run time, and how you can achieve automatic conversion of strings in their native representation to and from UTF-8. For an example of using string converters in C++, refer to the sample program provided in the `demo/Ice/converter` subdirectory of your Ice distribution.

By default, the Ice run time encodes strings as follows:

- Narrow strings (that is, strings mapped to `std::string`) are presented to the application in UTF-8 encoding and, similarly, the application is expected to provide narrow strings in UTF-8 encoding to the Ice run time for transmission.

With this default behavior, the application code is responsible for converting between the native codeset for 8-bit characters and UTF-8. For example, if the native codeset is ISO Latin-1, the application is responsible for converting between UTF-8 and narrow (8-bit) characters in ISO Latin-1 encoding.

Also note that the default behavior does not require the application to do anything if it only uses characters in the ASCII range. (This is because a string containing only characters in the (7-bit) ASCII range is also a valid UTF-8 string.)

- Wide strings (that is, strings mapped to `std::wstring`) are automatically encoded as Unicode by the Ice run time as appropriate for the platform. For example, for Windows, the Ice run time converts between UTF-8 and UTF-16 in little-endian representation whereas, for Linux, the Ice run time converts between UTF-8 and UTF-32 in the endian-ness appropriate for the host CPU.

With this default behavior, wide strings are transparently converted between their on-the-wire representation and their native C++ representation as appropriate, so application code need not do anything special. (The exception is if an application uses a non-Unicode encoding, such as Shift-JIS, as its native `wstring` codeset.)

Installing String Converters

The default behavior of the run time can be changed by providing application-specific string converters. If you install such converters, all Slice strings will be passed to the appropriate converter when they are marshaled and unmarshaled. Therefore, the string converters allow you to convert all strings transparently into their native representation without having to insert explicit conversion calls whenever a string crosses a Slice interface boundary.

You can install string converters by calling `IceUtil::setProcessStringConverter` for the narrow string converter, and `IceUtil::setProcessWstringConverter` for the wide string converter. Any strings that use the default (`std::string`) mapping are passed through the specified narrow string converter and any strings that use the wide (`std::wstring`) mapping are passed through the specified wide string converter.

You can also retrieve the previously installed string converters (or default string converters) with `IceUtil::getProcessStringConverter` and `IceUtil::getProcessWstringConverter`. The default narrow string converter is null, meaning all `std::strings` use the UTF-8 encoding.

The string converters are defined as follows:

C++

```
namespace IceUtil {

class UTF8Buffer {
public:
    virtual Byte* getMoreBytes(size_t howMany, Byte* firstUnused) = 0;
    virtual ~UTF8Buffer() {}
};

template<typename charT>
class BasicStringConverter : public IceUtil::Shared {
public:
    virtual Byte*
    toUTF8(const charT* sourceStart, const charT* sourceEnd,
          UTF8Buffer&) const = 0;

    virtual void fromUTF8(const Byte* sourceStart,
                          const Byte* sourceEnd,
                          std::basic_string<charT>& target) const;
};

typedef BasicStringConverter<char> StringConverter;
typedef IceUtil::Handle<StringConverter> StringConverterPtr;

typedef BasicStringConverter<wchar_t> WstringConverter;
typedef IceUtil::Handle<WstringConverter> WstringConverterPtr;

StringConverterPtr getProcessStringConverter();
void setProcessStringConverter(const StringConverterPtr&);

WstringConverterPtr getProcessWstringConverter();
void setProcessWstringConverter(const WstringConverterPtr&);
}
```

As you can see, both narrow and wide string converters are simply templates with either a narrow or a wide character (`char` or `wchar_t`) as the template parameter.

Each communicator caches the narrow string converter and wide string converter installed when this communicator is initialized.

You should always install your string converters before creating your communicator(s). When using a plugin to set your string converters, you need to set the string converters in the constructor of your plugin class (which is executed when the plugin is loaded) and not in the initialization function of the plugin class (which is executed after the communicator has read and cached the process-wide string converters).

See Also

- [Communicator Initialization](#)
- [C++ Mapping for Built-In Types](#)

UTF-8 Conversion

On this page:

- [Converting to UTF-8](#)
- [Converting from UTF-8](#)

Converting to UTF-8

If you have [installed a string converter](#), the Ice run time calls the converter's `toUTF8` function whenever it needs to convert a native string into UTF-8 representation for transmission. The `sourceStart` and `sourceEnd` pointers point at the first byte and one-beyond-the-last byte of the source string, respectively. The implementation of `toUTF8` must return a pointer to the first unused byte following the converted string.

Your implementation of `toUTF8` must allocate the returned string by calling the `getMoreBytes` member function of the `UTF8Buffer` class that is passed as the third argument. (`getMoreBytes` throws a `std::bad_alloc` if it cannot allocate enough memory.) The `firstUnused` parameter must point at the first unused byte of the allocated memory region. You can make several calls to `getMoreBytes` to incrementally allocate memory for the converted string. If you do, `getMoreBytes` may relocate the buffer in memory. (If it does, it copies the part of the string that was converted so far into the new memory region.) The function returns a pointer to the first unused byte of the (possibly relocated) memory.

Conversion can also fail because the encoding of the source string is internally incorrect. In that case, you should throw a `IceUtil::IllegalConversionException` exception from `toUTF8`, for example:

C++

```
throw IceUtil::IllegalConversionException(__FILE__, __LINE__, "bad
encoding because ...");
```

After it has marshaled the returned string into an internal marshaling buffer, the Ice run time deallocates the string.

Converting from UTF-8

During unmarshaling, the Ice run time calls the `fromUTF8` member function on the corresponding string converter. The function converts a UTF-8 byte sequence into its native form as a `std::string` or `std::wstring`. The string into which the function must place the converted characters is passed to `fromUTF8` as the `target` parameter.

See Also

- [Installing String Converters](#)

String Parameters in Local Calls

In C++, and indirectly in Python, Ruby, and PHP, all Ice local APIs are narrow-string based, meaning you could not for example recompile `Properties.ice` to get property names and values as wide strings.

Installing a narrow-string converter could cause trouble for these local calls if UTF-8 conversion occurs in the underlying implementation. For example, the `stringToIdentity` operation creates an intermediary UTF-8 string. If this string contains characters that are not in your native codeset (as determined by the narrow-string converter), the `stringToIdentity` call will fail.

Likewise, when Ice reads `properties` from a configuration file, it converts the input (UTF-8 characters) into native strings. This conversion can also fail if the native encoding cannot convert some characters.

Most strings in local calls are never problematic because Ice does not perform any conversion, for example:

- adapter names in `createObjectAdapter`
- property names and values in `Properties`
- `ObjectAdapter::createProxy`, where the identity conversion occurs only when the proxy is marshaled

Finally, consider the Slice type `Ice::Context`, which is mapped in C++ as a `map<string, string>`. The mapping for `Context` cannot be changed to `map<wstring, wstring>`, therefore you cannot send or receive any context entry that is not in your narrow-string native encoding when a narrow-string converter is installed.

Built-in String Converters

Ice provides three string converters to cover common conversion requirements:

- `UnicodeWstringConverter`
This is a string converter that converts between Unicode wide strings and UTF-8 strings. Unless you install a different string converter, this is the default converter that is used for wide strings.
- `IconvStringConverter` (Linux and Unix only)
The [iconv string converter](#) converts strings using the Linux and Unix `iconv` conversion facility. It can be used to convert either wide or narrow strings.
- `WindowsStringConverter` (Windows only)
This string converter converts between multi-byte and UTF-8 strings and uses `MultiByteToWideChar` and `WideCharToMultiByte` for its implementation.

These string converters are defined in the `IceUtil` namespace.

See Also

- [The iconv String Converter](#)

String Conversion Convenience Functions

The `IceUtil` namespace contains two helper functions that allow you to convert between narrow strings and UTF-8 encoded strings using a string converter:

C++

```
std::string nativeToUTF8(const std::string&, const StringConverterPtr&);
std::string UTF8ToNative(const std::string&, const StringConverterPtr&);
```

No conversion is performed when the provided string converter is null.

The `IceUtil` namespace contains two additional helper functions that allow you to convert between wide strings and narrow strings using the provided string converters:

C++

```
enum ConversionFlags { strictConversion, lenientConversion };

std::string wstringToString(const std::wstring&, const
    StringConverterPtr& = 0,
    const WstringConverterPtr& = 0,
    ConversionFlags = lenientConversion);
std::wstring stringToWstring(const std::string&, const
    StringConverterPtr& = 0,
    const WstringConverterPtr& = 0,
    ConversionFlags = lenientConversion);
```

When the narrow string converter given to `wstringToString` is null, the encoding of the returned narrow string is UTF-8. When the wide string converter given to `wstringToString` is null, the encoding of wide string parameter is UTF-16 or UTF-32, depending on the size of `wchar_t`.

Likewise for `stringToWstring`, when the wide string converter is null, the encoding of the returned wide string is UTF-16 or UTF-32 depending on the size of `wchar_t`. When the narrow string converter given to `stringToWstring` is null, the encoding of narrow string parameter is UTF-8.

When using the built-in converters (through null parameters), byte sequences that are illegal, such as `0xF4908080`, result in a `UTFConversionException`. For other errors, the `ConversionFlags` parameter determines how rigorously the functions check for errors. When set to `lenientConversion` (the default), the functions tolerate isolated surrogates and irregular sequences, and substitute the UTF-32 replacement character `0x0000FFFD` for character values above `0x10FFFF`. When set to `strictConversion`, the functions do not tolerate such errors and throw a `UTFConversionException` instead:

C++

```
enum ConversionError { partialCharacter, badEncoding };

class UTFConversionException : public Exception {
public:
    UTFConversionException(const char* file, int line,
        ConversionError r);

    ConversionError conversionError() const;
    // ...
};
```

The `conversionError` member function returns the reason for the failure:

- `partialCharacter`
The UTF-8 source string contains a trailing incomplete UTF-8 byte sequence.
- `badEncoding`
The UTF-8 source string contains a byte sequence that is not a valid UTF-8 encoded character, or the Unicode source string contains a bit pattern that does not represent a valid Unicode character.

See Also

- [UTF-8 Conversion](#)

The iconv String Converter

For Linux and Unix platforms, `IceUtil` provides an `IconvStringConverter` template class that uses the `iconv` conversion facility to convert between the native encoding and UTF-8. The only member function of interest is the constructor:

```

C++

template<typename charT>
class IconvStringConverter : public IceUtil::BasicStringConverter<charT>
{
public:
    IconvStringConverter(const char* = nl_langinfo(CODESET));

    // ...
};
```

To use this string converter, you specify whether the conversion you want is for narrow or wide characters via the template argument, and you specify the corresponding native encoding with the constructor argument. For example, to create a converter that converts between ISO Latin-1 and UTF-8, you can instantiate the converter as follows:

```

C++

StringConverterPtr
stringConverter = new IconvStringConverter<char>("ISO-8859-1");
```

Similarly, to convert between the internal wide character encoding and UTF-8, you can instantiate a converter as follows:

```

C++

WstringConverterPtr
wstringConverter = new IconvStringConverter<wchar_t>("WCHAR_T");
```

The string you pass to the constructor must be one of the values returned by `iconv -l`, which lists all the available character encodings for your machine.

Using the `IconvStringConverter` template makes it easy to install code converters for any available encoding without having to explicitly write (or call) conversion routines, whose implementation is typically non-trivial.

- [Installing String Converters](#)

The Ice String Converter Plug-in

The Ice run time includes a plug-in that supports [conversion](#) between UTF-8 and native encodings on Unix and Windows platforms. You can use this plug-in to install converters for narrow and wide strings into the communicator of an existing program. This feature is primarily intended for use in scripting language extensions such as Ice for Python; if you need to use string converters in your C++ application, we recommend using the technique described in [Installing String Converters](#) instead.

Note that an application must be designed to operate correctly in the presence of a string converter. A string converter assumes that it converts strings in the native encoding into the UTF-8 encoding, and vice versa. An application that performs its own conversions on strings that cross a Slice interface boundary can cause encoding errors when those strings are processed by a converter.

Configuring the Ice String Converter Plug-in

You can install the plug-in using a [configuration property](#) like the one shown below:

```
Ice.Plugin.IceStringConverter=Ice:createStringConverter
iconv=encoding[,encoding] windows=code-page
```

The first component of the property value represents the plug-in's [entry point](#), which includes the abbreviated name of the shared library or DLL (Ice) and the name of a factory function (createStringConverter).

The plug-in accepts the following arguments:

- `iconv=encoding[,encoding]`
This argument is optional on Unix platforms and ignored on Windows platforms. If specified, it defines the `iconv` names of the narrow string encoding and the optional wide-string encoding. If this argument is not specified, the plug-in installs a narrow string converter that uses the default locale-dependent encoding.
- `windows=code-page`
This argument is required on Windows platforms and ignored on Unix platforms. The `code-page` value represents a code page number, such as 1252.

The plug-in's argument semantics are designed so that the same configuration property can be used on both Windows and Unix platforms, as shown in the following example:

```
Ice.Plugin.IceStringConverter=Ice:createStringConverter
iconv=ISO8859-1 windows=1252
```

If the configuration file containing this property is shared by programs in multiple implementation languages, you can use an alternate syntax that is loaded only by the Ice for C++ run time:

```
Ice.Plugin.IceStringConverter.cpp=Ice:createStringConverter
iconv=ISO8859-1 windows=1252
```

If using Ice-E, you must call the `Ice::registerIceStringConverter()` function to ensure the plugin is linked with your application.

```
Ice::registerIceStringConverter is a simple helper function that calls Ice::registerPluginFactory.
```

Custom String Converter Plug-ins

If the default string converter plug-in does not satisfy your requirements, you can install your own string converters with a plugin, for example:

```

C++

class MyStringConverterPlugin : public Ice::Plugin {
public:

    MyStringConverterPlugin(const IceUtil::StringConverterPtr&
stringConverter,

const IceUtil::WstringConverterPtr& wstringConverter = 0)
    {
        IceUtil::setProcessStringConverter(stringConverter);
        IceUtil::setProcessWstringConverter(wstringConverter);
    }

    virtual void initialize() {}
    virtual void destroy() {}
};

```

Like in this example, you should install the string converters in your plugin's constructor. Do not install the string converters in `initialize`.

In order to create such a plug-in, you must do the following:

- Define and export a [factory function](#) that returns an instance of your plugin class
- Implement the string converter(s) that you will pass to your plugin's constructor, or use the ones [included with Ice](#).
- Package your code into a shared library or DLL.

To install your plug-in, use a [configuration property](#) like the one shown below:

```
Ice.Plugin.MyConverterPlugin=myconverter:createConverter ...
```

The first component of the property value represents the plug-in's [entry point](#), which includes the abbreviated name of the shared library or DLL (`myconverter`) and the name of a factory function (`createConverter`).

If the configuration file containing this property is shared by programs in multiple implementation languages, you can use an alternate syntax that is loaded only by the Ice for C++ run time:

```
Ice.Plugin.MyConverterPlugin.cpp=myconverter:createConverter ...
```

The C++ Utility Library

Ice for C++ includes a number of utility classes and functions in the `IceUtil` namespace, which we summarize here for your reference. Many of the classes and functions in `IceUtil` are documented elsewhere in this manual so, where appropriate, the sections here simply reference the relevant pages.

Threads and Concurrency with C++

Threading and concurrency control vary widely with different operating systems. To make threads programming easier and portable, Ice provides a simple thread abstraction layer that allows you to write portable source code regardless of the underlying platform.

This section looks at the threading and concurrency control mechanisms in Ice for C++. It explains the threading abstractions provided by Ice: mutexes, monitors, and threads. Using these APIs allows you to make your code thread safe and to create threads of your own without having to use non-portable APIs that differ in syntax or semantics across different platforms: Ice not only provides a portable API but also guarantees that the semantics of the various functions are the same across different platforms. This makes it easier to create thread-safe applications and lets you move your code between platforms with simple recompilation.

This section assumes you are familiar with light-weight threads and concurrency control. Also see [The Ice Threading Model](#), which provides a language-neutral introduction to the Ice threading model.

Library Overview

The Ice threading library provides the following thread-related abstractions:

- mutexes
- recursive mutexes
- monitors
- a thread abstraction that allows you to create, control, and destroy threads

The synchronization primitives permit you to implement concurrency control at different levels of granularity. In addition, the thread abstraction allows you to, for example, create a separate thread that can respond to GUI or other asynchronous events. All of the threading APIs are part of the `IceUtil` namespace.

The C++ Mutex Class

This page describes how to use mutexes — one of the available synchronization primitives.

On this page:

- [Mutex Member Functions](#)
- [Adding Thread Safety to the File System Application in C++](#)
- [Guaranteed Unlocking of Mutexes in C++](#)

Mutex Member Functions

The class `IceUtil::Mutex` (defined in `IceUtil/Mutex.h`) provides a simple non-recursive mutual exclusion mechanism:

C++

```

namespace IceUtil {
    enum MutexProtocol { PrioInherit, PrioNone };

    class Mutex {
    public:
        Mutex();
        Mutex(MutexProtocol p);
        ~Mutex();

        void lock() const;
        bool tryLock() const;
        void unlock() const;

        typedef LockT<Mutex> Lock;
        typedef TryLockT<Mutex> TryLock;
    };
}

```

The member functions of this class work as follows:

- `Mutex()`
`Mutex(MutexProtocol p)`
 You can optionally specify a mutex protocol when you construct a mutex. The mutex protocol controls how the mutex behaves with respect to [thread priorities](#). Default-constructed mutexes use a system-wide default.
- `lock`
 The `lock` function attempts to acquire the mutex. If the mutex is already locked, it suspends the calling thread until the mutex becomes available. The call returns once the calling thread has acquired the mutex.
- `tryLock`
 The `tryLock` function attempts to acquire the mutex. If the mutex is available, the call returns true with the mutex locked. Otherwise, if the mutex is locked by another thread, the call returns false.
- `unlock`
 The `unlock` function unlocks the mutex.

Note that `IceUtil::Mutex` is a non-recursive mutex implementation. This means that you must adhere to the following rules:

- Do not call `lock` on the same mutex more than once from a thread. The mutex is not recursive so, if the owner of a mutex attempts to lock it a second time, the behavior is undefined.
- Do not call `unlock` on a mutex unless the calling thread holds the lock. Calling `unlock` on a mutex that is not currently held by any thread, or calling `unlock` on a mutex that is held by a different thread, results in undefined behavior.

Use the `IceUtil::RecMutex` class if you need recursive semantics.

Adding Thread Safety to the File System Application in C++

Recall that the implementation of the `read` and `write` operations for our [file system server](#) is not thread safe:

C++
<pre> Filesystem::Lines Filesystem::FileI::read(const Ice::Current&) const { return _lines; // Not thread safe! } void Filesystem::FileI::write(const Filesystem::Lines& text, const Ice::Current&) { _lines = text; // Not thread safe! } </pre>

The problem here is that, if we receive concurrent invocations of `read` and `write`, one thread will be assigning to the `_lines` vector while another thread is reading that same vector. The outcome of such concurrent data access is undefined; to avoid the problem, we need to serialize access to the `_lines` member with a mutex. We can make the mutex a data member of the `FileI` class and lock and unlock it in the `read` and `write` operations:

C++

```

#include <IceUtil/Mutex.h>
// ...

namespace Filesystem {
    // ...

    class FileI : virtual public File,
                  virtual public Filesystem::NodeI {
    public:
        // As before...
    private:
        Lines _lines;
        IceUtil::Mutex _fileMutex;
    };
    // ...
}

Filesystem::Lines
Filesystem::FileI::read(const Ice::Current&) const
{
    _fileMutex.lock();
    Lines l = _lines;
    _fileMutex.unlock();
    return l;
}

void
Filesystem::FileI::write(const Filesystem::Lines& text,
const Ice::Current&)
{
    _fileMutex.lock();
    _lines = text;
    _fileMutex.unlock();
}

```

The `FileI` class here is identical to the original implementation, except that we have added the `_fileMutex` data member. The `read` and `write` operations lock and unlock the mutex to ensure that only one thread can read or write the file at a time. Note that, by using a separate mutex for each `FileI` instance, it is still possible for multiple threads to concurrently read or write files, as long as they each access a *different* file. Only concurrent accesses to the *same* file are serialized.

The implementation of `read` is somewhat awkward here: we must make a local copy of the file contents while we are holding the lock and return that copy. Doing so is necessary because we must unlock the mutex before we can return from the function. However, as we will see in the next section, the copy can be avoided by using a helper class that unlocks the mutex automatically when the function returns.

Guaranteed Unlocking of Mutexes in C++

Using the raw `lock` and `unlock` operations on mutexes has an inherent problem: if you forget to unlock a mutex, your program will deadlock. Forgetting to unlock a mutex is easier than you might suspect, for example:

C++

```

Filesystem::Lines
Filesystem::File::read(const Ice::Current&) const
{
    _fileMutex.lock();           // Lock the mutex
    Lines l = readFileContents(); // Read from database
    _fileMutex.unlock();        // Unlock the mutex
    return l;
}

```

Assume that we are keeping the contents of the file on secondary storage, such as a database, and that the `readFileContents` function accesses the file. The code is almost identical to the previous example but now contains a latent bug: if `readFileContents` throws an exception, the `read` function terminates without ever unlocking the mutex. In other words, this implementation of `read` is not exception-safe.

The same problem can easily arise if you have a larger function with multiple return paths. For example:

C++

```

void
SomeClass::someFunction(/* params here... */)
{
    _mutex.lock();           // Lock a mutex

    // Lots of complex code here...

    if (someCondition) {
        // More complex code here...
        return;             // Oops!!!
    }

    // More code here...

    _mutex.unlock();        // Unlock the mutex
}

```

In this example, the early return from the middle of the function leaves the mutex locked. Even though this example makes the problem quite obvious, in large and complex pieces of code, both exceptions and early returns can cause hard-to-track deadlock problems. To avoid this, the `Mutex` class contains two type definitions for helper classes, called `Lock` and `TryLock`:

C++

```

namespace IceUtil {

    class Mutex {
        // ...

        typedef LockT<Mutex> Lock;
        typedef TryLockT<Mutex> TryLock;
    };
}

```

`LockT` and `TryLockT` are simple templates that primarily consist of a constructor and a destructor; the `LockT` constructor calls `lock` on its argument, and the `TryLockT` constructor calls `tryLock` on its argument. The destructors call `unlock` if the mutex is locked when the template goes out of scope. By instantiating a local variable of type `Lock` or `TryLock`, we can avoid the deadlock problem entirely:

C++

```

void
SomeClass::someFunction(/* params here... */)
{
    IceUtil::Mutex::Lock lock(_mutex); // Lock a mutex

    // Lots of complex code here...

    if (someCondition) {
        // More complex code here...
        return; // No problem
    }

    // More code here...
} // Destructor of lock unlocks the mutex

```

This is an example of the *RAII (Resource Acquisition Is Initialization)* idiom [1].

On entry to `someFunction`, we instantiate a local variable `lock`, of type `IceUtil::Mutex::Lock`. The constructor of `lock` calls `lock` on the mutex so the remainder of the function is inside a critical region. Eventually, `someFunction` returns, either via an ordinary `return` (in the middle of the function or at the end) or because an exception was thrown somewhere in the function body. Regardless of how the function terminates, the C++ run time unwinds the stack and calls the destructor of `lock`, which unlocks the mutex, so we cannot get trapped by the deadlock problem we had previously.

Both the `Lock` and `TryLock` templates have a few member functions:

- `void acquire() const`
This function attempts to acquire the lock and blocks the calling thread until the lock becomes available. If the caller calls `acquire` on a mutex it has locked previously, the function throws `ThreadLockedException`.
- `bool tryAcquire() const`

This function attempts to acquire the mutex. If the mutex can be acquired, it returns true with the mutex locked; if the mutex cannot be acquired, it returns false. If the caller calls `tryAcquire` on a mutex it has locked previously, the function throws `ThreadLockedException`.

- `void release() const`
This function releases a previously locked mutex. If the caller calls `release` on a mutex it has unlocked previously, the function throws `ThreadLockedException`.
- `bool acquired() const`
This function returns true if the caller has locked the mutex previously, otherwise it returns false. If you use the `TryLock` template, you must call `acquired` after instantiating the template to test whether the lock actually was acquired.

These functions are useful if you want to use the `Lock` and `TryLock` templates for guaranteed unlocking, but need to temporarily release the lock:

C++

```

{
    IceUtil::Mutex::TryLock m(someMutex);

    if (m.acquired())
    {
        // Got the lock, do processing here...

        if (release_condition) {
            m.release();
        }

        // Mutex is now unlocked, someone else can lock it.
        // ...

        m.acquire(); // Block until mutex becomes available.

        // ...

        if (release_condition) {
            m.release();
        }

        // Mutex is now unlocked, someone else can lock it.

        // ...

        // Spin on the mutex until it becomes available.
        while (!m.tryLock()) {
            // Do some other processing here...
        }

        // Mutex locked again at this point.

        // ...
    }

} // Close scope, m is unlocked by its destructor.

```

Tip

You should make it a habit to always use the `Lock` and `TryLock` helpers instead of calling `lock` and `unlock` directly. Doing so results in code that is easier to understand and maintain.

Using the `Lock` helper, we can rewrite the implementation of our `read` and `write` operations as follows:

C++

```

Filesystem::Lines
Filesystem::FileI::read(const Ice::Current&) const
{
    IceUtil::Mutex::Lock lock(_fileMutex);
    return _lines;
}

void
Filesystem::FileI::write(const Filesystem::Lines& text,
const Ice::Current&)
{
    IceUtil::Mutex::Lock lock(_fileMutex);
    _lines = text;
}

```

Note that this also eliminates the need to make a copy of the `_lines` data member: the return value is initialized under protection of the mutex and cannot be modified by another thread once the destructor of `lock` unlocks the mutex.

The C++ RecMutex Class

A [non-recursive mutex](#) cannot be locked more than once, even by the thread that holds the lock. This frequently becomes a problem if a program contains a number of functions, each of which must acquire a mutex, and you want to call one function as part of the implementation of another function:

C++

```

IceUtil::Mutex _mutex;

void
f1()
{
    IceUtil::Mutex::Lock lock(_mutex);
    // ...
}

void
f2()
{
    IceUtil::Mutex::Lock lock(_mutex);
    // Some code here...

    // Call f1 as a helper function
    f1();                                // Deadlock!

    // More code here...
}

```

`f1` and `f2` each correctly lock the mutex before manipulating data but, as part of its implementation, `f2` calls `f1`. At that point, the program deadlocks because `f2` already holds the lock that `f1` is trying to acquire. For this simple example, the problem is obvious. However, in complex systems with many functions that acquire and release locks, it can get very difficult to track down this kind of situation: the locking conventions are not manifest anywhere but in the source code and each caller must know which locks to acquire (or not to acquire) before calling a function. The resulting complexity can quickly get out of hand.

Ice provides a recursive mutex class `RecMutex` (defined in `IceUtil/RecMutex.h`) that avoids this problem:

C++

```

namespace IceUtil {

    class RecMutex {
    public:
        RecMutex();
        RecMutex(MutexProtocol p);
        ~RecMutex();

        void lock() const;
        bool tryLock() const;
        void unlock() const;

        typedef LockT<RecMutex> Lock;
        typedef TryLockT<RecMutex> TryLock;
    };
}

```

Note that the signatures of the operations are the same as for `IceUtil::Mutex`. However, `RecMutex` implements a recursive mutex:

- `RecMutex()`
`RecMutex(MutexProtocol p)`
 You can optionally specify a mutex protocol when you construct a mutex. The mutex protocol controls how the mutex behaves with respect to [thread priorities](#). Default-constructed mutexes use a system-wide default.
- `lock`
 The `lock` function attempts to acquire the mutex. If the mutex is already locked by another thread, it suspends the calling thread until the mutex becomes available. If the mutex is available or is already locked by the calling thread, the call returns immediately with the mutex locked.
- `tryLock`
 The `tryLock` function works like `lock`, but, instead of blocking the caller, it returns false if the mutex is locked by another thread. Otherwise, the return value is true.
- `unlock`
 The `unlock` function unlocks the mutex.

As for non-recursive mutexes, you must adhere to a few simple rules for recursive mutexes:

- Do not call `unlock` on a mutex unless the calling thread holds the lock.
- You must call `unlock` as many times as you called `lock` for the mutex to become available to another thread. (Internally, a recursive mutex is implemented with a counter that is initialized to zero. Each call to `lock` increments the counter and each call to `unlock` decrements the counter; the mutex is made available to another thread when the counter returns to zero.)

Using recursive mutexes, the code fragment shown earlier works correctly:

C++

```

#include <IceUtil/RecMutex.h>
// ...

IceUtil::RecMutex _mutex;          // Recursive mutex

void
f1()
{
    IceUtil::RecMutex::Lock lock(_mutex);
    // ...
}

void
f2()
{
    IceUtil::RecMutex::Lock lock(_mutex);
    // Some code here...

    // Call f1 as a helper function
    f1();                               // Fine

    // More code here...
}

```

Note that the type of the mutex is now `RecMutex` instead of `Mutex`, and that we are using the `Lock` type definition provided by the `RecMutex` class, not the one provided by the `Mutex` class.

The C++ Monitor Class

The [recursive](#) and [non-recursive](#) mutex classes implement a simple mutual exclusion mechanism that allows only a single thread to be active in a critical region at a time. In particular, for a thread to enter the critical region, another thread must leave it. This means that, with mutexes, it is impossible to suspend a thread inside a critical region and have that thread wake up again at a later time, for example, when a condition becomes true.

To address this problem, Ice provides a monitor. Briefly, a monitor is a synchronization mechanism that protects a critical region: as for a mutex, only one thread may be active at a time inside the critical region. However, a monitor allows you to suspend a thread inside the critical region; doing so allows another thread to enter the critical region. The second thread can either leave the monitor (thereby unlocking the monitor), or it can suspend itself inside the monitor; either way, the original thread is woken up and continues execution inside the monitor. This extends to any number of threads, so several threads can be suspended inside a monitor.

The monitors provided by Ice have *Mesa* semantics, so called because they were first implemented by the Mesa programming language [1]. Mesa monitors are provided by a number of languages, including Java and Ada. With Mesa semantics, the signalling thread continues to run and another thread gets to run only once the signalling thread suspends itself or leaves the monitor.

Monitors provide a more flexible mutual exclusion mechanism than mutexes because they allow a thread to check a condition and, if the condition is false, put itself to sleep; the thread is woken up by some other thread that has changed the condition.

On this page:

- [Monitor Member Functions](#)
- [Using Monitors in C++](#)
- [Efficient Notification using Monitors in C++](#)

Monitor Member Functions

Ice provides monitors with the `IceUtil::Monitor` class (defined in `IceUtil/Monitor.h`):

C++

```

namespace IceUtil {

    template <class T>
    class Monitor {
    public:
        void lock() const;
        void unlock() const;
        bool tryLock() const;

        void wait() const;
        bool timedWait(const Time&) const;
        void notify();
        void notifyAll();

        typedef LockT<Monitor<T> > Lock;
        typedef TryLockT<Monitor<T> > TryLock;
    };
}

```

Note that `Monitor` is a template class that requires either `Mutex` or `RecMutex` as its template parameter. (Instantiating a `Monitor` with a `RecMutex` makes the monitor recursive.)

The member functions behave as follows:

- `lock`

This function attempts to lock the monitor. If the monitor is currently locked by another thread, the calling thread is suspended until the monitor becomes available. The call returns with the monitor locked.

- `tryLock`
This function attempts to lock a monitor. If the monitor is available, the call returns true with the monitor locked. If the monitor is locked by another thread, the call returns false.
- `unlock`
This function unlocks a monitor. If other threads are waiting to enter the monitor (are blocked inside a call to `lock`), one of the threads is woken up and locks the monitor.
- `wait`
This function suspends the calling thread and, at the same time, releases the lock on the monitor. A thread suspended inside a call to `wait` can be woken up by another thread that calls `notify` or `notifyAll`. When the call returns, the suspended thread resumes execution with the monitor locked.
- `timedWait`
This function suspends the calling thread for up to the specified timeout. If another thread calls `notify` or `notifyAll` and wakes up the suspended thread before the timeout expires, the call returns true and the suspended thread resumes execution with the monitor locked. Otherwise, if the timeout expires, the function returns false. Wait intervals are represented by instances of the `Time` class.
- `notify`
This function wakes up a single thread that is currently suspended in a call to `wait` or `timedWait`. If no thread is suspended in a call to `wait` or `timedWait` at the time `notify` is called, the notification is lost (that is, calls to `notify` are *not* remembered if there is no thread to be woken up). Note that notifying does not run another thread immediately. Another thread gets to run only once the notifying thread either calls `wait` or `timedWait` or unlocks the monitor (Mesa semantics).
- `notifyAll`
This function wakes up all threads that are currently suspended in a call to `wait` or `timedWait`. As for `notify`, calls to `notifyAll` are lost if no threads are suspended at the time. Also as for `notify`, `notifyAll` causes other threads to run only once the notifying thread has either called `wait` or `timedWait` or unlocked the monitor (Mesa semantics).

You must adhere to a few rules for monitors to work correctly:

- Do not call `unlock` unless you hold the lock. If you instantiate a monitor with a recursive mutex, you get recursive semantics, that is, you must call `unlock` as many times as you have called `lock` (or `tryLock`) for the monitor to become available.
- Do not call `wait` or `timedWait` unless you hold the lock.
- Do not call `notify` or `notifyAll` unless you hold the lock.
- When returning from a `wait` call, you *must* re-test the condition before proceeding (as shown below).

Using Monitors in C++

To illustrate how to use a monitor, consider a simple unbounded queue of items. A number of producer threads add items to the queue, and a number of consumer threads remove items from the queue. If the queue becomes empty, consumers must wait until a producer puts a new item on the queue. The queue itself is a critical region, that is, we cannot allow a producer to put an item on the queue while a consumer is removing an item. Here is a very simple implementation of a such a queue:

C++

```
template<class T> class Queue {
public:
    void put(const T& item) {
        _q.push_back(item);
    }

    T get() {
        T item = _q.front();
        _q.pop_front();
        return item;
    }

private:
    list<T> _q;
};
```

As you can see, producers call the `put` method to enqueue an item, and consumers call the `get` method to dequeue an item. Obviously, this implementation of the queue is not thread-safe and there is nothing to stop a consumer from attempting to dequeue an item from an empty queue.

Here is a version of the queue that uses a monitor to suspend a consumer if the queue is empty:

C++

```

#include <IceUtil/Monitor.h>

template<class T> class Queue
: public IceUtil::Monitor<IceUtil::Mutex> {
public:
    void put(const T& item) {
        IceUtil::Monitor<IceUtil::Mutex>::Lock lock(*this);
        _q.push_back(item);
        notify();
    }

    T get() {
        IceUtil::Monitor<IceUtil::Mutex>::Lock lock(*this);
        while (_q.size() == 0)
            wait();
        T item = _q.front();
        _q.pop_front();
        return item;
    }

private:
    list<T> _q;
};

```

Note that the `Queue` class now inherits from `IceUtil::Monitor<IceUtil::Mutex>`, that is, `Queue` *is-a* monitor.

Both the `put` and `get` methods lock the monitor when they are called. As for mutexes, instead of calling `lock` and `unlock` directly, we are using the `Lock` helper which automatically locks the monitor when it is instantiated and unlocks the monitor again when it is destroyed.

The `put` method first locks the monitor and then, now being in sole possession of the critical region, enqueues an item. Before returning (thereby unlocking the monitor), `put` calls `notify`. The call to `notify` will wake up any consumer thread that may be asleep in a `wait` call to inform the consumer that an item is available.

The `get` method also locks the monitor and then, before attempting to dequeue an item, tests whether the queue is empty. If so, the consumer calls `wait`. This suspends the consumer inside the `wait` call and unlocks the monitor, so a producer can enter the monitor to enqueue an item. Once that happens, the producer calls `notify`, which causes the consumer's `wait` call to complete, with the monitor again locked for the consumer. The consumer now dequeues an item and returns (thereby unlocking the monitor).

For this machinery to work correctly, the implementation of `get` does two things:

- `get` tests whether the queue is empty *after* acquiring the lock.
- `get` re-tests the condition in a loop around the call to `wait`; if the queue is still empty after `wait` returns, the `wait` call is re-entered.

You *must* always write your code to follow the same pattern:

- *Never* test a condition unless you hold the lock.
- *Always* re-test the condition in a loop around `wait`. If the test still shows the wrong outcome, call `wait` again.

Not adhering to these conditions will eventually result in a thread accessing shared data when it is not in its expected state, for the following reasons:

1. If you test a condition without holding the lock, there is nothing to prevent another thread from entering the monitor and changing its state before you can acquire the lock. This means that, by the time you get around to locking the monitor, the state of the monitor may no longer be in agreement with the result of the test.

2. Some thread implementations suffer from a problem known as *spurious wake-up*: occasionally, more than one thread may wake up in response to a call to `notify`, or a thread may wake up without any call to `notify` at all. As a result, each thread that returns from a call to `wait` must re-test the condition to ensure that the monitor is in its expected state: the fact that `wait` returns does *not* indicate that the condition has changed.

Efficient Notification using Monitors in C++

The previous implementation of our [thread-safe queue](#) unconditionally notifies a waiting reader whenever a writer deposits an item into the queue. If no reader is waiting, the notification is lost and does no harm. However, unless there is only a single reader and writer, many notifications will be sent unnecessarily, causing unwanted overhead.

Here is one way to fix the problem:

C++

```

#include <IceUtil/Monitor.h>

template<class T> class Queue : public IceUtil::Monitor<IceUtil::Mutex>
{
public:
    void put(const T& item) {
        IceUtil::Monitor<IceUtil::Mutex>::Lock lock(*this);
        _q.push_back(item);
        if (_q.size() == 1)
            notify();
    }

    T get() {
        IceUtil::Monitor<IceUtil::Mutex>::Lock lock(*this);
        while (_q.size() == 0)
            wait();
        T item = _q.front();
        _q.pop_front();
        return item;
    }

private:
    list<T> _q;
};

```

The only difference between this code and the implementation shown earlier is that a writer calls `notify` only if the queue length has just changed from empty to non-empty. That way, unnecessary `notify` calls are never made. However, this approach works only for a single reader thread. To see why, consider the following scenario:

1. Assume that the queue currently contains a number of items and that we have five reader threads.
2. The five reader threads continue to call `get` until the queue becomes empty and all five readers are waiting in `get`.
3. The scheduler schedules a writer thread. The writer finds the queue empty, deposits an item, and wakes up a single reader thread.
4. The awakened reader thread dequeues the single item on the queue.
5. The reader calls `get` a second time, finds the queue empty, and goes to sleep again.

The net effect of this is that there is a good chance that only one reader thread will ever be active; the other four reader threads end up being permanently asleep inside the `get` method.

One way around this problem is call `notifyAll` instead of `notify` once the queue length exceeds a certain amount, for example:

C++

```

#include <IceUtil/Monitor.h>

template<class T> class Queue : public IceUtil::Monitor<IceUtil::Mutex>
{
public:
    void put(const T& item) {
        IceUtil::Monitor<IceUtil::Mutex>::Lock lock(*this);
        _q.push_back(item);
        if (_q.size() >= _wakeupThreshold)
            notifyAll();
    }

    T get() {
        IceUtil::Monitor<IceUtil::Mutex>::Lock lock(*this);
        while (_q.size() == 0)
            wait();
        T item = _q.front();
        _q.pop_front();
        return item;
    }

private:
    list<T> _q;
    const int _wakeupThreshold = 100;
};

```

Here, we have added a private data member `_wakeupThreshold`; a writer wakes up *all* waiting readers once the queue length exceeds the threshold, in the expectation that all the readers will consume items more quickly than they are produced, thereby reducing the queue length below the threshold again.

This approach works, but has drawbacks as well:

- The appropriate value of `_wakeupThreshold` is difficult to determine and sensitive to things such as speed and number of processors and I/O bandwidth.
- If multiple readers are asleep, they are all made runnable by the thread scheduler once a writer calls `notifyAll`. On a multiprocessor machine, this may result in all readers running at once (one per CPU). However, as soon as the readers are made runnable, each of them attempts to reacquire the mutex that protects the monitor before returning from `wait`. Of course, only one of the readers actually succeeds and the remaining readers are suspended again, waiting for the mutex to become available. The net result is a large number of thread context switches as well as repeated and unnecessary locking of the system bus.

A better option than calling `notifyAll` is to wake up waiting readers one at a time. To do this, we keep track of the number of waiting readers and call `notify` only if a reader needs to be woken up:

C++

```

#include <IceUtil/Monitor.h>

template<class T> class Queue
: public IceUtil::Monitor<IceUtil::Mutex> {
public:
    Queue() : _waitingReaders(0) {}

    void put(const T& item) {
        IceUtil::Monitor<IceUtil::Mutex>::Lock lock(*this);
        _q.push_back(item);
        if (_waitingReaders)
            notify();
    }

    T get() {
        IceUtil::Monitor<IceUtil::Mutex>::Lock lock(*this);
        while (_q.size() == 0) {
            try {
                ++_waitingReaders;
                wait();
                --_waitingReaders;
            } catch (...) {
                --_waitingReaders;
                throw;
            }
        }
        T item = _q.front();
        _q.pop_front();
        return item;
    }

private:
    list<T> _q;
    short _waitingReaders;
};

```

This implementation uses a member variable `_waitingReaders` to keep track of the number of readers that are suspended. The constructor initializes the variable to zero and the implementation of `get` increments and decrements the variable around the call to `wait`. Note that these statements are enclosed in a `try-catch` block; this ensures that the count of waiting readers remains accurate even if `wait` throws an exception. Finally, `put` calls `notify` only if there is a waiting reader.

The advantage of this implementation is that it minimizes contention on the monitor mutex: a writer wakes up only a single reader at a time, so we do not end up with multiple readers simultaneously trying to lock the mutex. Moreover, the monitor `notify` implementation signals a waiting thread only *after* it has unlocked the mutex. This means that, when a thread wakes up from its call to `wait` and tries to reacquire the mutex, the mutex is likely to be unlocked. This results in more efficient operation because acquiring an unlocked mutex is typically very efficient, whereas forcefully putting a thread to sleep on a locked mutex is expensive (because it forces a thread context switch). The C++ Cond Class

Condition variables are similar to [monitors](#) in that they allow a thread to enter a critical region, test a condition, and sleep inside the critical region while releasing its lock. Another thread then is free to enter the critical region, change the condition, and eventually signal the sleeping thread, which resumes at the point where it went to sleep and with the critical region once again locked.

Note that condition variables provide a subset of the functionality of monitors, so a monitor can always be used instead of a condition variable. However, condition variables are smaller, which may be important if you are seriously constrained with respect to memory.

Condition variables are provided by the `IceUtil::Cond` class. Here is its interface:

```

C++

class Cond : private noncopyable {
public:

    Cond();
    ~Cond();

    void signal();
    void broadcast();

    template<typename Lock>
    void wait(const Lock& lock) const;

    template<typename Lock>
    bool timedWait(const Lock& lock, const Time& timeout) const;
};
```

Using a condition variable is very similar to using a monitor. The main difference in the `Cond` interface is that the `wait` and `timedWait` member functions are template functions, instead of the entire class being a template. The member functions behave as follows:

- `wait`
This function suspends the calling thread and, at the same time, releases the lock of the condition variable. A thread suspended inside a call to `wait` can be woken up by another thread that calls `signal` or `broadcast`. When `wait` completes, the suspended thread resumes execution with the lock held.
- `timedWait`
This function suspends the calling thread for up to the specified timeout. If another thread calls `signal` or `broadcast` and wakes up the suspended thread before the timeout expires, the call returns true and the suspended thread resumes execution with the lock held. Otherwise, if the timeout expires, the function returns false. Wait intervals are represented by instances of the `Time` class.
- `signal`
This function wakes up a single thread that is currently suspended in a call to `wait` or `timedWait`. If no thread is suspended in a call to `wait` or `timedWait` at the time `signal` is called, the signal is lost (that is, calls to `signal` are *not* remembered if there is no thread to be woken up). Note that signalling does not necessarily run another thread immediately; the thread calling `signal` may continue to run. However, depending on the underlying thread library, `signal` may also cause an immediate context switch to another thread.
- `broadcast`
This function wakes up all threads that are currently suspended in a call to `wait` or `timedWait`. As for `signal`, calls to `broadcast` are lost if no threads are suspended at the time.

You must adhere to a few rules for condition variables to work correctly:

- Do not call `wait` or `timedWait` unless you hold the lock.
- When returning from a `wait` call, you *must re-test the condition* before proceeding, just as for a monitor.

In contrast to monitors, which require you to call `notify` and `notifyAll` with the lock held, condition variables permit you to call `signal` a

and broadcast without holding the lock. Here is a code example that changes a condition and signals on a condition variable:

```
C++
```

```

Mutex m;
Cond c;

// ...

{
    Mutex::Lock sync(m);

    // Change some condition other threads may be sleeping on...

    c.signal();

    // ...
} // m is unlocked here

```

This code is correct and will work as intended, but it is potentially inefficient. Consider the code executed by the waiting thread:

```
C++
```

```

{
    Mutex::Lock sync(m);

    while(!condition) {
        c.wait(sync);
    }

    // Condition is now true, do some processing...

} // m is unlocked here

```

Again, this code is correct and will work as intended. However, consider what can happen once the first thread calls `signal`. It is possible that the call to `signal` will cause an immediate context switch to the waiting thread. But, even if the thread implementation does not cause such an immediate context switch, it is possible for the signalling thread to be suspended after it has called `signal`, but before it unlocks the mutex `m`. If this happens, the following sequence of events occurs:

1. The waiting thread is still suspended inside the implementation of `wait` and is now woken up by the call to `signal`.
2. The now-awake thread tries to acquire the mutex `m` but, because the signalling thread has not yet released the mutex, is suspended again waiting for the mutex to be unlocked.
3. The signalling thread is scheduled again and leaves the scope enclosing `sync`, which unlocks the mutex, making the thread waiting for the mutex runnable.
4. The thread waiting for the mutex acquires the mutex and retests its condition.

While the preceding scenario is functionally correct, it is inefficient because it incurs two extra context switches between the signalling thread and the waiting thread. Because context switches are expensive, this can have quite a large impact on run-time performance, especially if the critical region is small and the condition changes frequently.

You can avoid the inefficiency by unlocking the mutex *before* calling `signal`:

C++

```

Mutex m;
Cond c;

// ...

{
    Mutex::Lock sync(m);

    // Change some condition other threads may be sleeping on...

} // m is unlocked here

c.signal(); // Signal with the lock available

```

By arranging the code as shown, you avoid the additional context switches because, when the waiting thread is woken up by the call to `signal`, it succeeds in acquiring the mutex before returning from `wait` without being suspended and woken up again first.

As for monitors, you should exercise caution in using `broadcast`, particularly if you have many threads waiting on a condition. Condition variables suffer from the same potential problem as monitors with respect to `broadcast`, namely, that all threads that are currently suspended inside `wait` can immediately attempt to acquire the mutex, but only one of them can succeed and all other threads are suspended again. If your application is sensitive to this condition, you may want to consider [waking threads in a more controlled manner](#). See Also

The C++ Thread Classes

The server-side Ice run time by default creates a [thread pool](#) for you and automatically dispatches each incoming request in its own thread. As a result, you usually only need to worry about synchronization among threads to protect critical regions when you implement a server. However, you may wish to create threads of your own. For example, you might need a dedicated thread that responds to input from a user interface. And, if you have complex and long-running operations that can exploit parallelism, you might wish to use multiple threads for the implementation of that operation.

Ice provides a simple thread abstraction that permits you to write portable source code regardless of the native threading platform. This shields you from the native underlying thread APIs and guarantees uniform semantics regardless of your deployment platform.

On this page:

- [The C++ Thread Class](#)
- [Implementing Threads in C++](#)
- [Creating Threads in C++](#)
- [The C++ ThreadControl Class](#)
- [C++ Thread Example](#)

The C++ Thread Class

The basic thread abstraction in Ice is provided by two classes, `ThreadControl` and `Thread` (defined in `IceUtil/Thread.h`):

C++

```

namespace IceUtil {

    class Time;

    class ThreadControl {
    public:
#ifdef _WIN32
        typedef DWORD ID;
#else
        typedef pthread_t ID;
#endif

        ThreadControl();
#ifdef _WIN32
        ThreadControl(HANDLE, DWORD);
#else
        ThreadControl(explicit pthread_t);
#endif
        ID id() const;

        void join();
        void detach();

        static void sleep(const Time&);
        static void yield();

        bool operator==(const ThreadControl&) const;
        bool operator!=(const ThreadControl&) const;

    };

    class Thread :virtual public Shared {
    public:
        virtual void run() = 0;

        ThreadControl start(size_t stBytes = 0);
        ThreadControl start(size_t stBytes, int priority);
        ThreadControl getThreadControl() const;
        bool isAlive() const;

        bool operator==(const Thread&) const;
        bool operator!=(const Thread&) const;
        bool operator<(const Thread&) const;
    };
    typedef Handle<Thread> ThreadPtr;
}

```

The `Thread` class is an abstract base class with a pure virtual `run` method. To create a thread, you must specialize the `Thread` class and implement the `run` method (which becomes the starting stack frame for the new thread). Note that you must not allow any exceptions to

escape from `run`. The Ice run time installs an exception handler that calls `::std::terminate` if `run` terminates with an exception.

The remaining member functions behave as follows:

- `start(size_t stBytes = 0)`
`start(size_t stBytes, int priority)`
 This member function starts a newly-created thread (that is, calls the `run` method). The `stBytes` parameter specifies a stack size (in bytes) for the thread. The default value of zero creates the thread with a default stack size that is determined by the operating system.

You can also specify a priority for the thread. (If you do not supply a priority, the thread is created with the system default priority.) The priority value is system-dependent; on POSIX systems, the value must be a legal value for the `SCHED_RR` real-time scheduling policy. (`SCHED_RR` requires root privileges.) On Windows systems, the priority value is passed through to the Windows `setThreadPriority` function. [Priority Inversion in C++](#) provides information about how you can deal with priority inversion.

The return value is a `ThreadControl` object for the new thread.

You can start a thread only once; calling `start` on an already-started thread raises `ThreadStartedException`.

If the calling thread passes an invalid priority or, on POSIX systems, does not have root privileges, `start` raises `ThreadSyscallException`.

- `getThreadControl`
 This member function returns a `ThreadControl` object for the thread on which it is invoked. Calling this method before calling `start` raises a `ThreadNotStartedException`.
- `id`
 This method returns the underlying thread ID (`DWORD` for Windows and `pthread_t` for POSIX threads). This method is provided mainly for debugging purposes. Note also that `pthread_t` is, strictly-speaking, an opaque type, so you should not make any assumptions about what you can do with a thread ID.
- `isAlive`
 This method returns `false` before a thread's `start` method has been called and after a thread's `run` method has completed; otherwise, while the thread is still running, it returns `true`. `isAlive` is useful to implement a non-blocking join:

C++

```
ThreadPtr p = new MyThread();
// ...
while(p->isAlive()) {
    // Do something else...
}
p->getThreadControl().join(); // Will not block
```

- `operator==`
`operator!=`
`operator<`
 These member functions compare the in-memory address of two threads. They are provided so you can use `Thread` objects in sorted STL containers.

Note that `IceUtil` also defines the type `ThreadPtr`. This is the usual reference-counted [smart pointer](#) to guarantee automatic clean-up: the `Thread` destructor calls `delete` this once its reference count drops to zero.

Implementing Threads in C++

To illustrate how to implement threads, consider the following code fragment:

C++

```

#include <IceUtil/Thread.h>
// ...

Queue q;

class ReaderThread : public IceUtil::Thread {
    virtual void run() {
        for (int i = 0; i < 100; ++i)
            cout << q.get() << endl;
    }
};

class WriterThread : public IceUtil::Thread {
    virtual void run() {
        for (int i = 0; i < 100; ++i)
            q.put(i);
    }
};

```

This code fragment defines two classes, `ReaderThread` and `WriterThread`, that inherit from `IceUtil::Thread`. Each class implements the pure virtual `run` method it inherits from its base class. For this simple example, a writer thread places the numbers from 1 to 100 into an instance of the thread-safe `Queue` class we defined in our discussion of [monitors](#), and a reader thread retrieves 100 numbers from the queue and prints them to `stdout`.

Creating Threads in C++

To create a new thread, we simply instantiate the thread and call its `start` method:

C++

```

IceUtil::ThreadPtr t = new ReaderThread;
t->start();
// ...

```

Note that we assign the return value from `new` to a smart pointer of type `ThreadPtr`. This ensures that we do not suffer a memory leak:

1. When the thread is created, its reference count is set to zero.
2. Prior to calling `run` (which is called by the `start` method), `start` increments the reference count of the thread to 1.
3. For each `ThreadPtr` for the thread, the reference count of the thread is incremented by 1, and for each `ThreadPtr` that is destroyed, the reference count is decremented by 1.
4. When `run` completes, `start` decrements the reference count again and then checks its value: if the value is zero at this point, the `Thread` object deallocates itself by calling `delete this`; if the value is non-zero at this point, there are other smart pointers that reference this `Thread` object and deletion happens when the last smart pointer goes out of scope.

Note that, for all this to work, you *must* allocate your `Thread` objects on the heap — stack-allocated `Thread` objects will result in deallocation errors:

C++

```
ReaderThread thread;
IceUtil::ThreadPtr t = &thread; // Bad news!!!
```

This is wrong because the destructor of `t` will eventually call `delete`, which has undefined behavior for a stack-allocated object.

Similarly, you *must* use a `ThreadPtr` for an allocated thread. Do not attempt to explicitly delete a thread:

C++

```
Thread* t = new ReaderThread();

// ...

delete t; // Disaster!
```

This will result in a double deallocation of the thread because the thread's destructor will call `delete this`.

It is legal for a thread to call `start` on itself from within its own constructor. However, if so, the thread must not be (very) short lived:

C++

```
class ActiveObject : public Thread() {
public:
    ActiveObject() {
        start();
    }

    void done() {
        getThreadControl().join();
    }

    virtual void run() {
        // *Very* short lived...
    }
};
typedef Handle<ActiveObject> ActiveObjectPtr;

// ...

ActiveObjectPtr ao = new ActiveObject;
```

With this code, it is possible for `run` to complete before the assignment to the smart pointer `ao` completes; in that case, `start` will call `delete this` before it returns and `ao` ends up deleting an already-deleted object. However, note that this problem can arise only if `run` is indeed very short-lived and moreover, the scheduler allows the newly-created thread to run to completion before the assignment of the

return value of `operator new` to `ao` takes place. This is highly unlikely to happen — if you are concerned about this scenario, do not call `start` from within a thread's own constructor. That way, the smart pointer is assigned first, and the thread started second, so the problem cannot arise.

The C++ `ThreadControl` Class

The `start` method returns an object of type `ThreadControl`. The member functions of `ThreadControl` behave as follows:

- `ThreadControl`

The default constructor returns a `ThreadControl` object that refers to the calling thread. This allows you to get a handle to the current (calling) thread even if you had not previously saved a handle to that thread. For example:

```

C++

IceUtil::ThreadControl self;    // Get handle to self
cout << self.id() << endl;    // Print thread ID
```

This example also explains why we have two classes, `Thread` and `ThreadControl`: without a separate `ThreadControl`, it would not be possible to obtain a handle to an arbitrary thread. (Note that this code works even if the calling thread was not created by the Ice run time; for example, you can create a `ThreadControl` object for a thread that was created by the operating system.)

The (implicit) copy constructor and assignment operator create a `ThreadControl` object that refers to the same underlying thread as the source `ThreadControl` object.

Note that the constructor is overloaded. For Windows, the signature is

```

C++

ThreadControl(HANDLE, DWORD);
```

For Unix, the signature is

```

C++

ThreadControl(pthread_t);
```

These constructors allow you to create a `ThreadControl` object for the specified thread.

- `join`

This method suspends the calling thread until the thread on which `join` is called has terminated. For example:

```

C++

IceUtil::ThreadPtr t = new ReaderThread; // Create a thread
IceUtil::ThreadControl tc = t->start(); // Start it
tc.join();                               // Wait for it
```

If the reader thread has finished by the time the creating thread calls `join`, the call to `join` returns immediately; otherwise, the creating thread is suspended until the reader thread terminates.

Note that the `join` method of a thread must be called from only one other thread, that is, only one thread can wait for another thread to terminate. Calling `join` on a thread from more than one other thread has undefined behavior.

Calling `join` on a thread that was previously joined with or calling `join` on a detached thread has undefined behavior. You must join with each thread you create; failure to join with a thread has undefined behavior.

- `detach`

This method detaches a thread. Once a thread is detached, it cannot be joined with.

Calling `detach` on an already detached thread, or calling `detach` on a thread that was previously joined with has undefined behavior.

Note that, if you have detached a thread, you must ensure that the detached thread has terminated before your program leaves its `main` function. This means that, because detached threads cannot be joined with, they must have a life time that is shorter than that of the main thread.

- `sleep`

This method suspends the calling thread for the amount of time specified by the `Time` class.

- `yield`

This method causes the calling thread to relinquish the CPU, allowing another thread to run.

- `operator==`

`operator!=`

These operators compare thread IDs. (Note that `operator<` is not provided because it cannot be implemented portably.) These operators yield meaningful results only for threads that have not been detached or joined with.

As for all the synchronization primitives, you must adhere to a few rules when using threads to avoid undefined behavior:

- Do not allow `run` to throw an exception.
- Do not join with or detach a thread that you have not created yourself.
- For every thread you create, you must either join with that thread exactly once or detach it exactly once; failure to do so may cause resource leaks.
- Do not call `join` on a thread from more than one other thread.
- Do not leave `main` until all other threads you have created have terminated.
- Do not leave `main` until after you have destroyed all `Ice::Communicator` objects you have created (or use the `Ice::Application` class).
- A common mistake is to call `yield` from within a critical region. Doing so is usually pointless because the call to `yield` will look for another thread that can be run but, when that thread is run, it will most likely try to enter the critical region that is held by the yielding thread and go to sleep again. At best, this achieves nothing and, at worst, it causes many additional context switches for no gain. If you call `yield`, do so only in circumstances where there is at least a fair chance that another thread will actually be able to run and do something useful.

C++ Thread Example

Following is a small example that uses the `Queue` class we defined in our discussion of `monitors`. We create five writer and five reader threads. The writer threads each deposit 100 numbers into the queue, and the reader threads each retrieve 100 numbers and print them to `stdout`:

```

#include <vector>
#include <IceUtil/Thread.h>
// ...

Queue q;

class ReaderThread : public IceUtil::Thread {
    virtual void run() {
        for (int i = 0; i < 100; ++i)
            cout << q.get() << endl;
    }
};

class WriterThread : public IceUtil::Thread {
    virtual void run() {
        for (int i = 0; i < 100; ++i)
            q.put(i);
    }
};

int
main()
{
    vector<IceUtil::ThreadControl> threads;
    int i;

    // Create five reader threads and start them
    //
    for (i = 0; i < 5; ++i) {
        IceUtil::ThreadPtr t = new ReaderThread;
        threads.push_back(t->start());
    }

    // Create five writer threads and start them
    //
    for (i = 0; i < 5; ++i) {
        IceUtil::ThreadPtr t = new WriterThread;
        threads.push_back(t->start());
    }

    // Wait for all threads to finish
    //
    for (vector<IceUtil::ThreadControl>::iterator i = threads.begin();
         i != threads.end(); ++i) {
        i->join();
    }
}

```

The code uses the `threads` variable, of type `vector<IceUtil::ThreadControl>`, to keep track of the created threads. The code

creates five reader and five writer threads, storing the `ThreadControl` object for each thread in the `threads` vector. Once all the threads are created and running, the code joins with each thread before returning from `main`.

Note that you must not leave `main` without first joining with the threads you have created: many threading libraries crash if you return from `main` with other threads still running. (This is also the reason why you must not terminate a program without first calling `Communicator::destroy`; the `destroy` implementation joins with all outstanding threads before it returns.)

Priority Inversion in C++

In real-time systems, if you have threads with different priorities, it is possible to encounter a priority inversion. A priority inversion occurs when a low-priority thread prevents a higher-priority thread from running. This situation arises when a low-priority thread acquires a mutex and is pre-empted by one or more medium-priority threads that do not relinquish the CPU. If a high-priority thread then attempts to acquire the mutex locked by the low-priority thread, it will wait (potentially forever) for the medium-priority threads to complete.

One way to deal with this problem is to use a priority inheritance protocol. If a low-priority thread holds a mutex and a high-priority thread attempts to acquire the mutex, the priority of the thread holding the mutex is temporarily raised to the level of the thread waiting for the mutex. This allows the low-priority thread to keep running until it releases the mutex; as soon as it does, its priority is reduced back to its previous level and the high-priority thread acquires the mutex.

Ice supports the priority inheritance protocol on many POSIX platforms. (Windows does not provide such a protocol.)

For POSIX platforms that support the priority inheritance protocol, mutexes by default do not use it. You can use the `getDefaultMutexProtocol` function to retrieve the current default for your platform:

```

C++

namespace IceUtil {
    enum MutexProtocol { PrioInherit, PrioNone };

    MutexProtocol getDefaultMutexProtocol();
}

```

On Posix systems that do not support priority inheritance and on Windows, this function always returns `PrioNone`.

The return value of `getDefaultMutexProtocol` determines whether a default-constructed `Mutex` or `RecMutex` uses priority inheritance. By default, this function returns `PrioNone`. You can override this default by explicitly specifying a different protocol when you construct a `Mutex` or `RecMutex`. On Windows, if you specify `PrioInherit` when you construct a mutex, the setting is ignored and the mutex is constructed as if you had specified `PrioNone`.

To change the value returned by `getDefaultMutexProtocol`, you can edit `cpp/config/Make.rules`, modify the value of the `DEFAULT_MUTEX_PROTOCOL` macro, and then rebuild the `IceUtil` library.

Portable Signal Handling in C++

The `IceUtil::CtrlCHandler` class provides a portable mechanism to handle Ctrl+C and similar signals sent to a C++ process. On Windows, `IceUtil::CtrlCHandler` is a wrapper for `SetConsoleCtrlHandler`; on POSIX platforms, it handles `SIGHUP`, `SIGTERM` and `SIGINT` with a dedicated thread that waits for these signals using `sigwait`. Signals are handled by a callback function implemented and registered by the user. The callback is a simple function that takes an `int` (the signal number) and returns `void`; it must not throw any exception:

C++

```

namespace IceUtil {

    typedef void (*CtrlCHandlerCallback)(int);

    class CtrlCHandler {
    public:
        CtrlCHandler(CtrlCHandlerCallback = 0);
        ~CtrlCHandler();

        void setCallback(CtrlCHandlerCallback);
        CtrlCHandlerCallback getCallback() const;
    };
}

```

The member functions of `CtrlCHandler` behave as follows:

- `CtrlCHandler`
Constructs an instance with a callback function. Only one instance of `CtrlCHandler` can exist in a process at a given moment in time. On POSIX platforms, the constructor masks `SIGHUP`, `SIGTERM` and `SIGINT`, then starts a thread that waits for these signals using `sigwait`. For signal masking to work properly, it is imperative that the `CtrlCHandler` instance be created before starting any thread, and in particular before initializing an Ice communicator.
- `~CtrlCHandler`
Destroys the instance, after which the default signal processing behavior is restored on Windows (`TerminateProcess`). On POSIX platforms, the "sigwait" thread is terminated and joined, but the signal mask remains unchanged, so subsequent signals are ignored.
- `setCallback`
Sets a new callback function.
- `getCallback`
Gets the current callback function.

It is legal specify a value of zero (0) for the callback function, in which case signals are caught and ignored until a non-zero callback function is set.

A typical use for `CtrlCHandler` is to shutdown a communicator in an Ice server. For example, the `Ice::Application` class uses a `CtrlCHandler` in its implementation.

The C++ AbstractMutex Class

`AbstractMutex` defines a mutex base interface used by the Freeze [background save evictor](#). The interface allows the evictor to synchronize with servants that are stored in a Freeze database. The class has the following definition:

```

C++

class AbstractMutex {
public:
    typedef LockT<AbstractMutex> Lock;
    typedef TryLockT<AbstractMutex> TryLock;

    virtual ~AbstractMutex();

    virtual void lock() const = 0;
    virtual void unlock() const = 0;
    virtual bool tryLock() const = 0;
};
```

This class definition is provided in `IceUtil/AbstractMutex.h`. The same header file also defines a few template implementation classes that specialize `AbstractMutex`, as described below.

`AbstractMutexI`

This template class implements `AbstractMutex` by forwarding all member functions to its template argument:

```

C++

template <typename T>
class AbstractMutexI : public AbstractMutex, public T {
public:
    typedef LockT<AbstractMutexI> Lock;
    typedef TryLockT<AbstractMutexI> TryLock;

    virtual void lock() const {
        T::lock();
    }

    virtual void unlock() const {
        T::unlock();
    }

    virtual bool tryLock() const {
        return T::tryLock();
    }

    virtual ~AbstractMutexI() {}
};
```

`AbstractMutexReadI`

This template class implements a read lock by forwarding the `lock` and `tryLock` functions to the `readLock` and `tryReadLock` functions

of its template argument:

C++

```

template <typename T>
class AbstractMutexReadI : public AbstractMutex, public T {
public:
    typedef LockT<AbstractMutexReadI> Lock;
    typedef TryLockT<AbstractMutexReadI> TryLock;

    virtual void lock() const {
        T::readLock();
    }

    virtual void unlock() const {
        T::unlock();
    }

    virtual bool tryLock() const {
        return T::tryReadLock();
    }

    virtual ~AbstractMutexReadI() {}
};

```

AbstractMutexWriteI

This template class implements a write lock by forwarding the `lock` and `tryLock` functions to the `writeLock` and `tryWriteLock` functions of its template argument:

C++

```

template <typename T>
class AbstractMutexWriteI : public AbstractMutex, public T {
public:
    typedef LockT<AbstractMutexWriteI> Lock;
    typedef TryLockT<AbstractMutexWriteI> TryLock;

    virtual void lock() const {
        T::writeLock();
    }

    virtual void unlock() const {
        T::unlock();
    }

    virtual bool tryLock() const {
        return T::tryWriteLock();
    }

    virtual ~AbstractMutexWriteI() {}
};

```

Apart from use with Freeze servants, these templates are also useful if, for example, you want to implement your own evictor.

The C++ Cache Template

This class allows you to efficiently maintain a cache that is backed by secondary storage, such as a Berkeley DB database, without holding a lock on the entire cache while values are being loaded from the database. If you want to create [evictors](#) for servants that store their state in a database, the `Cache` class can simplify your evictor implementation considerably.

The `Cache` class has the following interface:

```

C++

template<typename Key, typename Value>
class Cache {
public:
    typedef typename std::map< /* ... */ , /* ... */>::iterator Position;

    bool pin(const Key& k, const Handle<Value>& v);
    Handle<Value> pin(const Key& k);
    void unpin(Position p);

    Handle<Value> putIfAbsent(const Key& k, const Handle<Value>& v);

    Handle<Value> getIfPinned(const Key&, bool = false) const;

    void clear();
    size_t size() const;

protected:
    virtual Handle<Value> load(const Key& k) = 0;
    virtual void pinned(const Handle<Value>& v, Position p);

    virtual ~Cache();
};
```

Note that `Cache` is an abstract base class — you must derive a concrete implementation from `Cache` and provide an implementation of the `load` and, optionally, of the `pinned` member function.

Internally, a `Cache` maintains a map of name-value pairs. The key and value type of the map are supplied by the `Key` and `Value` template arguments, respectively. The implementation of `Cache` takes care of maintaining the map; in particular, it ensures that concurrent lookups by callers are possible without blocking even if some of the callers are currently loading values from the backing store. In turn, this is useful for evictor implementations, such as the Freeze [background save evictor](#). The `Cache` class does not limit the number of entries in the cache — it is the job of the evictor implementation to limit the map size by calling `unpin` on elements of the map that it wants to evict.

Your concrete implementation class must implement the `load` function, whose job it is to load the value for the key `k` from the backing store and to return a handle to that value. Note that `load` returns a value of type `IceUtil::Handle`, that is, the value must be heap-allocated and support the usual reference-counting functions for smart pointers. (The easiest way to achieve this is to derive the value from `IceUtil::Shared`.)

If `load` cannot locate a record for the given key because no such record exists, it must return a null handle. If `load` fails for some other reason, it can throw an exception, which is propagated back to the application code.

Your concrete implementation class typically will also override the `pinned` function (unless you want to have a cache that does not limit the number of entries; the provided default implementation of `pinned` is a no-op). The `Cache` implementation calls `pinned` whenever it has added a value to the map as a result of a call to `pin`; the `pinned` function is therefore a callback that allows the derived class to find out when a value has been added to the cache and informs the derived class of the value and its position in the cache.

The `Position` parameter is a `std::iterator` into the cache's internal map that records the position of the corresponding map entry.

(Note that the element type of map is opaque, so you should not rely on knowledge of the cache's internal key and value types.) Your implementation of `pinned` must remember the position of the entry because that position is necessary to remove the corresponding entry from the cache again.

The public member functions of `Cache` behave as follows:

```
bool pin(const Key& k, const Handle<Value>& v);
```

To add a key-value pair to the cache, your evictor can call `pin`. The return value is true if the key and value were added; a false return value indicates that the map already contained an entry with the given key and the original value for that key is unchanged.

`pin` calls `pinned` if it adds an entry.

This version of `pin` does *not* call `load` to retrieve the entry from backing store if it is not yet in the cache. This is useful when you add a newly-created object to the cache.

Once an entry is in the cache, it is guaranteed to remain in the cache at the same position in memory, and without its value being overwritten by another thread, until that entry is unpinned by a call to `unpin`.

```
Handle<Value> pin(const Key& k);
```

A second version of `pin` looks for the entry with the given key in the cache. If the entry is already in the cache, `pin` returns the entry's value. If no entry with the given key is in the cache, `pin` calls `load` to retrieve the corresponding entry. If `load` returns an entry, `pin` adds it to the cache and returns the entry's value. If the entry cannot be retrieved from the backing store, `pin` returns null.

`pin` calls `pinned` if it adds an entry.

The function is thread-safe, that is, it calls `load` only once all other threads have unpinned the entry.

Once an entry is in the cache, it is guaranteed to remain in the cache at the same position in memory, and without its value being overwritten by another thread, until that entry is unpinned by a call to `unpin`.

```
Handle<Value> putIfAbsent(const Key& k, const Handle<Value>& v);
```

This function adds a key-value pair to the cache and returns a smart pointer to the value. If the map already contains an entry with the given key, that entry's value remains unchanged and `putIfAbsent` returns its value. If no entry with the given key is in the cache, `putIfAbsent` calls `load` to retrieve the corresponding entry. If `load` returns an entry, `putIfAbsent` adds it to the cache and returns the entry's value. If the entry cannot be retrieved from the backing store, `putIfAbsent` returns null.

`putIfAbsent` calls `pinned` if it adds an entry.

The function is thread-safe, that is, it calls `load` only once all other threads have unpinned the entry.

Once an entry is in the cache, it is guaranteed to remain in the cache at the same position in memory, and without its value being overwritten by another thread, until that entry is unpinned by a call to `unpin`.

```
Handle<Value> getIfPinned(const Key& k, bool wait = false) const;
```

This function returns the value stored for the key `k`.

- If an entry for the given key is in the map, the function returns the value immediately, regardless of the value of `wait`.
- If no entry for the given key is in the map and the `wait` parameter is false, the function returns a null handle.
- If no entry for the given key is in the map and the `wait` parameter is true, the function blocks the calling thread if another thread is currently attempting to load the same entry; once the other thread completes, `getIfPinned` completes and returns the value added by the other thread.

```
void unpin(Position p);
```

This function removes an entry from the map. The iterator `p` determines which entry to remove. (It must be an iterator that previously was passed to `pinned`.) The iterator `p` is invalidated by this operation, so you must not use it again once `unpin` returns. (Note that the `Cache` implementation ensures that updates to the map never invalidate iterators to existing entries in the map; `unpin` invalidates only the iterator for the removed entry.)

```
void clear();
```

This function removes all entries in the map.

```
size_t size() const;
```

This function returns the number of entries in the map.

The C++ Exception Class

This class is at the root of the derivation tree for `Ice` exceptions and encapsulates functionality that is common to all `Ice` and `IceUtil` exceptions:

C++

```

class Exception : public std::exception {
public:
    Exception();
    Exception(const char* file, int line);
    virtual ~Exception() throw();

    virtual std::string ice_name() const;
    virtual void ice_print(std::ostream&) const;
    virtual const char* what() const throw();
    virtual Exception* ice_clone() const;
    virtual void ice_throw() const;
    const char* ice_file() const;
    int ice_line() const;
    const std::string& ice_stackTrace() const;
};

```

The second constructor stores a file name and line number in the exception that are returned by the `ice_file` and `ice_line` member functions, respectively. This allows you to identify the source of an exception by passing the `__FILE__` and `__LINE__` preprocessor macros to the constructor.

The `what` member function is a synonym for `ice_print`. The default implementation of `ice_print` prints the file name, line number, and the name of the exception.

The `ice_stackTrace` function returns the full stack trace when the exception was constructed, or an empty string, depending on the value of the `Ice.PrintStackTraces` property.

The remaining member functions are described in the [C++ Mapping for Exceptions](#).

See Also

- [C++ Mapping for Exceptions](#)

The C++ generateUUID Function

Universally-unique identifiers (UUIDs) are often used in the [identities](#) of Ice objects. The C++ standard does not include a function for generating UUIDs, therefore Ice provides the `IceUtil::generateUUID` function for use in portable applications. The signature of `generateUUID` is:

C++

```
std::string generateUUID();
```

The function returns a string like the following:

```
02b066f5-c762-431c-8dd3-9b1941355e41
```

Each invocation returns a new identifier that differs from all previous ones.

- [Object Identity](#)

The C++ Handle Template

`IceUtil::Handle` implements a smart reference-counted pointer type. [Smart pointers](#) are used to guarantee automatic deletion of heap-allocated class instances.

`Handle` is a template class with the following interface:

C++

```
template<typename T>
class Handle : /* ... */ {
public:

    typedef T element_type;

    T* _ptr;

    T* operator->() const;
    T& operator*() const;
    T* get() const;

    operator bool() const;

    void swap(HandleBase& other);

    Handle(T* p = 0);

    template<typename Y>
    Handle(const Handle<Y>& r);

    Handle(const Handle& r);

    ~Handle();

    Handle& operator=(T* p);

    template<typename Y>
    Handle& operator=(const Handle<Y>& r);

    Handle& operator=(const Handle& r);

    template<class Y>
    static Handle dynamicCast(const HandleBase<Y>& r);

    template<class Y>
    static Handle dynamicCast(Y* p);
};

template<typename T, typename U>
bool operator==(const Handle<T>& lhs, const Handle<U>& rhs);
```

```
template<typename T, typename U>
bool operator!=(const Handle<T>& lhs, const Handle<U>& rhs);

template<typename T, typename U>
bool operator<(const Handle<T>& lhs, const Handle<U>& rhs);

template<typename T, typename U>
bool operator<=(const Handle<T>& lhs, const Handle<U>& rhs);

template<typename T, typename U>
bool operator>(const Handle<T>& lhs, const Handle<U>& rhs);
```

```
template<typename T, typename U>
bool operator>=(const Handle<T>& lhs, const Handle<U>& rhs);
```

Note that the actual implementation is split into a base and a derived class. For simplicity, we show the combined interface here. If you want to see the full implementation detail, it can be found in `IceUtil/Handle.h`.

The template argument must be a class that derives from `Shared` or `SimpleShared` (or that implements reference counting with the same interface as these classes).

This is quite a large interface, but all it really does is to faithfully mimic the behavior of ordinary C++ class instance pointers. Rather than discussing each member function in detail, we provide a simple overview here that outlines the most important points. Please see the discussion of [Ice objects](#) for more examples of using smart pointers.

`element_type`

This type definition follows the STL convention of defining the element type with the fixed name `element_type` so you can use it for template programming or the definition of generic containers.

`_ptr`

This data member stores the pointer to the underlying heap-allocated class instance.

Constructors, copy constructor, and assignment operators

These member functions allow you to construct, copy, and assign smart pointers as if they were ordinary pointers. In particular, the constructor and assignment operator are overloaded to work with raw C++ class instance pointers, which results in the "adoption" of the raw pointer by the smart pointer. For example, the following code works correctly and does not cause a memory leak:

C++

```
typedef Handle<MyClass> MyClassPtr;

void foo(const MyClassPtr&);

// ...

foo(new MyClass); // OK, no leak here.
```

`operator->`, `operator*`, and `get`

The arrow and indirection operators allow you to apply the usual pointer syntax to smart pointers to use the target of a smart pointer. The `get` member function returns the class instance pointer to the underlying reference-counted class instance; the return value is the value of `_ptr`.

`dynamicCast`

This member function works exactly like a C++ `dynamic_cast`: it tests whether the argument supports the specified type and, if so, returns a non-null pointer; if the target does not support the specified type, it returns null.

The reason for not using an actual `dynamic_cast` and using a `dynamicCast` function instead is that `dynamic_cast` only operates on pointer types, but `IceUtil::Handle` is a class.

For example:

C++

```

MyClassPtr p = ...;
MyOtherClassPtr o = ...;

o = MyOtherClassPtr::dynamicCast(p);
if (o)
{
    // o points at an instance of type MyOtherClass.
}
else
{
    // p points at something that is
    // not compatible with MyOtherClass.
}

```

Note that this example also illustrates the use of `operator bool`: when used in a boolean context, a smart pointer returns true if it is non-null and false otherwise.

Comparison operators: `==`, `!=`, `<`, `<=`, `>`, `>=`

The comparison operators for smart pointers delegate to the operators of the underlying class, therefore the author of the reference-counted class defines the semantics of smart pointer comparison. For example, in the case of [Slice classes](#), the base class `Ice::Object` implements the comparison operators in terms of pointer addresses. On the other hand, the base class for [Slice proxies](#) implements comparison using value semantics.

- [C++ Mapping for Interfaces](#)
- [The C++ Shared and SimpleShared Classes](#)

The C++ Handle Template Adaptors

`IceUtil` provides adaptors that support use of [smart pointers](#) with STL algorithms. Each template function returns a corresponding function object that is for use by an STL algorithm. The adaptors are defined in the header `IceUtil/Functional.h`.

Here is a list of the adaptors:

```
memFun
memFun1
voidMemFun
voidMemFun1

secondMemFun
secondMemFun1
secondVoidMemFun
secondVoidMemFun1

constMemFun
constMemFun1
constVoidMemFun
constVoidMemFun1

secondConstMemFun
secondConstMemFun1
secondConstVoidMemFun
secondConstVoidMemFun1
```

As you can see, the adaptors are in two groups. The first group operates on non-const smart pointers, whereas the second group operates on `const` smart pointers (for example, on smart pointers declared as `const MyClassPtr`).

Each group is further divided into two sub-groups. The adaptors in the first group operate on the target of a smart pointer, whereas the `second<name>` adaptors operate on the second element of a pair, where that element is a smart pointer.

Each of the four sub-groups contains four adaptors:

```
memFun
```

This adaptor is used for member functions that return a value and do not accept an argument. For example:

C++

```

class MyClass : public IceUtil::Shared {
public:
    MyClass(int i) : _i(i) {}
    int getVal() { return _i; }
private:
    int _i;
};

typedef IceUtil::Handle<MyClass> MyClassPtr;

// ...

vector<MyClassPtr> mcp;
mcp.push_back(new MyClass(42));
mcp.push_back(new MyClass(99));

transform(mcp.begin(), mcp.end(),
          ostream_iterator<int>(cout, " "),
          IceUtil::memFun(&MyClass::getVal));
cout << endl;

```

This code invokes the member function `getVal` on each instance that is pointed at by smart pointers in the vector `mcp` and prints the return value of `getVal` on `cout`, separated by spaces. The output from this code is:

```
42 99
```

`memFun1`

This adaptor is used for member functions that return a value and accept a single argument. For example:

C++

```

class MyClass : public IceUtil::Shared {
public:
    MyClass(int i) : _i(i) {}
    int plus(int v) { return _i + v; }
private:
    int _i;
};

typedef IceUtil::Handle<MyClass> MyClassPtr;

// ...

vector<MyClassPtr> mcp;
mcp.push_back(new MyClass(2));
mcp.push_back(new MyClass(4));
mcp.push_back(new MyClass(6));

int A[3] = { 5, 7, 9 };
transform(mcp.begin(), mcp.end(), A,
         ostream_iterator<int>(cout, " "),
         IceUtil::memFun1(&MyClass::plus));
cout << endl;

```

This code invokes the member function `plus` on each instance that is pointed at by smart pointers in the vector `mcp` and prints the return value of a call to `plus` on `cout`, separated by spaces. The calls to `plus` are successively passed the values stored in the array `A`. The output from this code is:

```
7 11 15
```

`voidMemFun`

This adaptor is used for member functions that do not return a value and do not accept an argument. For example:

C++

```

class MyClass : public IceUtil::Shared {
public:
    MyClass(int i) : _i(i) {}
    void print() { cout << _i << endl; }
private:
    int _i;
};

typedef IceUtil::Handle<MyClass> MyClassPtr;

// ...

vector<MyClassPtr> mcp;
mcp.push_back(new MyClass(2));
mcp.push_back(new MyClass(4));
mcp.push_back(new MyClass(6));

for_each(mcp.begin(), mcp.end(), IceUtil::voidMemFun(&MyClass::print));

```

This code invokes the member function `print` on each instance that is pointed at by smart pointers in the vector `mcp`. The output from this code is:

```

2
4
6

```

`voidMemFun1`

This adaptor is used for member functions that do not return a value and accept a single argument. For example:

C++

```

class MyClass : public IceUtil::Shared {
public:
    MyClass(int i) : _i(i) {}
    void printPlus(int v) { cout << _i + v << endl; }
private:
    int _i;
};

typedef IceUtil::Handle<MyClass> MyClassPtr;

vector<MyClassPtr> mcp;
mcp.push_back(new MyClass(2));
mcp.push_back(new MyClass(4));
mcp.push_back(new MyClass(6));

for_each(
    mcp.begin(), mcp.end(),
    bind2nd(IceUtil::voidMemFun1(&MyClass::printPlus), 3));

```

This code invokes the member function `printPlus` on each instance that is pointed at by smart pointers in the vector `mcp`. The output from this code is:

```

5
7
9

```

As mentioned earlier, the `second<name>` versions of the adaptors operate on the second element of a `std::pair<T1, T2>`, where `T2` must be a smart pointer. Most commonly, these adaptors are used to apply an algorithm to each lookup value of a map or multi-map. Here is an example:

C++

```

class MyClass : public IceUtil::Shared {
public:
    MyClass(int i) : _i(i) {}
    int plus(int v) { return _i + v; }
private:
    int _i;
};

typedef IceUtil::Handle<MyClass> MyClassPtr;

// ...

map<string, MyClassPtr> m;
m["two"] = new MyClass(2);
m["four"] = new MyClass(4);
m["six"] = new MyClass(6);

int A[3] = { 5, 7, 9 };
transform(
    m.begin(), m.end(), A,
    ostream_iterator<int>(cout, " "),
    IceUtil::secondMemFun1<int, string, MyClass>(&MyClass::plus));

```

This code invokes the `plus` member function on the class instance denoted by the `second` smart pointer member of each pair in the dictionary `m`. The output from this code is:

```
9 13 11
```

Note that `secondMemFun1` is a template that requires three arguments: the return type of the member function to be invoked, the key type of the dictionary, and the type of the class that is pointed at by the smart pointer.

In general, the `second<name>` adaptors require the following template arguments:

C++

```

secondMemFun<R, K, T>
secondMemFun1<R, K, T>
secondVoidMemFun<K, T>
secondVoidMemFun<K, T>

```

where `R` is the return type of the member function, `K` is the type of the first member of the pair, and `T` is the class that contains the member function.

- [The C++ Handle Template](#)

The C++ ScopedArray Template

`IceUtil::ScopedArray` is a smart pointer class similar to `Handle`. However, instead of managing the memory for class instances, `ScopedArray` manages memory for an array. This class is provided mainly for use with the [stream API](#). However, you can use it with arrays for other purposes.

Here is the definition of the template in full:

C++

```

template<typename T>
class ScopedArray : private IceUtil::noncopyable
{
public:
    explicit ScopedArray(T* ptr = 0)
        : _ptr(ptr) { }

    ScopedArray(const ScopedArray& other) {
        _ptr = other._ptr;
        const_cast<ScopedArray&>(other)._ptr = 0;
    }

    ~ScopedArray() {
        if (_ptr != 0)
            delete[] _ptr;
    }

    void reset(T* ptr = 0) {
        assert(ptr == 0 || ptr != _ptr);
        if (_ptr != 0)
            delete[] _ptr;
        _ptr = ptr;
    }

    T& operator[](size_t i) const {
        assert(_ptr != 0);
        assert(i >= 0);
        return _ptr[i];
    }

    T* get() const {
        return _ptr;
    }

    void swap(ScopedArray& a) {
        T* tmp = a._ptr;
        a._ptr = _ptr;
        _ptr = tmp;
    }

private:
    T* _ptr;
};

```

The class allows you to allocate an array on the heap and assign its pointer to a `ScopedArray` instance. When the instance goes out of scope, it calls `delete[]` on the array, so you do not need to deallocate the array explicitly yourself. This greatly reduces the risk of a

memory leak due to an early return or uncaught exception.

- [C++ Streaming Interfaces](#)

The C++ Shared and SimpleShared Classes

`IceUtil::Shared` and `IceUtil::SimpleShared` are base classes that implement the reference-counting mechanism for [smart pointers](#). The two classes provide identical interfaces; the difference between `Shared` and `SimpleShared` is that `SimpleShared` is not thread-safe and, therefore, can only be used if the corresponding class instances are accessed only by a single thread. (`SimpleShared` is marginally faster than `Shared` because it avoids the locking overhead that is incurred by `Shared`.)

The interface of `Shared` looks as follows. (Because `SimpleShared` has the same interface, we do not show it separately here.)

```
C++
```

```
class Shared {
public:
    Shared();
    Shared(const Shared&);
    virtual ~Shared();

    Shared& operator=(const Shared&);

    virtual void __incRef();
    virtual void __decRef();
    virtual int __getRef() const;
    virtual void __setNoDelete(bool);
};
```

The class maintains a reference that is initialized to zero by the constructor. `__incRef` increments the reference count and `__decRef` decrements it. If, during a call to `__decRef`, after decrementing the reference count, the reference count drops to zero, `__decRef` calls `delete this`, which causes the corresponding class instance to delete itself. The copy constructor increments the reference count of the copied instance, and the assignment operator increments the reference count of the source and decrements the reference count of the target.

The `__getRef` member function returns the value of the reference count and is useful mainly for debugging.

The `__setNoDelete` member function can be used to temporarily disable self-deletion and re-enable it again. This provides [exception safety](#) when you initialize a smart pointer with the `this` pointer of a class instance during construction.

To create a class that is reference-counted, you simply derive the class from `Shared` and define a smart pointer type for the class, for example:

```
C++
```

```
class MyClass : public IceUtil::Shared {
    // ...
};

typedef IceUtil::Handle<MyClass> MyClassPtr;
```

- [Smart Pointers for Classes](#)

The C++ Time Class

The `Time` class provides basic facilities for getting the current time, constructing time intervals, adding and subtracting times, and comparing times:

C++

```
namespace IceUtil {

    typedef ... Int64;

    class Time {
    public:
        enum Clock { Realtime, Monotonic };
        Time(Clock = Realtime);
        static Time now();
        static Time seconds(Int64);
        static Time milliseconds(Int64);
        static Time microseconds(Int64);

        Int64 toSeconds() const;
        Int64 toMilliseconds() const;
        Int64 toMicroseconds() const;

        double toSecondsDouble() const;
        double toMillisecondsDouble() const;
        double toMicrosecondsDouble() const;

        std::string toDateTime() const;
        std::string toDuration() const;

        Time operator-() const;

        Time operator-(const Time&) const;
        Time operator+(const Time&) const;

        Time operator*(int) const;
        Time operator*(Int64) const;
        Time operator*(double) const;

        double operator/(const Time&) const;
        Time operator/(int) const;
        Time operator/(Int64) const;
        Time operator/(double) const;

        Time& operator--=(const Time&);
        Time& operator+=(const Time&);

        Time& operator*=(int);
        Time& operator*=(Int64);
```

```
Time& operator*=(double);

Time& operator/=(int);
Time& operator/=(Int64);
Time& operator/=(double);

bool operator<(const Time&) const;
bool operator<=(const Time&) const;
bool operator>(const Time&) const;
bool operator>=(const Time&) const;
bool operator==(const Time&) const;
bool operator!=(const Time&) const;

#ifdef _WIN32
operator timeval() const;
#endif
};
```

```
std::ostream& operator<<(std::ostream&, const Time&);
}
```

The member functions behave as follows:

`Time`

Internally, the `Time` class stores ticks in microsecond units. For absolute time, this is the number of microseconds since the Unix epoch (00:00:00 UTC on 1 Jan. 1970). For durations, this is the number of microseconds in the duration. The default constructor initializes the tick count to zero and selects the real-time clock. Constructing `Time` with an argument of `Monotonic` selects the monotonic clock on platforms that support it; the real-time clock is used on other platforms.

`now`

This function constructs a `Time` object that is initialized to the current time of day.

`seconds`, `milliSeconds`, `microSeconds`

These functions construct `Time` objects from the argument in the specified units. For example, the following statement creates a time duration of one minute:

C++

```
IceUtil::Time t = IceUtil::Time::seconds(60);
```

`toSeconds`, `toMilliSeconds`, `toMicroSeconds`

The member functions provide explicit conversion of a duration to seconds, milliseconds, and microseconds, respectively. The return value is a 64-bit signed integer (`IceUtil::Int64`). For example:

C++

```
IceUtil::Time t = IceUtil::Time::milliSeconds(2000);
IceUtil::Int64 secs = t.toSeconds(); // Returns 2
```

`toSecondsDouble`, `toMilliSecondsDouble`, `toMicroSecondsDouble`

The member functions provide explicit conversion of a duration to seconds, milliseconds, and microseconds, respectively. The return value is of type `double`.

`toDateTime`

This function returns a human-readable representation of a `Time` value as a date and time.

`toDuration`

This function returns a human-readable representation of a `Time` value as a duration.

Operators

`Time` provides operators that allow you to add, subtract, multiply, and divide times. For example:

C++

```
IceUtil::Time oneMinute = IceUtil::Time::seconds(60);
IceUtil::Time oneMinuteAgo = IceUtil::Time::now() - oneMinute;
```

The multiplication and division operators permit you to multiply and divide a duration. Note that these operators provide overloads for `int`, `l`

ong long, and double.

The comparison operators allow you to compare times and time intervals with each other, for example:

```
IceUtil::Time oneMinute = IceUtil::Time::seconds(60);
IceUtil::Time twoMinutes = IceUtil::Time::seconds(120);
assert(oneMinute < twoMinutes);
```

The `timeval` operator converts a `Time` object to a `struct timeval`, defined as follows:

C++

```
struct timeval {
    long tv_sec;
    long tv_usec;
};
```

The conversion is useful for API calls that require a `struct timeval` argument, such as `select`. To convert a duration into a `timeval` structure, simply assign a `Time` object to a `struct timeval`:

C++

```
IceUtil::Time oneMinute = IceUtil::Time::seconds(60);
struct timeval tv;
tv = t;
```

Note that this member function is not available under Windows.

```
std::ostream& operator<<(std::ostream&, Time&);
```

This operator prints the number of whole seconds since the epoch.

- [The C++ Timer and TimerTask Classes](#)

The C++ Timer and TimerTask Classes

The `Timer` class allows you to schedule some code for once-only or repeated execution after some time interval elapses. The code to be executed resides in a class you derive from `TimerTask`:

```

C++

class Timer;
typedef IceUtil::Handle<Timer> TimerPtr;

class TimerTask : virtual public IceUtil::Shared {
public:
    virtual ~TimerTask() { }
    virtual void runTimerTask() = 0;
};

typedef IceUtil::Handle<TimerTask> TimerTaskPtr;
```

Your derived class must override the `runTimerTask` member function; the code in this method is executed by the timer. If the code you want to run requires access to some program state, you can pass that state into the constructor of your class or, alternatively, set that state via member functions of your class before scheduling it with a timer.

The `Timer` class invokes the `runTimerTask` member function to run your code. The class has the following definition:

```

C++

class Timer : /* ... */ {
public:
    Timer();
    Timer(int priority);

    void schedule(const TimerTaskPtr& task,
const IceUtil::Time& interval);

    void scheduleRepeated(const TimerTaskPtr& task,
const IceUtil::Time& interval);

    bool cancel(const TimerTaskPtr& task);

    void destroy();
};

typedef IceUtil::Handle<Timer> TimerPtr;
```

Intervals are specified using [Time](#) objects.

The constructor is overloaded to allow you specify a [thread priority](#). The priority controls the priority of the thread that executes your task.

The `schedule` member function schedules an instance of your timer task for once-only execution after the specified time interval has elapsed. Your code is executed by a separate thread that is created by the `Timer` class. The function throws an `IllegalArgumentException` if you invoke it on a destroyed timer.

The `scheduleRepeated` member function runs your task repeatedly, at the specified time interval. Your code is executed by a separate

thread that is created by the `Timer` class; the same thread is used every time your code runs. The function throws an `IllegalArgumentException` if you invoke it on a destroyed timer.

If your code throws an exception, the `Timer` class ignores the exception, that is, for a task that is scheduled to run repeatedly, an exception in the current execution does not cancel the next execution.

If your code takes longer to execute than the time interval you have specified for repeated execution, the second execution is delayed accordingly. For example, if you ask for repeated execution once every five seconds, and your code takes ten seconds to complete, then the second execution of your task starts five seconds after the previous execution finishes, that is, the interval specifies the wait time between successive executions.

A `TimerTask` instance that has already been scheduled with a `Timer` instance cannot be scheduled again with the same `Timer` instance until the task has completed or been canceled.

For a single `Timer` instance, the execution of all registered tasks is serialized. The wait interval applies on a per-task basis so, if you schedule task A at an interval of five seconds, and task B at an interval of ten seconds, successive runs of task A start no sooner than five seconds after the previous task A has finished, and successive runs of task B start no sooner than ten seconds after the previous task B has finished. If, at the time a task is scheduled to run, another task is still running, the new task's execution is delayed until the previous task has finished.

If you want scheduled tasks to run concurrently, you can create several `Timer` instances; tasks then execute in as many threads concurrently as there are `Timer` instances.

The `cancel` member function removes a task from a timer's schedule. In other words, it stops a task that is scheduled from being executed. If you cancel a task while it is executing, `cancel` returns immediately and the currently running task is allowed to complete normally; that is, `cancel` does not wait for any currently running task to complete.

The return value is true if `cancel` removed the task from the schedule. This is the case if you invoke `cancel` on a task that is scheduled for repeated execution and this was the first time you cancelled that task; subsequent calls to `cancel` return false. Calling `cancel` on a task scheduled for once-only execution always returns false, as does calling `cancel` on a destroyed timer.

The `destroy` member function removes all tasks from the timer's schedule. If you call `destroy` from any thread other than the timer's own execution thread, it joins with the currently executing task (if any), so the function does not return until the current task has completed. If you call `destroy` from the timer's own execution thread, it instead detaches the timer's execution thread. Calling `destroy` a second time on the same `Timer` instance has no effect. Similarly, calling `cancel` on a destroyed timer has no effect.

Note that you must call `destroy` on a `Timer` instance before allowing it to go out of scope; failing to do so causes undefined behavior.

Calls to `schedule` or `scheduleRepeated` on a destroyed timer raises an `IceUtil::IllegalArgumentException`.

Client-Side Slice-to-C-Sharp Mapping

The client-side Slice-to-C# mapping defines how Slice data types are translated to C# types, and how clients invoke operations, pass parameters, and handle errors. Much of the C# mapping is intuitive. For example, by default, Slice sequences map to C# arrays, so there is little you have learn in order to use Slice sequences in C#.

The C# API to the Ice run time is fully thread-safe. Obviously, you must still synchronize access to data from different threads. For example, if you have two threads sharing a sequence, you cannot safely have one thread insert into the sequence while another thread is iterating over the sequence. However, you only need to concern yourself with concurrent access to your own data — the Ice run time itself is fully thread safe, and none of the Ice API calls require you to acquire or release a lock before you safely can make the call.

Much of what appears in this chapter is reference material. We suggest that you skim the material on the initial reading and refer back to specific sections as needed. However, we recommend that you read at least the mappings for [exceptions](#), [interfaces](#), and [operations](#) in detail because these sections cover how to call operations from a client, pass parameters, and handle exceptions.

In order to use the C# mapping, you should need no more than the Slice definition of your application and knowledge of the C# mapping rules. In particular, looking through the generated code in order to discern how to use the C# mapping is likely to be inefficient, due to the amount of detail. Of course, occasionally, you may want to refer to the generated code to confirm a detail of the mapping, but we recommend that you otherwise use the material presented here to see how to write your client-side code.

The Ice Namespace

All of the APIs for the Ice run time are nested in the `Ice` namespace, to avoid clashes with definitions for other libraries or applications. Some of the contents of the `Ice` namespace are generated from Slice definitions; other parts of the `Ice` namespace provide special-purpose definitions that do not have a corresponding Slice definition. We will incrementally cover the contents of the `Ice` namespace throughout the remainder of the manual.

C-Sharp Mapping for Identifiers

Slice identifiers map to an identical C# identifier. For example, the Slice identifier `clock` becomes the C# identifier `clock`. If a Slice identifier is the same as a C# keyword, the corresponding C# identifier is a *verbatim identifier* (an identifier prefixed with `@`). For example, the Slice identifier `while` is mapped as `@while`.

You should try to [avoid such identifiers](#) as much as possible.

The Slice-to-C# compiler generates classes that inherit from interfaces or base classes in the .NET framework. These interfaces and classes introduce a number of methods into derived classes. To avoid name clashes between Slice identifiers that happen to be the same as an inherited method, such identifiers are prefixed with `ice_` and suffixed with `_` in the generated code. For example, the Slice identifier `Clone` maps to the C# identifier `ice_Clone_` if it would clash with an inherited `Clone`. The complete list of identifiers that are so changed is:

<code>Clone</code>	<code>Equals</code>	<code>Finalize</code>
<code>GetBaseException</code>	<code>GetHashCode</code>	<code>GetObjectData</code>
<code>GetType</code>	<code>MemberwiseClone</code>	<code>ReferenceEquals</code>
<code>ToString</code>	<code>checkedCast</code>	<code>uncheckedCast</code>

Note that Slice identifiers in this list are translated to the corresponding C# identifier only where necessary. For example, structures do not derive from `ICloneable`, so if a Slice structure contains a member named `Clone`, the corresponding C# structure's member is named `Clone` as well. On the other hand, classes do derive from `ICloneable`, so, if a Slice class contains a member named `Clone`, the corresponding C# class's member is named `ice_Clone_`.

Also note that, for the purpose of prefixing, Slice identifiers are case-insensitive, that is, both `Clone` and `clone` are escaped and map to `ice_Clone_` and `ice_clone_`, respectively.

- [C-Sharp Mapping for Exceptions](#)

C-Sharp Mapping for Modules

Slice modules map to C# namespaces with the same name as the Slice module. The mapping preserves the nesting of the Slice definitions. For example:

Slice
<pre> module M1 { // Definitions for M1 here... module M2 { // Definitions for M2 here... }; }; // ... module M1 { // Reopen M1 // More definitions for M1 here... }; </pre>

This definition maps to the corresponding C# definitions:

C#
<pre> namespace M1 { namespace M2 { // ... } // ... } // ... namespace M1 // Reopen M1 { // ... } </pre>

If a Slice module is reopened, the corresponding C# namespace is reopened as well.

C-Sharp Mapping for Built-In Types

The Slice built-in types are mapped to C# types as shown below:

Slice	C#
bool	bool
byte	byte
short	short
int	int
long	long
float	float
double	double
string	string

Mapping of Slice built-in types to C#.

- [C-Sharp Mapping for Exceptions](#)

C-Sharp Mapping for Enumerations

A Slice enumeration maps to the corresponding enumeration in C#. For example:

Slice
<pre>enum Fruit { Apple, Pear, Orange };</pre>

Not surprisingly, the generated C# definition is very similar:

C#
<pre>public enum Fruit { Apple, Pear, Orange }</pre>

Suppose we modify the Slice definition to include a custom enumerator value:

Slice
<pre>enum Fruit { Apple, Pear = 3, Orange };</pre>

The generated C# definition now includes an explicit initializer for every enumerator:

C#
<pre>public enum Fruit { Apple = 0, Pear = 3, Orange = 4 }</pre>

C-Sharp Mapping for Structures

Ice for .NET supports two different mappings for Slice **structures**. By default, Slice structures map to C# structures if they (recursively) contain only value types. If a Slice structure (recursively) contains a string, proxy, class, sequence, or dictionary member, it maps to a C# class. A [metadata directive](#) allows you to force the mapping to a C# class for Slice structures that contain only value types.

In addition, for either mapping, you can control whether Slice data members are mapped to fields or to [properties](#).

On this page:

- [Structure Mapping for Structures in C#](#)
- [Class Mapping for Structures in C#](#)
- [Property Mapping for Structures in C#](#)

Structure Mapping for Structures in C#

Consider the following structure:

Slice
<pre>struct Point { double x; double y; };</pre>

This structure consists of only value types and so, by default, maps to a C# partial structure:

C#
<pre>public partial struct Point { public double x; public double y; public Point(double x, double y); public override int GetHashCode(); public override bool Equals(object other); public static bool operator==(Point lhs, Point rhs); public static bool operator!=(Point lhs, Point rhs); }</pre>

For each data member in the Slice definition, the C# structure contains a corresponding public data member of the same name.

The generated constructor accepts one argument for each structure member, in the order in which they are defined in the Slice definition. This allows you to construct and initialize a structure in a single statement:

C#

```
Point p = new Point(5.1, 7.8);
```

Note that C# does not allow a value type to declare a default constructor or to assign default values to data members.

The structure overrides the `GetHashCode` and `Equals` methods to allow you to use it as the key type of a dictionary. (Note that the static two-argument version of `Equals` is inherited from `System.Object`.) Two structures are equal if (recursively) all their data members are equal. Otherwise, they are not equal. For structures that contain reference types, `Equals` performs a deep comparison; that is, reference types are compared for value equality, not reference equality.

Class Mapping for Structures in C#

The mapping for Slice structures to C# structures provides value semantics. Usually, this is appropriate, but there are situations where you may want to change this:

- If you use structures as members of a collection, each access to an element of the collection incurs the cost of boxing or unboxing. Depending on your situation, the performance penalty may be noticeable.
- On occasion, it is useful to be able to assign null to a structure, for example, to support "not there" semantics (such as when implementing parameters that are conceptually optional).

To allow you to choose the correct performance and functionality trade-off, the Slice-to-C# compiler provides an alternative mapping of structures to classes, for example:

Slice

```
["clr:class"] struct Point {
    double x;
    double y;
};
```

The `"clr:class"` metadata directive instructs the Slice-to-C# compiler to generate a mapping to a C# partial class for this structure. The generated code is almost identical, except that the keyword `struct` is replaced by the keyword `class` and that the class has a default constructor and inherits from `ICloneable`:

C#

```

public partial class Point : _System.ICloneable
{
    public double x;
    public double y;

    public Point();
    public Point(double x, double y);

    public object Clone();

    public override int GetHashCode();
    public override bool Equals(object other);

    public static bool operator==(Point lhs, Point rhs);
    public static bool operator!=(Point lhs, Point rhs);
}

```

Some of the generated marshaling code differs for the class mapping of structures, but this is irrelevant to application code.

The class has a default constructor that initializes data members as follows:

Data Member Type	Default Value
string	Empty string
enum	Zero
struct	Default-constructed value
Numeric	Zero
bool	False
sequence	Null
dictionary	Null
class/interface	Null

The constructor won't explicitly initialize a data member if the default C# behavior for that type produces the desired results.

If you wish to ensure that data members of primitive and enumerated types are initialized to specific values, you can declare default values in your [Slice definition](#). The default constructor initializes each of these data members to its declared value instead.

The class also provides a second constructor that has one parameter for each data member. This allows you to construct and initialize a class instance in a single statement:

C#

```

Point p = new Point(5.1, 7.8);

```

The `Clone` method performs a shallow memberwise copy, and the comparison methods have the usual semantics (they perform value comparison).

Note that you can influence the mapping for structures only at the point of definition of a structure, that is, for a particular structure type, you must decide whether you want to use the structure or the class mapping. (You cannot override the structure mapping elsewhere, for example, for individual structure members or operation parameters.)

As we mentioned previously, if a Slice structure (recursively) contains a member of reference type, it is automatically mapped to a C# class. (The compiler behaves as if you had explicitly specified the `"clr:class"` metadata directive for the structure.)

Here is our `Employee` structure once more:

Slice
<pre>struct Employee { long number; string firstName; string lastName; };</pre>

The structure contains two strings, which are reference types, so the Slice-to-C# compiler generates a C# class for this structure:

C#
<pre>public partial class Employee : _System.ICloneable { public long number; public string firstName; public string lastName; public Employee(); public Employee(long number, string firstName, string lastName); public object Clone(); public override int GetHashCode(); public override bool Equals(object other); public static bool operator==(Employee lhs, Employee rhs); public static bool operator!=(Employee lhs, Employee rhs); }</pre>

Property Mapping for Structures in C#

You can instruct the compiler to emit property definitions instead of public data members. For example:

Slice

```
["clr:property"] struct Point {
    double x;
    double y;
};
```

The "clr:property" metadata directive causes the compiler to generate a property for each Slice data member:

C#

```
public partial struct Point
{
    private double x_prop;
    public double x {
        get {
            return x_prop;
        }
        set {
            x_prop = value;
        }
    }

    private double y_prop;
    public double y {
        get {
            return y_prop;
        }
        set {
            y_prop = value;
        }
    }

    // Other methods here...
}
```

Note that the properties are non-virtual because C# structures cannot have virtual properties. However, if you apply the "clr:property" directive to a structure that contains a member of reference type, or if you combine the "clr:property" and "clr:class" directives, the generated properties are virtual. For example:

Slice

```
["clr:property", "clr:class"]
struct Point {
    double x;
    double y;
};
```

This generates the following code:

C#

```
public partial class Point : System.ICloneable
{
    private double x_prop;
    public virtual double x {
        get {
            return x_prop;
        }
        set {
            x_prop = value;
        }
    }

    private double y_prop;
    public virtual double y {
        get {
            return y_prop;
        }
        set {
            y_prop = value;
        }
    }

    // Other methods here...
}
```

C-Sharp Mapping for Sequences

Ice for .NET supports several different mappings for [sequences](#). By default, sequences are mapped to arrays. You can use [metadata directives](#) to map sequences to a number of alternative types:

- `System.Collections.Generic.List`
- `System.Collections.Generic.LinkedList`
- `System.Collections.Generic.Queue`
- `System.Collections.Generic.Stack`
- User-defined custom types that derive from `System.Collections.Generic.IEnumerable<T>`.

The different mappings allow you to map a sequence to a container type that provides the correct performance trade-off for your application.

On this page:

- [Array Mapping for Sequences in C#](#)
- [Mapping to Predefined Generic Containers for Sequences in C#](#)
- [Mapping to Custom Types for Sequences in C#](#)
- [Multi-Dimensional Sequences in C#](#)

Array Mapping for Sequences in C#

By default, the Slice-to-C# compiler maps sequences to arrays. Interestingly, no code is generated in this case; you simply define an array of elements to model the Slice sequence. For example:

```

Slice

sequence<Fruit> FruitPlatter;
```

Given this definition, to create a sequence containing an apple and an orange, you could write:

```

C#

Fruit[] fp = { Fruit.Apple, Fruit.Orange };
```

Or, alternatively:

```

C#

Fruit fp[] = new Fruit[2];
fp[0] = Fruit.Apple;
fp[1] = Fruit.Orange;
```

The array mapping for sequences is both simple and efficient, especially for sequences that do not need to provide insertion or deletion other than at the end of the sequence.

Mapping to Predefined Generic Containers for Sequences in C#

With metadata directives, you can change the default mapping for sequences to use generic containers provided by .NET. For example:

Slice

```
["clr:generic:List"] sequence<string> StringSeq;
["clr:generic:LinkedList"] sequence<Fruit> FruitSeq;
["clr:generic:Queue"] sequence<int> IntQueue;
["clr:generic:Stack"] sequence<double> DoubleStack;
```

The `"clr:generic:<type>"` metadata directive causes the `slice2cs` compiler to map the corresponding sequence to one of the containers in the `System.Collections.Generic` namespace. For example, the `Queue` sequence maps to `System.Collections.Generic.Queue<int>` due to its metadata directive.

The predefined containers allow you to select an appropriate space-performance trade-off, depending on how your application uses a sequence. In addition, if a sequence contains value types, such as `int`, the generic containers do not incur the cost of boxing and unboxing and so are quite efficient. (For example, `System.Collections.Generic.List<int>` performs within a few percentage points of an integer array for insertion and deletion at the end of the sequence, but has the advantage of providing a richer set of operations.)

Generic containers can be used for sequences of any element type except objects. For sequences of objects, only `List` is supported because it provides the functionality required for efficient unmarshaling. Metadata that specifies any other generic type is ignored with a warning:

Slice

```
class MyClass {
    // ...
};

["clr:generic:List"]
sequence<MyClass> MyClassList; // OK

["clr:generic:LinkedList"]
sequence<MyClass> MyClassLinkedList; // Ignored
```

In this example, sequence type `MyClassList` maps to the generic container `System.Collections.Generic.List<MyClass>`, but sequence type `MyClassLinkedList` uses the default array mapping.

Mapping to Custom Types for Sequences in C#

If the array mapping and the predefined containers are unsuitable for your application (for example, because you may need a priority queue, which does not come with .NET), you can implement your own custom containers and direct `slice2cs` to map sequences to these custom containers. For example:

Slice

```
["clr:generic:MyTypes.PriorityQueue"] sequence<int> Queue;
```

This metadata directive causes the `Slice Queue` sequence to be mapped to the type `MyTypes.PriorityQueue`. You must specify the fully-qualified name of your custom type following the `clr:generic:` prefix. This is because the generated code prepends a `global::` qu

alifier to the type name you provide; for the preceding example, the generated code refers to your custom type as `global::MyTypes.PriorityQueue<int>`.

Your custom type can have whatever interface you deem appropriate, but it must meet the following requirements:

- The custom type must derive from `System.Collections.Generic.IEnumerable<T>`.
- The custom type must provide a readable `Count` property that returns the number of elements in the collection.
- The custom type must provide an `Add` method that appends an element to the end of the collection.
- If (and only if) the `Slice` sequence contains elements that are `Slice` classes, the custom type must provide an indexer that sets the value of an element at a specific index. (Indexes, as usual, start at zero.)

As an example, here is a minimal class (omitting implementation) that meets these criteria:

```
C#
```

```
public class PriorityQueue<T> : IEnumerable<T>
{
    public IEnumerator<T> GetEnumerator();

    public int Count
        get;

    public void Add(T elmt);

    public T this[int index] // Needed for class elements only.
        set;

    // Other methods and data members here...
}
```

Multi-Dimensional Sequences in C#

`Slice` permits you to define sequences of sequences, for example:

```
Slice
```

```
enum Fruit { Apple, Orange, Pear };
["clr:generic:List"] sequence<Fruit> FruitPlatter;
["clr:generic:LinkedList"] sequence<FruitPlatter> Cornucopia;
```

If we use these definitions as shown, the type of `FruitPlatter` in the generated code is:

```
C#
```

```
System.Collections.Generic.LinkedList<System.Collections.Generic.List<Fruit>>
```

Here the outer sequence contains elements of type `List<Fruit>`, as you would expect.

Now let us modify the definition to change the mapping of `FruitPlatter` to an array:

Slice

```
enum Fruit { Apple, Orange, Pear };
sequence<Fruit> FruitPlatter;
["clr:LinkedList"] sequence<FruitPlatter> Cornucopia;
```

With this definition, the type of `Cornucopia` becomes:

C#

```
System.Collections.Generic.LinkedList<Fruit[]>
```

The generated code now no longer mentions the type `FruitPlatter` anywhere and deals with the outer sequence elements as an array of `Fruit` instead.

C-Sharp Mapping for Dictionaries

Ice for .NET supports two mappings for dictionaries. By default, a dictionary maps to `System.Collections.Generic.Dictionary<T>`. You can use a `metadata` directive to map a dictionary to `System.Collections.Generic.SortedDictionary` instead.

On this page:

- [Default Mapping for Dictionaries in C#](#)
- [Custom Mapping for Dictionaries in C#](#)

Default Mapping for Dictionaries in C#

Here is the definition of our `EmployeeMap` once more:

Slice
<code>dictionary<long, Employee> EmployeeMap;</code>

By default, the Slice-to-C# compiler maps the dictionary to the following type:

C#
<code>System.Collections.Generic.Dictionary<long, Employee></code>

Custom Mapping for Dictionaries in C#

You can use the `"clr:generic:SortedDictionary"` metadata directive to change the default mapping to use a sorted dictionary instead:

Slice
<code>["clr:generic:SortedDictionary"] dictionary<long, Employee> EmployeeMap;</code>

With this definition, the type of the dictionary becomes:

C#
<code>System.Collections.Generic.SortedDictionary<long, Employee></code>

- [C-Sharp Mapping for Sequences](#)
- [C-Sharp Collection Comparison](#)
- [C-Sharp Mapping for Constants](#)

- [C-Sharp Mapping for Exceptions](#)

C-Sharp Collection Comparison

The utility class `Ice.CollectionComparer` allows you to compare collections for equality:

```

C#

```
public class CollectionComparer {
 public static bool
 Equals(System.Collections.IDictionary d1,
 System.Collections.IDictionary d2);

 public static bool
 Equals(System.Collections.ICollection c1,
 System.Collections.ICollection c2);

 public static bool
 Equals(System.Collections.IEnumerable c1,
 System.Collections.IEnumerable c2);
}
```

```

Equality of the elements in a collection is determined by calling the elements' `Equals` method.

Two dictionaries are equal if they contain the same number of entries with identical keys and values.

Two collections that derive from `ICollection` or `IEnumerable` are equal if they contain the same number of entries and entries compare equal. Note that order is significant, so corresponding entries must not only be equal but must also appear in the same position.

- [C-Sharp Mapping for Sequences](#)
- [C-Sharp Mapping for Dictionaries](#)
- [C-Sharp Mapping for Constants](#)
- [C-Sharp Mapping for Exceptions](#)

C-Sharp Mapping for Constants

Here are the sample constant definitions once more:

```

Slice

const bool      AppendByDefault = true;  
const byte      LowerNibble = 0x0f;  
const string    Advice = "Don't Panic!";  
const short     TheAnswer = 42;  
const double    PI = 3.1416;  
  
enum Fruit { Apple, Pear, Orange };  
const Fruit     FavoriteFruit = Pear;
```

Here are the generated definitions for these constants:

C#

```

public abstract class AppendByDefault
{
    public const bool value = true;
}

public abstract class LowerNibble
{
    public const byte value = 15;
}

public abstract class Advice
{
    public const string value = "Don't Panic!";
}

public abstract class TheAnswer
{
    public const short value = 42;
}

public abstract class PI
{
    public const double value = 3.1416;
}

public enum Fruit { Apple, Pear, Orange }

public abstract class FavoriteFruit
{
    public const Fruit value = Fruit.Pear;
}

```

As you can see, each Slice constant is mapped to a class with the same name as the constant. The class contains a member named `value` that holds the value of the constant.

The mapping to classes instead of to plain constants is necessary because C# does not permit constant definitions at namespace scope.

Slice string literals that contain non-ASCII characters or universal character names are mapped to C# string literals with universal character names. For example:

Slice

```
const string Egg = "œuf";
const string Heart = "c\u0153ur";
const string Banana = "\U0001F34C";
```

is mapped to:

C++

```
public abstract class Egg
{
    public const string value = "\u0153uf";
}

public abstract class Heart
{
    public const string value = "c\u0153ur";
}

public abstract class Banana
{
    public const string value = "\ud83c\udf4c";
}
```

C-Sharp Mapping for Exceptions

On this page:

- [Inheritance Hierarchy for Exceptions in C#](#)
- [C# Mapping for User Exceptions](#)
- [C# Default Constructors for User Exceptions](#)
- [C# Mapping for Run-Time Exceptions](#)

Inheritance Hierarchy for Exceptions in C#

The mapping for exceptions is based on the inheritance hierarchy shown below:

Inheritance structure for exceptions.

The ancestor of all exceptions is `System.Exception`. Derived from that is `Ice.Exception`, which provides the definitions of a number of constructors. `Ice.LocalException` and `Ice.UserException` are derived from `Ice.Exception` and form the base of all run-time and user exceptions, respectively.

The constructors defined in `Ice.Exception` have the following signatures:

C#

```

public abstract class Exception : System.Exception
{
    public Exception();
    public Exception(System.Exception ex);
}

```

Each concrete derived exception class implements these constructors. The second constructor initializes the `InnerException` property of `System.Exception`. (Both constructors set the `Message` property to the empty string.)

C# Mapping for User Exceptions

Here is a fragment of the [Slice definition](#) for our world time server once more:

```

Slice

```
exception GenericError {
 string reason;
};

exception BadTimeVal extends GenericError {};

exception BadZoneName extends GenericError {};
```

```

These exception definitions map as follows:

C#

```

public partial class GenericError : Ice.UserException
{
    public string reason;

    public GenericError();
    public GenericError(System.Exception ex__);
    public GenericError(string reason);
    public GenericError(string reason, System.Exception ex__);

    // GetHashCode and comparison methods defined here,
    // as well as mapping-internal methods.
}

public partial class BadTimeVal : M.GenericError
{
    public BadTimeVal();
    public BadTimeVal(System.Exception ex__);
    public BadTimeVal(string reason);
    public BadTimeVal(string reason, System.Exception ex__);

    // GetHashCode and comparison methods defined here,
    // as well as mapping-internal methods.
}

public partial class BadZoneName : M.GenericError
{
    public BadZoneName();
    public BadZoneName(System.Exception ex__);
    public BadZoneName(string reason);
    public BadZoneName(string reason, System.Exception ex__);

    // GetHashCode and comparison methods defined here,
    // as well as mapping-internal methods.
}

```

Each Slice exception is mapped to a C# partial class with the same name. For each exception member, the corresponding class contains a public data member. (Obviously, because `BadTimeVal` and `BadZoneName` do not have members, the generated classes for these exceptions also do not have members.) [Optional data members](#) are mapped to instances of the `Ice.Optional` type.

The inheritance structure of the Slice exceptions is preserved for the generated classes, so `BadTimeVal` and `BadZoneName` inherit from `GenericError`.

All user exceptions are derived from the base class `Ice.UserException`. This allows you to catch all user exceptions generically by installing a handler for `Ice.UserException`. Similarly, you can catch all Ice run-time exceptions with a handler for `Ice.LocalException`, and you can catch all Ice exceptions with a handler for `Ice.Exception`.

All exceptions provide the usual `GetHashCode` and `Equals` methods, as well as the `==` and `!=` comparison operators.

The generated exception classes also contain other member functions that are not shown here; these member functions are internal to the C# mapping and are not meant to be called by application code.

C# Default Constructors for User Exceptions

An exception has a default constructor that initializes data members as follows:

Data Member Type	Default Value
string	Empty string
enum	Zero
struct	Default-constructed value
Numeric	Zero
bool	False
sequence	Null
dictionary	Null
class/interface	Null

The constructor won't explicitly initialize a data member if the default C# behavior for that type produces the desired results.

If you wish to ensure that data members of primitive and enumerated types are initialized to specific values, you can declare default values in your [Slice definition](#). The default constructor initializes each of these data members to its declared value instead.

An exception also provides a constructor that accepts one parameter for each data member so that you can construct and initialize a class instance in a single statement (instead of first having to construct the instance and then assign to its members). For a derived exception, this constructor accepts one argument for each base exception member, plus one argument for each derived exception member, in base-to-derived order. For each optional data member, the constructor accepts an `Ice.Optional` parameter of the appropriate type.

C# Mapping for Run-Time Exceptions

The Ice run time throws run-time exceptions for a number of pre-defined error conditions. All run-time exceptions directly or indirectly derive from `Ice.LocalException` (which, in turn, derives from `Ice.Exception`).

`Ice.LocalException` implements a `Clone` method that is inherited by its derived exceptions, so you can make memberwise shallow copies of exceptions.

By catching exceptions at the appropriate point in the inheritance hierarchy, you can handle exceptions according to the category of error they indicate:

- `Ice.Exception`
This is the root of the inheritance tree for both run-time and user exceptions.
- `Ice.LocalException`
This is the root of the inheritance tree for run-time exceptions.
- `Ice.UserException`
This is the root of the inheritance tree for user exceptions.
- `Ice.TimeoutException`
This is the base exception for both operation-invocation and connection-establishment timeouts.
- `Ice.ConnectTimeoutException`
This exception is raised when the initial attempt to establish a connection to a server times out.

For example, a `ConnectTimeoutException` can be handled as `ConnectTimeoutException`, `TimeoutException`, `LocalException`, or `Exception`.

You will probably have little need to catch run-time exceptions as their most-derived type and instead catch them as `LocalException`; the fine-grained error handling offered by the remainder of the hierarchy is of interest mainly in the implementation of the Ice run time. Exceptions to this rule are the exceptions related to [facet](#) and [object](#) life cycles, which you may want to catch explicitly. These exceptions are `FacetNotExistException` and `ObjectNotExistException`, respectively.

C-Sharp Mapping for Interfaces

The mapping of Slice [interfaces](#) revolves around the idea that, to invoke a remote operation, you call a member function on a local class instance that is a [proxy](#) for the remote object. This makes the mapping easy and intuitive to use because making a remote procedure call is no different from making a local procedure call (apart from error semantics).

On this page:

- [Proxy Interfaces in C#](#)
- [The Ice.ObjectPrx Interface in C#](#)
- [Proxy Helpers in C#](#)
- [Using Proxy Methods in C#](#)
- [Object Identity and Proxy Comparison in C#](#)

Proxy Interfaces in C#

On the client side, a Slice interface maps to a C# interface with member functions that correspond to the operations on that interface. Consider the following simple interface:

Slice
<pre>interface Simple { void op(); };</pre>

The Slice compiler generates the following definition for use by the client:

C#
<pre>public interface SimplePrx : Ice.ObjectPrx { void op(); void op(System.Collections.Generic.Dictionary<string, string> __context); }</pre>

As you can see, the compiler generates a *proxy interface* `SimplePrx`. In general, the generated name is `<interface-name>Prx`. If an interface is nested in a module `M`, the generated interface is part of namespace `M`, so the fully-qualified name is `M.<interface-name>Prx`.

In the client's address space, an instance of `SimplePrx` is the local ambassador for a remote instance of the `Simple` interface in a server and is known as a *proxy instance*. All the details about the server-side object, such as its address, what protocol to use, and its object identity are encapsulated in that instance.

Note that `SimplePrx` inherits from `Ice.ObjectPrx`. This reflects the fact that all Ice interfaces implicitly inherit from `Ice::Object`.

For each operation in the interface, the proxy class has a member function of the same name. For the preceding example, we find that the operation `op` has been mapped to the method `op`. Also note that `op` is overloaded: the second version of `op` has a parameter `__context`, which is a dictionary of string pairs. This parameter is for use by the Ice run time to store information about how to deliver a request. You normally do not need to use it. (We examine the `__context` parameter in detail in [Request Contexts](#). The parameter is also used by `IceStor m`.)

Because all the `<interface-name>Prx` types are interfaces, you cannot instantiate an object of such a type. Instead, proxy instances are always instantiated on behalf of the client by the Ice run time, so client code never has any need to instantiate a proxy directly. The proxy references handed out by the Ice run time are always of type `<interface-name>Prx`; the concrete implementation of the interface is part of the Ice run time and does not concern application code.

A value of `null` denotes the null proxy. The null proxy is a dedicated value that indicates that a proxy points "nowhere" (denotes no object).

The `Ice.ObjectPrx` Interface in C#

All Ice objects have `Object` as the ultimate ancestor type, so all proxies inherit from `Ice.ObjectPrx`. `ObjectPrx` provides a number of methods:

```

C#

namespace Ice
{
    public interface ObjectPrx
    {
        Identity ice_getIdentity();
        bool ice_isA(string id);
        string ice_id();
        void ice_ping();

        int GetHashCode();
        bool Equals(object r);

        // Defined in a helper class:
        //
        public static bool Equals(Ice.ObjectPrx lhs, ObjectPrx rhs);
        public static bool operator==(ObjectPrx lhs, ObjectPrx rhs);
        public static bool operator!=(ObjectPrx lhs, ObjectPrx rhs);

        // ...
    }
}

```

Note that the static methods are not actually defined in `Ice.ObjectPrx`, but in a helper class that becomes a base class of an instantiated proxy. However, this is simply an internal detail of the C# mapping — conceptually, these methods belong with `Ice.ObjectPrx`, so we discuss them here.

The methods behave as follows:

- **`ice_getIdentity`**
This method returns the identity of the object denoted by the proxy. The identity of an Ice object has the following Slice type:

```

Slice

module Ice {
    struct Identity {
        string name;
        string category;
    };
};

```

To see whether two proxies denote the same object, first obtain the identity for each object and then compare the identities:

C#

```
Ice.ObjectPrx o1 = ...;
Ice.ObjectPrx o2 = ...;
Ice.Identity i1 = o1.ice_getIdentity();
Ice.Identity i2 = o2.ice_getIdentity();

if (i1.Equals(i2))
    // o1 and o2 denote the same object
else
    // o1 and o2 denote different objects
```

- **ice_isA**

The `ice_isA` method determines whether the object denoted by the proxy supports a specific interface. The argument to `ice_isA` is a [type ID](#). For example, to see whether a proxy of type `ObjectPrx` denotes a `Printer` object, we can write:

C#

```
Ice.ObjectPrx o = ...;
if (o != null && o.ice_isA("::Printer"))
    // o denotes a Printer object
else
    // o denotes some other type of object
```

Note that we are testing whether the proxy is null before attempting to invoke the `ice_isA` method. This avoids getting a `NullReferenceException` if the proxy is null.

- **ice_ids**

The `ice_ids` method returns an array of strings representing all of the [type IDs](#) that the object denoted by the proxy supports.

- **ice_id**

The `ice_id` method returns the [type ID](#) of the object denoted by the proxy. Note that the type returned is the type of the actual object, which may be more derived than the static type of the proxy. For example, if we have a proxy of type `BasePrx`, with a static type ID of `::Base`, the return value of `ice_id` might be `::Base`, or it might something more derived, such as `::Derived`.

- **ice_ping**

The `ice_ping` method provides a basic reachability test for the object. If the object can physically be contacted (that is, the object exists and its server is running and reachable), the call completes normally; otherwise, it throws an exception that indicates why the object could not be reached, such as `ObjectNotExistException` or `ConnectTimeoutException`.

- **Equals**

This method compares two proxies for equality. Note that all aspects of proxies are compared by this operation, such as the communication endpoints for the proxy. This means that, in general, if two proxies compare unequal, that does *not* imply that they denote different objects. For example, if two proxies denote the same Ice object via different transport endpoints, `equals` returns `false` even though the proxies denote the same object.

The `ice_isA`, `ice_ids`, `ice_id`, and `ice_ping` methods are remote operations and therefore support an additional overloading that accepts a [request context](#). Also note that there are [other methods](#) in `ObjectPrx`, not shown here. These methods provide different ways to dispatch a call and also provide access to an object's [facets](#).

Proxy Helpers in C#

For each Slice interface, apart from the proxy interface, the Slice-to-C# compiler creates a helper class: for an interface `Simple`, the name of the generated helper class is `SimplePrxHelper`.

You can ignore the `ObjectPrxHelperBase` base class — it exists for mapping-internal purposes.

The helper class contains two methods of interest:

C#

```
public class SimplePrxHelper : Ice.ObjectPrxHelperBase, SimplePrx
{
    public static SimplePrx checkedCast(Ice.ObjectPrx b);
    public static SimplePrx checkedCast(
        Ice.ObjectPrx b,
        System.Collections.Generic.Dictionary<string, string> ctx);
    public static SimplePrx uncheckedCast(Ice.ObjectPrx b);
    public static string ice_staticId();

    // ...
}
```

For `checkedCast`, if the passed proxy is for an object of type `Simple`, or a proxy for an object with a type derived from `Simple`, the cast returns a non-null reference to a proxy of type `SimplePrx`; otherwise, if the passed proxy denotes an object of a different type (or if the passed proxy is null), the cast returns a null reference.

Given a proxy of any type, you can use a `checkedCast` to determine whether the corresponding object supports a given type, for example:

C#

```
Ice.ObjectPrx obj = ...;           // Get a proxy from somewhere...

SimplePrx simple = SimplePrxHelper.checkedCast(obj);
if (simple != null)
    // Object supports the Simple interface...
else
    // Object is not of type Simple...
```

Note that a `checkedCast` contacts the server. This is necessary because only the implementation of an object in the server has definite knowledge of the type of an object. As a result, a `checkedCast` may throw a `ConnectTimeoutException` or an `ObjectNotExistException`. (This also explains the need for the helper class: the Ice run time must contact the server, so we cannot use a C# down-cast.)

In contrast, an `uncheckedCast` does not contact the server and unconditionally returns a proxy of the requested type. However, if you do use an `uncheckedCast`, you must be certain that the proxy really does support the type you are casting to; otherwise, if you get it wrong, you will most likely get a run-time exception when you invoke an operation on the proxy. The most likely error for such a type mismatch is `OperationNotExistException`. However, other exceptions, such as a marshaling exception are possible as well. And, if the object happens to have an operation with the correct name, but different parameter types, no exception may be reported at all and you simply end up sending the invocation to an object of the wrong type; that object may do rather nonsensical things. To illustrate this, consider the following two interfaces:

Slice

```
interface Process {
    void launch(int stackSize, int dataSize);
};

// ...

interface Rocket {
    void launch(float xCoord, float yCoord);
};
```

Suppose you expect to receive a proxy for a `Process` object and use an `uncheckedCast` to down-cast the proxy:

C#

```
Ice.ObjectPrx obj = ...; // Get proxy...
ProcessPrx process
= ProcessPrxHelper.uncheckedCast(obj); // No worries...
process.launch(40, 60); // Oops...
```

If the proxy you received actually denotes a `Rocket` object, the error will go undetected by the Ice run time: because `int` and `float` have the same size and because the Ice protocol does not tag data with its type on the wire, the implementation of `Rocket::launch` will simply misinterpret the passed integers as floating-point numbers.

In fairness, this example is somewhat contrived. For such a mistake to go unnoticed at run time, both objects must have an operation with the same name and, in addition, the run-time arguments passed to the operation must have a total marshaled size that matches the number of bytes that are expected by the unmarshaling code on the server side. In practice, this is extremely rare and an incorrect `uncheckedCast` typically results in a run-time exception.

A final warning about down-casts: you must use either a `checkedCast` or an `uncheckedCast` to down-cast a proxy. If you use a C# cast, the behavior is undefined.

Another method defined by every helper class is `ice_staticId`, which returns the `type ID` string corresponding to the interface. As an example, for the Slice interface `Simple` in module `M`, the string returned by `ice_staticId` is `"::M::Simple"`.

Using Proxy Methods in C#

The base proxy class `ObjectPrx` supports a variety of methods for [customizing a proxy](#). Since proxies are immutable, each of these "factory methods" returns a copy of the original proxy that contains the desired modification. For example, you can obtain a proxy configured with a ten second timeout as shown below:

C#

```
Ice.ObjectPrx proxy = communicator.stringToProxy(...);
proxy = proxy.ice_timeout(10000);
```

A factory method returns a new proxy object if the requested modification differs from the current proxy, otherwise it returns the current proxy. With few exceptions, factory methods return a proxy of the same type as the current proxy, therefore it is generally not necessary to

repeat a `checkedCast` or `uncheckedCast` after using a factory method. However, a regular cast is still required, as shown in the example below:

```
C#
```

```
Ice.ObjectPrx base = communicator.stringToProxy(...);
HelloPrx hello = HelloPrxHelper.checkedCast(base);
hello = (HelloPrx)hello.ice_timeout(10000); # Type is preserved
hello.sayHello();
```

The only exceptions are the factory methods `ice_facet` and `ice_identity`. Calls to either of these methods may produce a proxy for an object of an unrelated type, therefore they return a base proxy that you must subsequently down-cast to an appropriate type.

Object Identity and Proxy Comparison in C#

Proxies provide an `Equals` method that compares proxies:

```
C#
```

```
public interface ObjectPrx {
    bool Equals(object r);
}
```

Note that proxy comparison with `Equals` uses *all* of the information in a proxy for the comparison. This means that not only the object identity must match for a comparison to succeed, but other details inside the proxy, such as the protocol and endpoint information, must be the same. In other words, comparison with `Equals` (or `==` and `!=`) tests for *proxy* identity, *not* object identity. A common mistake is to write code along the following lines:

```
C#
```

```
Ice.ObjectPrx p1 = ...;           // Get a proxy...
Ice.ObjectPrx p2 = ...;           // Get another proxy...

if (!p1.Equals(p2)) {
    // p1 and p2 denote different objects           // WRONG!
} else {
    // p1 and p2 denote the same object             // Correct
}
```

Even though `p1` and `p2` differ, they may denote the same Ice object. This can happen because, for example, both `p1` and `p2` embed the same object identity, but each use a different protocol to contact the target object. Similarly, the protocols may be the same, but denote different endpoints (because a single Ice object can be contacted via several different transport endpoints). In other words, if two proxies compare equal with `Equals`, we know that the two proxies denote the same object (because they are identical in all respects); however, if two proxies compare unequal with `Equals`, we know absolutely nothing: the proxies may or may not denote the same object.

To compare the object identities of two proxies, you can use a helper function in the `Ice.Util` class:

C#

```
public sealed class Util {
    public static int proxyIdentityCompare(ObjectPrx lhs,
    ObjectPrx rhs);
    public static int proxyIdentityAndFacetCompare(ObjectPrx lhs,
    ObjectPrx rhs);
    // ...
}
```

`proxyIdentityCompare` allows you to correctly compare proxies for identity:

C#

```
Ice.ObjectPrx p1 = ...;           // Get a proxy...
Ice.ObjectPrx p2 = ...;           // Get another proxy...

if (Ice.Util.proxyIdentityCompare(p1, p2) != 0) {
    // p1 and p2 denote different objects      // Correct
} else {
    // p1 and p2 denote the same object        // Correct
}
```

The function returns 0 if the identities are equal, -1 if `p1` is less than `p2`, and 1 if `p1` is greater than `p2`. (The comparison uses `name` as the major and `category` as the minor sort key.)

The `proxyIdentityAndFacetCompare` function behaves similarly, but compares both the identity and the [facet name](#).

The C# mapping also provides two helper classes in the `Ice` namespace that allow you to insert proxies into hashtables or ordered collections, based on the identity, or the identity plus the facet name:

C#

```
public class ProxyIdentityKey
    : System.Collections.IHashCodeProvider,
      System.Collections.IComparer {

    public int GetHashCode(object obj);
    public int Compare(object obj1, object obj2);
}

public class ProxyIdentityFacetKey
    : System.Collections.IHashCodeProvider,
      System.Collections.IComparer {

    public int GetHashCode(object obj);
    public int Compare(object obj1, object obj2);
}
```

Note these classes derive from `IHashCodeProvider` and `IComparer`, so they can be used for both hash tables and ordered collections.

Basic C# Mapping for Operations

As we saw in the [C# mapping for interfaces](#), for each [operation](#) on an interface, the proxy class contains a corresponding member function with the same name. To invoke an operation, you call it via the proxy. For example, here is part of the definitions for our [file system](#):

Slice

```

module Filesystem {
    interface Node {
        idempotent string name();
    };
    // ...
};

```

The `name` operation returns a value of type `string`. Given a proxy to an object of type `Node`, the client can invoke the operation as follows:

C#

```

NodePrx node = ...;           // Initialize proxy
string name = node.name();    // Get name via RPC

```

This illustrates the typical pattern for receiving return values: return values are returned by reference for complex types, and by value for simple types (such as `int` or `double`).

Normal and idempotent Operations in C#

You can add an `idempotent` qualifier to a Slice operation. As far as the signature for the corresponding proxy method is concerned, `idempotent` has no effect. For example, consider the following interface:

Slice

```

interface Example {
    string op1();
    idempotent string op2();
};

```

The proxy interface for this is:

```

C#

public interface ExamplePrx : Ice.ObjectPrx
{
    string op1();
    string op2();
}

```

Because `idempotent` affects an aspect of call dispatch, not interface, it makes sense for the two methods to be mapped the same.

Passing Parameters in C#

In-Parameters in C#

The parameter passing rules for the C# mapping are very simple: parameters are passed either by value (for value types) or by reference (for reference types). Semantically, the two ways of passing parameters are identical: it is guaranteed that the value of a parameter will not be changed by the invocation.

Here is an interface with operations that pass parameters of various types from client to server:

```

Slice

struct NumberAndString {
    int x;
    string str;
};

sequence<string> StringSeq;

dictionary<long, StringSeq> StringTable;

interface ClientToServer {
    void op1(int i, float f, bool b, string s);
    void op2(NumberAndString ns, StringSeq ss, StringTable st);
    void op3(ClientToServer* proxy);
};

```

The Slice compiler generates the following proxy for these definitions:

C#

```
public interface ClientToServerPrx : Ice.ObjectPrx
{
    void op1(int i, float f, bool b, string s);
    void op2(NumberAndString ns, string[] ss, Dictionary<long, string[]
> st);
    void op3(ClientToServerPrx proxy);
}
```

Given a proxy to a `ClientToServer` interface, the client code can pass parameters as in the following example:

C#

```
ClientToServerPrx p = ...; // Get proxy...

p.op1(42, 3.14f, true, "Hello world!"); // Pass simple literals

int i = 42;
float f = 3.14f;
bool b = true;
string s = "Hello world!";
p.op1(i, f, b, s); // Pass simple variables

NumberAndString ns = new NumberAndString();
ns.x = 42;
ns.str = "The Answer";
string[] ss = new string[1];
ss[0] = "Hello world!";
Dictionary<long, string[]> st = new Dictionary<long, string[]>();
st[0] = ss;
p.op2(ns, ss, st); // Pass complex variables

p.op3(p); // Pass proxy
```

Out-Parameters in C#

Slice out parameters simply map to C# out parameters.

Here again are the same Slice definitions we saw earlier, but this time with all parameters being passed in the `out` direction:

Slice

```

struct NumberAndString {
    int x;
    string str;
};

sequence<string> StringSeq;

dictionary<long, StringSeq> StringTable;

interface ServerToClient {
    void op1(out int i, out float f, out bool b, out string s);
    void op2(out NumberAndString ns, out StringSeq ss,
out StringTable st);
    void op3(out ServerToClient* proxy);
};

```

The Slice compiler generates the following code for these definitions:

C#

```

public interface ServerToClientPrx : Ice.ObjectPrx
{
    void op1(out int i, out float f, out bool b, out string s);
    void op2(out NumberAndString ns,
        out string[] ss,
        out Dictionary<long, string[]> st);
    void op3(out ServerToClientPrx proxy);
}

```

Given a proxy to a `ServerToClient` interface, the client code can pass parameters as in the following example:

C#

```

ClientToServerPrx p = ...;           // Get proxy...

int i;
float f;
bool b;
string s;
p.op1(out i, out f, out b, out s);

NumberAndString ns;
string[] ss;
Dictionary<long, string[]> st;
p.op2(out ns, out ss, out st);

ServerToClientPrx stc;
p.op3(out stc);

System.Console.WriteLine(i); // Show one of the values

```

Null Parameters in C#

Some Slice types naturally have "empty" or "not there" semantics. Specifically, C# sequences (if mapped to `CollectionBase`), dictionaries, strings, and structures (if mapped to `classes`) all can be `null`, but the corresponding Slice types do not have the concept of a null value.

- Slice sequences, dictionaries, and strings cannot be null, but can be empty. To make life with these types easier, whenever you pass a C# `null` reference as a parameter or return value of type sequence, dictionary, or string, the Ice run time automatically sends an empty sequence, dictionary, or string to the receiver.
- If you pass a C# `null` reference to a Slice structure that is mapped to a C# `class` as a parameter or return value, the Ice run time automatically sends a structure whose elements are default-initialized. This means that all proxy members are initialized to `null`, sequence and dictionary members are initialized to empty collections, strings are initialized to the empty string, and members that have a value type are initialized to their default values.

This behavior is useful as a convenience feature: especially for deeply-nested data types, members that are structures, sequences, dictionaries, or strings automatically arrive as an empty value at the receiving end. This saves you having to explicitly initialize, for example, every string element in a large sequence before sending the sequence in order to avoid `NullReferenceException`. Note that using null parameters in this way does *not* create null semantics for Slice sequences, dictionaries, or strings. As far as the object model is concerned, these do not exist (only *empty* sequences, dictionaries, and strings do). For example, whether you send a string as `null` or as an empty string makes no difference to the receiver: either way, the receiver sees an empty string.

Optional Parameters in C#

The mapping for `optional parameters` is the same as for required parameters, except each optional parameter is encapsulated in an `Ice.Optional` value. Consider the following operation:

Slice

```
optional(1) int execute(optional(2) string params, out optional(3) float
value);
```

The C# mapping for this operation is shown below:

C#

```
Ice.Optional<int> execute(Ice.Optional<string> params, out
Ice.Optional<float> value, ...);
```

The constructors and conversion operators provided by the `Ice.Optional` type simplify the use of optional parameters:

C#

```
Ice.Optional<int> i;
Ice.Optional<float> v;

i = proxy.execute("--file log.txt", out v); // string converted to
Optional<string>
i = proxy.execute(Ice.Util.None, out v);    // params is unset

if(v.HasValue)
    Console.WriteLine("value = " + v.Value);
```

A well-behaved program must not assume that an optional parameter always has a value.

Exception Handling in C#

Any operation invocation may throw a [run-time exception](#) and, if the operation has an exception specification, may also throw [user exceptions](#). Suppose we have the following simple interface:

Slice

```
exception Tantrum {
    string reason;
};

interface Child {
    void askToCleanUp() throws Tantrum;
};
```

Slice exceptions are thrown as C# exceptions, so you can simply enclose one or more operation invocations in a `try-catch` block:

```

C#

```
ChildPrx child = ...; // Get child proxy...

try
{
 child.askToCleanUp();
}
catch (Tantrum t)
{
 System.Console.Write("The child says: ");
 System.Console.WriteLine(t.reason);
}
```

```

Typically, you will catch only a few exceptions of specific interest around an operation invocation; other exceptions, such as unexpected run-time errors, will typically be handled by exception handlers higher in the hierarchy. For example:

C#

```

public class Client
{
    private static void run() {
        ChildPrx child = ...;           // Get child proxy...
        try
        {
            child.askToCleanUp();
        }
        catch (Tantrum t)
        {
            System.Console.WriteLine("The child says: ");
            System.Console.WriteLine(t.reason);
            child.scold();               // Recover from error...
        }
        child.praise();                 // Give positive feedback...
    }

    static void Main(string[] args)
    {
        try
        {
            // ...
            run();
            // ...
        }
        catch (Ice.Exception e)
        {
            System.Console.WriteLine(e);
        }
    }
}

```

This code handles a specific exception of local interest at the point of call and deals with other exceptions generically. (This is also the strategy we used for our [first simple application](#).)

Note that the `ToString` method of exceptions prints the name of the exception, any inner exceptions, and the stack trace. Of course, you can be more selective in the way exceptions are displayed. For example, `e.GetType().Name` returns the (unscoped) name of an exception.

Exceptions and Out-Parameters in C#

The Ice run time makes no guarantees about the state of out-parameters when an operation throws an exception: the parameter may still have its original value or may have been changed by the operation's implementation in the target object. In other words, for out-parameters, Ice provides the weak exception guarantee [1] but does not provide the strong exception guarantee.

This is done for reasons of efficiency: providing the strong exception guarantee would require more overhead than can be justified.

Basic C# Mapping for Classes

A Slice `class` is mapped to a C# class with the same name. By default, the generated class contains a public data member for each Slice data member (just as for structures and exceptions), and a member function for each operation. Alternatively, you can use the [property mapping](#) by specifying the `"clr:property"` metadata directive, which generates classes with virtual properties instead of data members.

Consider the following class definition:

Slice	
<pre>class TimeOfDay { short hour; // 0 - 23 short minute; // 0 - 59 short second; // 0 - 59 string format(); // Return time as hh:mm:ss };</pre>	

The Slice compiler generates the following code for this definition:

C#

```

public interface TimeOfDayOperations_
{
    string format(Ice.Current __current);
}

public interface TimeOfDayOperationsNC_
{
    string format();
}

public abstract partial class TimeOfDay
    : Ice.ObjectImpl,
      TimeOfDayOperations_,
      TimeOfDayOperationsNC_
{
    public short hour;
    public short minute;
    public short second;

    public TimeOfDay()
    {
    }

    public TimeOfDay(short hour, short minute, short second)
    {
        this.hour = hour;
        this.minute = minute;
        this.second = second;
    }

    public string format()
    {
        return format(new Ice.Current());
    }

    public abstract string format(Ice.Current __current);
}

```

There are a number of things to note about the generated code:

1. The compiler generates "operations interfaces" called `TimeOfDayOperations_` and `TimeOfDayOperationsNC_`. These interfaces contain a method for each Slice operation of the class.
2. The generated class `TimeOfDay` inherits (indirectly) from `Ice.Object`. This means that all classes implicitly inherit from `Ice.Object`, which is the ultimate ancestor of all classes. Note that `Ice.Object` is *not* the same as `Ice.ObjectPrx`. In other words, you *cannot* pass a class where a proxy is expected and vice versa. If a class has only data members, but no operations, the compiler generates a non-abstract class.
3. The generated class contains a public member for each Slice data member.
4. The generated class inherits member functions for each Slice operation from the operations interfaces.

5. The generated class contains two constructors.

There is quite a bit to discuss here, so we will look at each item in turn.

Operations Interfaces in C#

The methods in the `<interface-name>Operations_` interface have an additional trailing parameter of type `Ice.Current`, whereas the methods in the `<interface-name>OperationsNC_` interface lack this additional trailing parameter. The methods without the `Current` parameter simply forward to the methods with a `Current` parameter, supplying a default `Current`. For now, you can ignore this parameter and pretend it does not exist.

If a class has only data members, but no operations, the compiler omits generating the `<interface-name>Operations_` and `<interface-name>OperationsNC_` interfaces.

Inheritance from `Ice.Object` in C#

Like interfaces, classes implicitly inherit from a common base class, `Ice.Object`. However, as shown in the illustration below, classes inherit from `Ice.Object` instead of `Ice.ObjectPrx` (which is at the base of the inheritance hierarchy for proxies). As a result, you cannot pass a class where a proxy is expected (and vice versa) because the base types for classes and proxies are not compatible.

Inheritance from `Ice.ObjectPrx` and `Ice.Object`.

`Ice.Object` contains a number of member functions:

C#

```

namespace Ice
{
    public interface Object : System.ICloneable
    {
        bool ice_isA(string s);
        bool ice_isA(string s, Current current);

        void ice_ping();
        void ice_ping(Current current);

        string[] ice_ids();
        string[] ice_ids(Current current);

        string ice_id();
        string ice_id(Current current);

        void ice_preMarshal();
        void ice_postUnmarshal();

        DispatchStatus ice_dispatch(Request request,
        DispatchInterceptorAsyncCallback cb);
    }
}

```

The member functions of `Ice.Object` behave as follows:

- `ice_isA`
This function returns `true` if the object supports the given `type ID`, and `false` otherwise.
- `ice_ping`
As for interfaces, `ice_ping` provides a basic reachability test for the class.
- `ice_ids`
This function returns a string sequence representing all of the `type IDs` supported by this object, including `::Ice::Object`.
- `ice_id`
This function returns the actual run-time `type ID` for a class. If you call `ice_id` through a reference to a base instance, the returned `type id` is the actual (possibly more derived) `type ID` of the instance.
- `ice_preMarshal`
The Ice run time invokes this function prior to marshaling the object's state, providing the opportunity for a subclass to validate its declared data members.
- `ice_postUnmarshal`
The Ice run time invokes this function after unmarshaling an object's state. A subclass typically overrides this function when it needs to perform additional initialization using the values of its declared data members.
- `ice_dispatch`
This function dispatches an incoming request to a servant. It is used in the implementation of `dispatch interceptors`.

Note that the generated class does *not* override `GetHashCode` and `Equals`. This means that classes are compared using shallow reference equality, not value equality (as is used for structures).

The class also provides a `Clone` method (whose implementation is inherited from `Ice.ObjectImpl`); the `Clone` method returns a shallow

memberwise copy.

Class Data Members in C#

By default, data members of classes are mapped exactly as for structures and exceptions: for each data member in the Slice definition, the generated class contains a corresponding public data member. [Optional data members](#) are mapped to instances of the `Ice.Optional` type.

If you wish to restrict access to a data member, you can modify its visibility using the `protected` metadata directive. The presence of this directive causes the Slice compiler to generate the data member with protected visibility. As a result, the member can be accessed only by the class itself or by one of its subclasses. For example, the `TimeOfDay` class shown below has the `protected` metadata directive applied to each of its data members:

Slice
<pre>class TimeOfDay { ["protected"] short hour; // 0 - 23 ["protected"] short minute; // 0 - 59 ["protected"] short second; // 0 - 59 string format(); // Return time as hh:mm:ss };</pre>

The Slice compiler produces the following generated code for this definition:

C#
<pre>public abstract partial class TimeOfDay : Ice.ObjectImpl, TimeOfDayOperations_, TimeOfDayOperationsNC_ { protected short hour; protected short minute; protected short second; public TimeOfDay() { } public TimeOfDay(short hour, short minute, short second) { this.hour = hour; this.minute = minute; this.second = second; } // ... }</pre>

For a class in which all of the data members are protected, the metadata directive can be applied to the class itself rather than to each member individually. For example, we can rewrite the `TimeOfDay` class as follows:

Slice
<pre>["protected"] class TimeOfDay { short hour; // 0 - 23 short minute; // 0 - 59 short second; // 0 - 59 string format(); // Return time as hh:mm:ss };</pre>

If a protected data member also has the `clr:property` directive, the generated property has protected visibility. Consider the `TimeOfDay` class once again:

Slice
<pre>["protected", "clr:property"] class TimeOfDay { short hour; // 0 - 23 short minute; // 0 - 59 short second; // 0 - 59 string format(); // Return time as hh:mm:ss };</pre>

The effects of combining these two metadata directives are shown in the generated code below:

C#
<pre>public abstract partial class TimeOfDay : Ice.ObjectImpl, TimeOfDayOperations_, TimeOfDayOperationsNC_ { private short hour_prop; protected short hour { get { return hour_prop; } set { hour_prop = value; } } // ... }</pre>

Refer to the [structure mapping](#) for more information on the property mapping for data members.

Class Operations in C#

Operations of classes are mapped to abstract member functions in the generated class. This means that, if a class contains operations (such as the `format` operation of our `TimeOfDay` class), you must provide an implementation of the operation in a class that is derived from the generated class. For example:

```

C#

```

public class TimeOfDayI : TimeOfDay
{
 public string format(Ice.Current current)
 {
 return hour.ToString("D2") + ":"
 + minute.ToString("D2") + ":"
 + second.ToString("D2");
 }
}

```

```

Class Factories in C#

Having created a class such as `TimeOfDayI`, we have an implementation and we can instantiate the `TimeOfDayI` class, but we cannot receive it as the return value or as an out-parameter from an operation invocation. To see why, consider the following simple interface:

```

Slice

```

interface Time {
 TimeOfDay get();
};

```

```

When a client invokes the `get` operation, the Ice run time must instantiate and return an instance of the `TimeOfDay` class. However, `TimeOfDay` is an abstract class that cannot be instantiated. Unless we tell it, the Ice run time cannot magically know that we have created a `TimeOfDayI` class that implements the abstract `format` operation of the `TimeOfDay` abstract class. In other words, we must provide the Ice run time with a factory that knows that the `TimeOfDay` abstract class has a `TimeOfDayI` concrete implementation. The `Ice::CommunicatorI` interface provides us with the necessary operations:

Slice

```

module Ice {
    local interface ObjectFactory {
        Object create(string type);
        void destroy();
    };

    local interface Communicator {
        void addObjectFactory(ObjectFactory factory, string id);
        ObjectFactory findObjectFactory(string id);
        // ...
    };
};

```

To supply the Ice run time with a factory for our `TimeOfDayI` class, we must implement the `ObjectFactory` interface:

C#

```

class ObjectFactory : Ice.ObjectFactory
{
    public Ice.Object create(string type)
    {
        if (type.Equals(M.TimeOfDay.ice_staticId()))
            return new TimeOfDayI();
        System.Diagnostics.Debug.Assert(false);
        return null;
    }

    public void destroy()
    {
        // Nothing to do
    }
}

```

The object factory's `create` method is called by the Ice run time when it needs to instantiate a `TimeOfDay` class. The factory's `destroy` method is called by the Ice run time when its communicator is destroyed.

The `create` method is passed the `type ID` of the class to instantiate. For our `TimeOfDay` class, the type ID is `"::M::TimeOfDay"`. Our implementation of `create` checks the type ID: if it matches, the method instantiates and returns a `TimeOfDayI` object. For other type IDs, the method asserts because it does not know how to instantiate other types of objects.

Note that we used the `ice_staticId` method to obtain the type ID rather than embedding a literal string. Using a literal type ID string in your code is discouraged because it can lead to errors that are only detected at run time. For example, if a Slice class or one of its enclosing modules is renamed and the literal string is not changed accordingly, a receiver will fail to unmarshal the object and the Ice run time will raise `NoObjectFactoryException`. By using `ice_staticId` instead, we avoid any risk of a misspelled or obsolete type ID, and we can discover at compile time if a Slice class or module has been renamed.

Given a factory implementation, such as our `ObjectFactory`, we must inform the Ice run time of the existence of the factory:

C#

```
Ice.Communicator ic = ...;
ic.addObjectFactory(new ObjectFactory(), M.TimeOfDay.ice_staticId());
```

Now, whenever the Ice run time needs to instantiate a class with the type ID "`::M::TimeOfDay`", it calls the `create` method of the registered `ObjectFactory` instance, which returns a `TimeOfDayI` instance to the Ice run time.

The `destroy` operation of the object factory is invoked by the Ice run time when the communicator is destroyed. This gives you a chance to clean up any resources that may be used by your factory. Do not call `destroy` on the factory while it is registered with the communicator — if you do, the Ice run time has no idea that this has happened and, depending on what your `destroy` implementation is doing, may cause undefined behavior when the Ice run time tries to next use the factory.

The run time guarantees that `destroy` will be the last call made on the factory, that is, `create` will not be called concurrently with `destroy`, and `create` will not be called once `destroy` has been called. However, calls to `create` can be made concurrently.

Note that you cannot register a factory for the same type ID twice: if you call `addObjectFactory` with a type ID for which a factory is registered, the Ice run time throws an `AlreadyRegisteredException`.

Finally, keep in mind that if a class has only data members, but no operations, you need not create and register an object factory to transmit instances of such a class. Only if a class has operations do you have to define and register an object factory.

Class Constructors in C#

A class has a default constructor that initializes data members as follows:

Data Member Type	Default Value
<code>string</code>	Empty string
<code>enum</code>	Zero
<code>struct</code>	Default-constructed value
Numeric	Zero
<code>bool</code>	False
<code>sequence</code>	Null
<code>dictionary</code>	Null
<code>class/interface</code>	Null

The constructor won't explicitly initialize a data member if the default C# behavior for that type produces the desired results.

If you wish to ensure that data members of primitive and enumerated types are initialized to specific values, you can declare default values in your [Slice definition](#). The default constructor initializes each of these data members to its declared value instead.

A class also provides a constructor that accepts one argument for each member of the class. This allows you to create and initialize a class in a single statement, for example:

C#

```
TimeOfDayI tod = new TimeOfDayI(14, 45, 00); // 2:45pm
```

For a derived class, the constructor requires one argument for every member of the class, including inherited members. For example, consider the the definition from [Class Inheritance](#) once more:

Slice

```
class TimeOfDay {
    short hour;          // 0 - 23
    short minute;       // 0 - 59
    short second;       // 0 - 59
};

class DateTime extends TimeOfDay {
    short day;          // 1 - 31
    short month;        // 1 - 12
    short year;         // 1753 onwards
};
```

The Slice compiler generates the following constructors for these types:

C#

```

public partial class TimeOfDay : Ice.ObjectImpl
{
    public TimeOfDay() {}

    public TimeOfDay(short hour, short minute, short second)
    {
        this.hour = hour;
        this.minute = minute;
        this.second = second;
    }

    // ...
}

public partial class DateTime : TimeOfDay
{
    public DateTime() : base() {}

    public DateTime(short hour,
                    short minute,
                    short second,
                    short day,
                    short month,
                    short year) : base(hour, minute, second)
    {
        this.day = day;
        this.month = month;
        this.year = year;
    }

    // ...
}

```

If you want to instantiate and initialize a `DateTime` instance, you must either use the default constructor or provide values for all of the data members of the instance, including data members of its base class.

For each optional data member of a class, the constructor accepts an `Ice.Optional` parameter of the appropriate type. You can pass the value `Ice.Util.None` as the value of any optional data member to initialize it to an unset condition.

C-Sharp Mapping for Optional Values

On this page:

- [The Ice.Optional Type](#)
- [The Ice.Util.None Value](#)

The Ice.Optional Type

The C# mapping uses a generic structure to hold the values of optional data members and parameters:

```

C#

namespace Ice
{
    public struct NoneType {}

    [Serializable]
    public struct Optional<T> : System.ISerializable {
        public Optional(NoneType none);
        public Optional(T v);
        public Optional(Optional<T> v);

        public static explicit operator T(Optional<T> v);
        public static implicit operator Optional<T>(T v);
        public static implicit operator Optional<T>(NoneType v);

        public T Value { get; }
        public bool HasValue { get; }

        public override bool Equals(object other);
        public override int GetHashCode();

        ...
    }
}

```

The `Ice.Optional` type provides constructors and conversion operators that allow you to initialize an instance using the element type or an existing optional value. The default constructor initializes an instance to an unset condition. The `Value` property and conversion operator retrieve the current value held by the instance, or throw `System.InvalidOperationException` if no value is currently set. Use the `HasValue` property to test whether the instance has a value prior to accessing it.

The implicit conversion operators allow you to initialize an `Optional` instance without a cast. However, the conversion operator that extracts the current value is declared as `explicit` and therefore requires a cast:

C#

```
Ice.Optional<int> i = 5; // No cast necessary
int j = i;             // Error!
int k = (int)i;       // OK
```

This operator raises an exception if no value is set, so the proper way to write this is shown below:

C#

```
Ice.Optional<int> i = 5;
int j;
if(i.HasValue)
    j = (int)i;
else
    ...
```

The Ice.Util.None Value

The `Ice.Optional` type provides a constructor and conversion operator that accept `NoneType`. Ice defines an instance of this type, `Ice.Util.None`, that you can use to initialize (or reset) an `Optional` instance to an unset condition:

C#

```
Ice.Optional<int> i = 5;
i = Ice.Util.None;
Debug.Assert(!i.HasValue); // true
```

You can pass `Ice.Util.None` anywhere an `Ice.Optional` value is expected.

Serializable Objects in C-Sharp

In addition to serializing Slice types, applications may also need to incorporate foreign types into their Slice definitions. Ice allows you to pass CLR serializable objects directly as operation parameters or as fields of another data type. For example:

```

Slice

["clr:serializable:SomeNamespace.CLRClass"]
sequence<byte> CLRObj;
struct MyStruct {
    int i;
    CLRObj o;
};

interface Example {
    void op(CLRObj o, MyStruct s);
};

```

The generated code for `MyStruct` contains member `i` of type `int` and a member `o` of type `SomeNamespace.CLRClass`:

```

C#

public partial class MyStruct : _System.ICloneable {
    public int i;
    public SomeNamespace.CLRClass o;

    // ...
}

```

Similarly, the signature for `op` has parameters of type `CLRClass` and `MyStruct`:

```

C#

void op(SomeNamespace.CLRClass o, MyStruct s);

```

Of course, your client and server code must have an implementation of `CLRClass` that sets the `Serializable` attribute:

C#

```
namespace SomeNamespace {  
    [Serializable]  
    public class CLRClass {  
        // ...  
    }  
}
```

You can implement this class in any way you see fit — the Ice run time does not place any other requirements on the implementation. However, note that the CLR requires the class to reside in the same assembly for client and server.

C-Sharp Specific Metadata Directives

The `slice2cs` compiler supports `metadata` directives that allow you to inject C# attribute specifications into the generated code. The metadata directive is `cs:attribute:.` For example:

Slice
<pre>["cs:attribute:System.Serializable"] struct Point { double x; double y; };</pre>

This results in the following code being generated for S:

C#
<pre>[System.Serializable] public partial struct Point { public double x; public double y; // ... }</pre>

You can apply this metadata directive to any Slice construct, such as structure, operation, or parameter definitions.

You can use this directive also at global level. For example:

Slice
<pre>[["cs:attribute:assembly: AssemblyDescription(\"My assembly\")"]]</pre>

This results in the following code being inserted after any `using` directives and before any definitions:

C#
<pre>[assembly: AssemblyDescription("My assembly")]</pre>

Asynchronous Method Invocation (AMI) in C-Sharp

Asynchronous Method Invocation (AMI) is the term used to describe the client-side support for the asynchronous programming model. AMI supports both oneway and twoway requests, but unlike their synchronous counterparts, AMI requests never block the calling thread. When a client issues an AMI request, the Ice run time hands the message off to the local transport buffer or, if the buffer is currently full, queues the request for later delivery. The application can then continue its activities and poll or wait for completion of the invocation, or receive a callback when the invocation completes.

AMI is transparent to the server: there is no way for the server to tell whether a client sent a request synchronously or asynchronously.

Basic Asynchronous API in C#

Consider the following simple Slice definition:

Slice

```

module Demo {
    interface Employees {
        string getName(int number);
    };
};

```

Asynchronous Proxy Methods in C#

Besides the synchronous proxy methods, `slice2cs` generates the following asynchronous proxy methods:

C#

```
public interface EmployeesPrx : Ice.ObjectPrx {
    Ice.AsyncResult<Demo.Callback_Employees_getName>
    begin_getName(int number);

    Ice.AsyncResult<Demo.Callback_Employees_getName>
    begin_getName(int number,

    _System.Collections.Generic.Dictionary<string, string> ctx__);

    string end_getName(Ice.AsyncResult r__);
}
```

Two additional overloads of `begin_getName` are generated for use with [generic completion callbacks](#).

As you can see, the single `getName` operation results in `begin_getName` and `end_getName` methods. (The `begin_` method is overloaded so you can pass a [per-invocation context](#).)

- The `begin_getName` method sends (or queues) an invocation of `getName`. This method does not block the calling thread.
- The `end_getName` method collects the result of the asynchronous invocation. If, at the time the calling thread calls `end_getName`, the result is not yet available, the calling thread blocks until the invocation completes. Otherwise, if the invocation completed some time before the call to `end_getName`, the method returns immediately with the result.

A client could call these methods as follows:

C#

```
EmployeesPrx e = ...;
Ice.AsyncResult r = e.begin_getName(99);

// Continue to do other things here...

string name = e.end_getName(r);
```

Because `begin_getName` does not block, the calling thread can do other things while the operation is in progress.

Note that `begin_getName` returns a value of type `Ice.AsyncResult`. (The class derives from `System.IAsyncResult`.) This value contains the state that the Ice run time requires to keep track of the asynchronous invocation. You must pass the `AsyncResult` that is returned by the `begin_` method to the corresponding `end_` method.

The `begin_` method has one parameter for each in-parameter of the corresponding Slice operation. Similarly, the `end_` method has one out-parameter for each out-parameter of the corresponding Slice operation (plus the `AsyncResult` parameter). For example, consider the following operation:

Slice

```
double op(int inp1, string inp2, out bool outp1, out long outp2);
```

The `begin_op` and `end_op` methods have the following signature:

C#

```
Ice.AsyncResult<Demo.Callback_Employees_op>
begin_op(int inp1, string inp2);

double end_op(out bool outp1, out long outp2, Ice.AsyncResult r__);
```

Asynchronous Exception Semantics in C#

If an invocation raises an exception, the exception is thrown by the `end_` method, even if the actual error condition for the exception was encountered during the `begin_` method ("on the way out"). The advantage of this behavior is that all exception handling is located with the code that calls the `end_` method (instead of being present twice, once where the `begin_` method is called, and again where the `end_` method is called).

There is one exception to the above rule: if you destroy the communicator and then make an asynchronous invocation, the `begin_` method throws `CommunicatorDestroyedException`. This is necessary because, once the run time is finalized, it can no longer throw an exception from the `end_` method.

The only other exception that is thrown by the `begin_` and `end_` methods is `System.ArgumentException`. This exception indicates that you have used the API incorrectly. For example, the `begin_` method throws this exception if you call an operation that has a return value or out-parameters on a oneway proxy. Similarly, the `end_` method throws this exception if you use a different proxy to call the `end_` method than the proxy you used to call the `begin_` method, or if the `AsyncResult` you pass to the `end_` method was obtained by calling the `begin_` method for a different operation.

AsyncResult Interface in C#

The `AsyncResult` that is returned by the `begin_` method encapsulates the state of the asynchronous invocation:

C#

```

public interface AsyncResult : System.IAsyncResult
{
    void cancel();

    Ice.Communicator getCommunicator();
    Ice.Connection getConnection();
    ObjectPrx getProxy();
    string getOperation();
    object AsyncState { get; }

    bool IsCompleted { get; }
    void waitForCompleted();

    bool isSent();
    void waitForSent();

    void throwLocalException();

    bool sentSynchronously();

    AsyncResult whenSent(Ice.AsyncCallback cb);
    AsyncResult whenSent(Ice.SentCallback cb);
    AsyncResult whenCompleted(Ice.ExceptionCallback ex);
}

public interface AsyncResult<T> : AsyncResult
{
    AsyncResult<T> whenCompleted(T cb, Ice.ExceptionCallback excb);

    new AsyncResult<T> whenCompleted(Ice.ExceptionCallback excb);
    new AsyncResult<T> whenSent(Ice.SentCallback cb);
}

```

The methods and properties have the following semantics:

- `void cancel()`
This method prevents a queued invocation from being sent or, if the invocation has already been sent, ignores a reply if the server sends one. `cancel` is a local operation and has no effect on the server. A canceled invocation is considered to be completed, meaning `IsCompleted` returns true, and the result of the invocation is an `Ice.InvocationCanceledException`.
- `Communicator getCommunicator()`
This method returns the communicator that sent the invocation.
- `Connection getConnection()`
This method returns the connection that was used for the invocation. Note that, for typical asynchronous proxy invocations, this method returns a nil value because the possibility of automatic retries means the connection that is currently in use could change unexpectedly. The `getConnection` method only returns a non-nil value when the `AsyncResult` object is obtained by calling `begin_flushBatchRequests` on a `Connection` object.
- `ObjectPrx getProxy()`

This method returns the proxy that was used to call the `begin_` method, or nil if the `AsyncResult` object was not obtained via an asynchronous proxy invocation.

- `string getOperation()`
This method returns the name of the operation.
- `object AsyncState { get; }`
This property stores an object that you can use to pass shared state from the `begin_` to the `end_` method.
- `bool IsCompleted { get; }`
This property is true if, at the time it is called, the result of an invocation is available, indicating that a call to the `end_` method will not block the caller. Otherwise, if the result is not yet available, the method returns false.
- `void waitForCompleted()`
This method blocks the caller until the result of an invocation becomes available.
- `bool isSent()`
When you call the `begin_` method, the Ice run time attempts to write the corresponding request to the client-side transport. If the transport cannot accept the request, the Ice run time queues the request for later transmission. `isSent` returns true if, at the time it is called, the request has been written to the local transport (whether it was initially queued or not). Otherwise, if the request is still queued or an exception occurred before the request could be sent, `isSent` returns false.
- `void waitForSent()`
This method blocks the calling thread until a request has been written to the client-side transport, or an exception occurs. After `waitForSent` returns, `isSent` returns true if the request was successfully written to the client-side transport, or false if an exception occurred. In the case of a failure, you can call the corresponding `end_` method or `throwLocalException` to obtain the exception.
- `void throwLocalException()`
This method throws the local exception that caused the invocation to fail. If no exception has occurred yet, `throwLocalException` does nothing.
- `bool sentSynchronously()`
This method returns true if a request was written to the client-side transport without first being queued. If the request was initially queued, `sentSynchronously` returns false (independent of whether the request is still in the queue or has since been written to the client-side transport).
- `AsyncResult whenSent(Ice.SentCallback cb)`
`AsyncResult<T> whenSent(Ice.SentCallback cb)`
`AsyncResult whenCompleted(Ice.ExceptionCallback ex)`
`AsyncResult<T> whenCompleted(T cb, Ice.ExceptionCallback excb)`
`AsyncResult<T> whenCompleted(Ice.ExceptionCallback excb)`
These methods allow you to specify callback methods that are called by the Ice run time. The `whenSent` methods set a callback that triggers when an asynchronous invocation is written to the client-side transport. The `whenCompleted` methods set a callback that triggers when an asynchronous invocation completes (also see [Generic Completion Callbacks in C#](#)).

Polling for Completion in C#

The `AsyncResult` methods allow you to poll for call completion. Polling is useful in a variety of cases. As an example, consider the following simple interface to transfer files from client to server:

Slice

```
interface FileTransfer
{
    void send(int offset, ByteSeq bytes);
};
```

The client repeatedly calls `send` to send a chunk of the file, indicating at which offset in the file the chunk belongs. A naïve way to transmit a file would be along the following lines:

C#

```
FileHandle file = open(...);
FileTransferPrx ft = ...;
const int chunkSize = ...;
int offset = 0;
while (!file.eof()) {
    byte[] bs;
    bs = file.read(chunkSize); // Read a chunk
    ft.send(offset, bs);      // Send the chunk
    offset += bs.Length;
}
```

This works, but not very well: because the client makes synchronous calls, it writes each chunk on the wire and then waits for the server to receive the data, process it, and return a reply before writing the next chunk. This means that both client and server spend much of their time doing nothing — the client does nothing while the server processes the data, and the server does nothing while it waits for the client to send the next chunk.

Using asynchronous calls, we can improve on this considerably:

C#

```

FileHandle file = open(...);
FileTransferPrx ft = ...;
const int chunkSize = ...;
int offset = 0;

LinkedList<Ice.AsyncResult> results = new LinkedList<Ice.AsyncResult>();
const int numRequests = 5;

while (!file.eof()) {
    byte[] bs;
    bs = file.read(chunkSize);

    // Send up to numRequests + 1 chunks asynchronously.
    Ice.AsyncResult r = ft.begin_send(offset, bs);
    offset += bs.Length;

    // Wait until this request has been passed to the transport.
    r.waitForSent();
    results.AddLast(r);

    // Once there are more than numRequests, wait for the least
    // recent one to complete.
    while (results.Count > numRequests) {
        Ice.AsyncResult r = results.First;
        results.RemoveFirst();
        r.waitForCompleted();
    }
}

// Wait for any remaining requests to complete.
while (results.Count > 0) {
    Ice.AsyncResult r = results.First;
    results.RemoveFirst();
    r.waitForCompleted();
}

```

With this code, the client sends up to `numRequests + 1` chunks before it waits for the least recent one of these requests to complete. In other words, the client sends the next request without waiting for the preceding request to complete, up to the limit set by `numRequests`. In effect, this allows the client to "keep the pipe to the server full of data": the client keeps sending data, so both client and server continuously do work.

Obviously, the correct chunk size and value of `numRequests` depend on the bandwidth of the network as well as the amount of time taken by the server to process each request. However, with a little testing, you can quickly zoom in on the point where making the requests larger or queuing more requests no longer improves performance. With this technique, you can realize the full bandwidth of the link to within a percent or two of the theoretical bandwidth limit of a native socket connection.

Generic Completion Callbacks in C#

The `begin_` method is overloaded to allow you to provide completion callbacks. Here are the corresponding methods for the `getName` operation:

```
C#
```

```
Ice.AsyncResult begin_getName(
    int number,
    Ice.AsyncCallback cb__,
    object cookie__);

Ice.AsyncResult begin_getName(
    int number,
    _System.Collections.Generic.Dictionary<string, string> ctx__,
    Ice.AsyncCallback cb__,
    object cookie__);
```

The second version of `begin_getName` lets you override the default context. (We discuss the purpose of the `cookie` parameter in the next section.) Following the in-parameters, the `begin_` method accepts a parameter of type `Ice.AsyncCallback`, which is a delegate for a callback method. The Ice run time invokes the callback method when an asynchronous operation completes. Your callback method must have `void` return type and accept a single parameter of type `AsyncResult`, for example:

```
C#
```

```
private class MyCallback
{
    public void finished(Ice.AsyncResult r)
    {
        EmployeesPrx e = (EmployeesPrx)r.getProxy();
        try {
            string name = e.end_getName(r);
            System.Console.WriteLine("Name is: " + name);
        } catch (Ice.Exception ex) {
            System.Console.Err.WriteLine("Exception is: " + ex);
        }
    }
}
```

The implementation of your callback method must call the `end_` method. The proxy for the call is available via the `getProxy` method on the `AsyncResult` that is passed by the Ice run time. The return type of `getProxy` is `Ice.ObjectPrx`, so you must down-cast the proxy to its correct type.

Your callback method should catch and handle any exceptions that may be thrown by the `end_` method. If you allow an exception to escape from the callback method, the Ice run time produces a log entry by default and ignores the exception. (You can disable the log message by setting the property `Ice.Warn.AMICallback` to zero.)

To inform the Ice run time that you want to receive a callback for the completion of the asynchronous call, you pass a delegate for your callback method to the `begin_` method:

C#

```

EmployeesPrx e = ...;

MyCallback cb = new MyCallback();
Ice.AsyncCallback del = new Ice.AsyncCallback(cb.finished);

e.begin_getName(99, del, null);

```

The trailing `null` argument specifies a cookie, which we will discuss shortly.

You can avoid explicit instantiation of the delegate and, more tersely, write:

C#

```

EmployeesPrx e = ...;

MyCallback cb = new MyCallback();
e.begin_getName(99, cb.finished, null);

```

In fact, there's often no need to define a callback class at all. An anonymous method is one alternative:

C#

```

EmployeesPrx e = ...;

e.begin_getName(99,
    delegate(Ice.AsyncResult r)
    {
        EmployeesPrx e = (EmployeesPrx)r.getProxy();
        try {
            string name = e.end_getName(r);
            System.Console.WriteLine("Name is: " + name);
        } catch (Ice.Exception ex) {
            System.Console.Err.WriteLine("Exception is: " + ex);
        }
    }, null);

```

A lambda is another alternative:

C#

```

EmployeesPrx e = ...;

e.begin_getName(99,
  r => {
    EmployeesPrx e = (EmployeesPrx)r.getProxy();
    try {
      string name = e.end_getName(r);
      System.Console.WriteLine("Name is: " + name);
    } catch (Ice.Exception ex) {
      System.Console.Err.WriteLine("Exception is: " + ex);
    }
  }, null);

```

Using Cookies for Generic Completion Callbacks in C#

It is common for the `end_` method to require access to some state that is established by the code that calls the `begin_` method. As an example, consider an application that asynchronously starts a number of operations and, as each operation completes, needs to update different user interface elements with the results. In this case, the `begin_` method knows which user interface element should receive the update, and the `end_` method needs access to that element.

The API allows you to pass such state by providing a cookie. A cookie is any class instance; the class can contain whatever data you want to pass, as well as any methods you may want to add to manipulate that data.

Here is an example implementation that stores a `Widget`. (We assume that this class provides whatever methods are needed by the `end_` method to update the display.) When you call the `begin_` method, you pass the appropriate cookie instance to inform the `end_` method how to update the display:

C#

```

// Invoke the getName operation with different widget cookies.
MyCallback cb = ...;
e.begin_getName(99, cb.finished, widget1);
e.begin_getName(24, cb.finished, widget2);

```

The `end_` method can retrieve the cookie from the `AsyncResult` by reading the `AsyncState` property. For this example, we assume that widgets have a `writeString` method that updates the relevant UI element:

C#

```

public void finished(Ice.AsyncResult r)
{
    EmployeesPrx e = (EmployeesPrx)r.getProxy();
    Widget widget = (Widget)r.AsyncState;
    try {
        string name = e.end_getName(r);
        widget.writeString(name);
    } catch (Ice.Exception ex) {
        handleException(ex);
    }
}

```

The cookie provides a simple and effective way for you to pass state between the point where an operation is invoked and the point where its results are processed. Moreover, if you have a number of operations that share common state, you can pass the same cookie instance to multiple invocations.

Type-Safe Completion Callbacks in C#

The [generic callback API](#) is not entirely type-safe:

- You must down-cast the return value of `getProxy` to the correct proxy type before you can call the `end_` method.
- You must call the correct `end_` method to match the operation called by the `begin_` method.
- You must remember to catch exceptions when you call the `end_` method; if you forget to do this, you will not know that the operation failed.

`slice2cs` generates an additional type-safe API that takes care of these chores for you. To use type-safe callbacks, you supply delegates for two callback methods:

- a success callback that is called if the operation succeeds
- a failure callback that is called if the operation raises an exception

Here is a callback class for an invocation of the `getName` operation:

C#

```

public class MyCallback
{
    public void getNameCB(string name)
    {
        System.Console.WriteLine("Name is: " + name);
    }

    public void failureCB(Ice.Exception ex)
    {
        System.Console.Err.WriteLine("Exception is: " + ex);
    }
}

```

The callback methods can have any name you prefer and must have `void` return type. The failure callback always has a single parameter of type `Ice.Exception`. The success callback parameters depend on the operation signature. If the operation has non-`void` return type, the first parameter of the success callback is the return value. The return value (if any) is followed by a parameter for each out-parameter of the corresponding Slice operation, in the order of declaration.

At the calling end, you call the `begin_` method as follows:

```
C#
```

```
MyCallback cb = new MyCallback();

e.begin_getName(99).whenCompleted(cb.getNameCB, cb.failureCB);
```

Note the `whenCompleted` method on the `AsyncResult` that is returned by the `begin_` method. This method establishes the link between the `begin_` method and the callbacks that are called by the Ice run time by setting the delegates for the success and failure methods.

It is legal to pass a null delegate for the success or failure methods. For the success callback, this is legal only for operations that have `void` return type and no out-parameters. This is useful if you do not care when the operation completes but want to know if the call failed. If you pass a null exception delegate, the Ice run time will ignore any exception that is raised by the invocation.

Defining a callback class as we've shown above is only necessary in practice when the callback has additional state to manage. In many cases, there's no need for a callback class and the delegates can be defined inline:

```
C#
```

```
e.begin_getName(99).whenCompleted(
    delegate(string name)
    {
        System.Console.WriteLine("Name is: " + name);
    },
    delegate(Ice.Exception ex)
    {
        System.Console.Err.WriteLine("Exception is: " + ex);
    });
```

Using lambda functions makes the callbacks even more compact:

```
C#
```

```
e.begin_getName(99).whenCompleted(
    name => {
        System.Console.WriteLine("Name is: " + name);
    },
    ex => {
        System.Console.Err.WriteLine("Exception is: " + ex);
    });
```

Using Cookies for Type-Safe Completion Callbacks in C#

The type-safe API does not support cookies. If you want to pass state from the `begin_` method to the `end_` method, you must use the [generic API](#) or, alternatively, place the state into the callback class containing the callback methods. Here is a simple implementation of a callback class that stores a widget that can be retrieved by the `end_` method:

```

C#

```

public class MyCallback
{
 public MyCallback(Widget w)
 {
 _w = w;
 }

 private Widget _w;

 public void getNameCB(string name)
 {
 _w.writeString(name);
 }

 public void failureCB(Ice.Exception ex)
 {
 _w.writeError(ex);
 }
}

```

```

When you call the `begin_` method, you pass the appropriate callback instance to inform the `end_` method how to update the display:

```

C#

```

EmployeesPrx e = ...;
Widget widget1 = ...;
Widget widget2 = ...;

MyCallback cb1 = new MyCallback(widget1);
MyCallback cb2 = new MyCallback(widget2);

// Invoke the getName operation with different widget callbacks.

e.begin_getName(99).whenCompleted(cb1.getNameCB, cb1.failureCB);
e.begin_getName(24).whenCompleted(cb2.getNameCB, cb2.failureCB);

```

```

Asynchronous Oneway Invocations in C#

You can invoke operations via oneway proxies asynchronously, provided the operation has `void` return type, does not have any out-parameters, and does not raise user exceptions. If you call the `begin_` method on a oneway proxy for an operation that returns values or raises a user exception, the `begin_` method throws a `System.ArgumentException`.

For the generic API, the callback method looks exactly as for a twoway invocation. However, for oneway invocations, the Ice run time does not call the callback method unless the invocation raised an exception during the `begin_` method ("on the way out").

For the type-safe API, you only specify a delegate for the failure method. For example, here is how you could call `ice_ping` asynchronously :

```
C#
```

```
ObjectPrx p = ...;
MyCallback cb = new MyCallback();
p.begin_ice_ping().whenCompleted(cb.failureCB);
```

Flow Control in C#

Asynchronous method invocations never block the thread that calls the `begin_` method: the Ice run time checks to see whether it can write the request to the local transport. If it can, it does so immediately in the caller's thread. (In that case, `AsyncResult.sentSynchronously` returns true.) Alternatively, if the local transport does not have sufficient buffer space to accept the request, the Ice run time queues the request internally for later transmission in the background. (In that case, `AsyncResult.sentSynchronously` returns false.)

This creates a potential problem: if a client sends many asynchronous requests at the time the server is too busy to keep up with them, the requests pile up in the client-side run time until, eventually, the client runs out of memory.

The API provides a way for you to implement flow control by counting the number of requests that are queued so, if that number exceeds some threshold, the client stops invoking more operations until some of the queued operations have drained out of the local transport.

For the [generic API](#), you can create an additional callback method:

```
C#
```

```
public class MyCallback
{
    public void finished(Ice.AsyncResult r)
    {
        // ...
    }

    public void sent(Ice.AsyncResult r)
    {
        // ...
    }
}
```

As with any other callback method, you are free to choose any name you like. For this example, the name of the callback method is `sent`. You inform the Ice run time that you want to be informed when a call has been passed to the local transport by calling `whenSent`:

C#

```
MyCallback cb = new MyCallback();

e.begin_getName(99).whenCompleted(cb.getNameCB,
cb.failureCB).whenSent(cb.sent);
```

If the Ice run time can immediately pass the request to the local transport, it does so and invokes the `sent` method from the thread that calls the `begin_` method. On the other hand, if the run time has to queue the request, it calls the `sent` method from a different thread once it has written the request to the local transport. In addition, you can find out from the `AsyncResult` that is returned by the `begin_` method whether the request was sent synchronously or was queued, by calling `sentSynchronously`.

For the [generic API](#), the `sent` method has the following signature:

C#

```
void sent(Ice.AsyncResult r);
```

For the [type-safe API](#), the signature is:

C#

```
void sent(bool sentSynchronously);
```

For the generic API, you can find out whether the request was sent synchronously by calling `sentSynchronously` on the `AsyncResult`. For the type-safe API, the boolean `sentSynchronously` parameter provides the same information.

The `sent` methods allow you to limit the number of queued requests by counting the number of requests that are queued and decrementing the count when the Ice run time passes a request to the local transport.

Asynchronous Batch Requests in C#

Applications that send [batched requests](#) can either flush a batch explicitly or allow the Ice run time to flush automatically. The proxy method `ice_flushBatchRequests` performs an immediate flush using the synchronous invocation model and may block the calling thread until the entire message can be sent. Ice also provides asynchronous versions of this method so you can flush batch requests asynchronously.

`begin_ice_flushBatchRequests` and `end_ice_flushBatchRequests` are proxy methods that flush any batch requests queued by that proxy.

In addition, similar methods are available on the communicator and the `Connection` object that is returned by `AsyncResult.getConnection`. These methods flush batch requests sent via the same communicator and via the same connection, respectively.

Concurrency Semantics for AMI in C#

The Ice run time always invokes your callback methods from a separate thread, with one exception: it calls the `sent` callback from the thread calling the `begin_` method if the request could be sent synchronously. In the `sent` callback, you know which thread is calling the callback by looking at the `sentSynchronously` member or parameter.

slice2cs Command-Line Options

The Slice-to-C# compiler, `slice2cs`, offers the following command-line options in addition to the standard options described in [Using the Slice Compilers](#):

- `--tie`
Generate [tie classes](#).
- `--impl`
Generate sample implementation files. This option will not overwrite an existing file.
- `--impl-tie`
Generate sample implementation files using [tie classes](#). This option will not overwrite an existing file.
- `--checksum`
Generate [checksums](#) for Slice definitions.
- `--stream`
Generate [streaming helper methods](#) for Slice types.

See Also

- [Using the Slice Compilers](#)
- [Tie Classes in C-Sharp](#)
- [Streaming Interfaces](#)

Using Slice Checksums in C-Sharp

The Slice compilers can optionally generate [checksums](#) of Slice definitions. For `slice2cs`, the `--checksum` option causes the compiler to generate checksums in each C# source file that are added to a member of the `Ice.SliceChecksums` class:

```

C#

namespace Ice {
    public sealed class SliceChecksums {
        public readonly static
        System.Collections.Generic.Dictionary<string, string> checksums;
    }
}
```

The `checksums` map is initialized automatically prior to first use; no action is required by the application.

In order to verify a server's checksums, a client could simply compare the dictionaries using the `Equals` function. However, this is not feasible if it is possible that the server might be linked with more Slice definitions than the client. A more general solution is to iterate over the local checksums as demonstrated below:

```

C#

System.Collections.Generic.Dictionary<string, string> serverChecksums =
...
foreach(System.Collections.Generic.KeyValuePair<string, string> e
in Ice.SliceChecksums.checksums) {
    string checksum;
    if (!serverChecksums.TryGetValue(e.Key, out checksum)) {
        // No match found for type id!
    } else if (!checksum.Equals(e.Value)) {
        // Checksum mismatch!
    }
}
```

In this example, the client first verifies that the server's dictionary contains an entry for each Slice type ID, and then it proceeds to compare the checksums.

Example of a File System Client in C-Sharp

This page presents a very simple client to access a server that implements the file system we developed in [Slice for a Simple File System](#). The C# code hardly differs from the code you would write for an ordinary C# program. This is one of the biggest advantages of using Ice: accessing a remote object is as easy as accessing an ordinary, local C# object. This allows you to put your effort where you should, namely, into developing your application logic instead of having to struggle with arcane networking APIs. This is true for the server side as well, meaning that you can develop distributed applications easily and efficiently.

We now have seen enough of the client-side C# mapping to develop a complete client to access our remote file system. For reference, here is the Slice definition once more:

```

Slice

module Filesystem {
    interface Node {
        idempotent string name();
    };

    exception GenericError {
        string reason;
    };

    sequence<string> Lines;

    interface File extends Node {
        idempotent Lines read();
        idempotent void write(Lines text) throws GenericError;
    };

    sequence<Node*> NodeSeq;

    interface Directory extends Node {
        idempotent NodeSeq list();
    };
};
```

To exercise the file system, the client does a recursive listing of the file system, starting at the root directory. For each node in the file system, the client shows the name of the node and whether that node is a file or directory. If the node is a file, the client retrieves the contents of the file and prints them.

The body of the client code looks as follows:

```

C#

using System;
using Filesystem;

public class Client
{
    // Recursively print the contents of directory "dir"
    // in tree fashion. For files, show the contents of
```

```

// each file. The "depth" parameter is the current
// nesting level (for indentation).

static void listRecursive(DirectoryPrx dir, int depth)
{
    string indent = new string('\t', ++depth);

    NodePrx[] contents = dir.list();

    foreach (NodePrx node in contents)
        DirectoryPrx subdir = DirectoryPrxHelper.checkedCast(node);
        FilePrx file = FilePrxHelper.uncheckedCast(node);
        Console.WriteLine(
            indent + node.name() +
(subdir != null ? " (directory):" : " (file):"));
        if (subdir != null) {
            listRecursive(subdir, depth);
        } else {
            string[] text = file.read();
            for (int j = 0; j < text.Length; ++j)
                Console.WriteLine(indent + "\t" + text[j]);
        }
    }
}

public static void Main(string[] args)
{
    int status = 0;
    try {
        // Create a communicator
        //
        using(Ice.Communicator ic = Ice.Util.initialize(ref args)) {
            // Create a proxy for the root directory
            //
            Ice.ObjectPrx obj
= ic.stringToProxy("RootDir:default -p 10000");

            // Down-cast the proxy to a Directory proxy
            //
            DirectoryPrx rootDir
= DirectoryPrxHelper.checkedCast(obj);

            // Recursively list the contents of the root directory
            //
            Console.WriteLine("Contents of root directory:");
            listRecursive(rootDir, 0);
        }
    } catch (Exception e) {
        Console.Error.WriteLine(e);
        status = 1;
    }
}

```

```
}  
Environment.Exit(status);
```

```

    }
}

```

The `Client` class defines two methods: `listRecursive`, which is a helper function to print the contents of the file system, and `Main`, which is the main program. Let us look at `Main` first:

1. The structure of the code in `Main` follows what we saw in [Hello World Application](#). After initializing the run time, the client creates a proxy to the root directory of the file system. For this example, we assume that the server runs on the local host and listens using the default protocol (TCP/IP) at port 10000. The object identity of the root directory is known to be `RootDir`.
2. The client down-casts the proxy to `DirectoryPrx` and passes that proxy to `listRecursive`, which prints the contents of the file system.

Most of the work happens in `listRecursive`. The function is passed a proxy to a directory to list, and an indent level. (The indent level increments with each recursive call and allows the code to print the name of each node at an indent level that corresponds to the depth of the tree at that node.) `listRecursive` calls the `list` operation on the directory and iterates over the returned sequence of nodes:

1. The code does a `checkedCast` to narrow the `Node` proxy to a `Directory` proxy, as well as an `uncheckedCast` to narrow the `Node` proxy to a `File` proxy. Exactly one of those casts will succeed, so there is no need to call `checkedCast` twice: if the `Node` is a `Directory`, the code uses the `DirectoryPrx` returned by the `checkedCast`; if the `checkedCast` fails, we *know* that the `Node` is a `File` and, therefore, an `uncheckedCast` is sufficient to get a `FilePrx`.
In general, if you know that a down-cast to a specific type will succeed, it is preferable to use an `uncheckedCast` instead of a `checkedCast` because an `uncheckedCast` does not incur any network traffic.
2. The code prints the name of the file or directory and then, depending on which cast succeeded, prints "(directory)" or "(file)" following the name.
3. The code checks the type of the node:
 - If it is a directory, the code recurses, incrementing the indent level.
 - If it is a file, the code calls the `read` operation on the file to retrieve the file contents and then iterates over the returned sequence of lines, printing each line.

Assume that we have a small file system consisting of two files and a directory as follows:

A small file system.

The output produced by the client for this file system is:

```
Contents of root directory:
```

```
  README (file):
```

```
    This file system contains a collection of poetry.
```

```
  Coleridge (directory):
```

```
    Kubla_Khan (file):
```

```
      In Xanadu did Kubla Khan
```

```
      A stately pleasure-dome decree:
```

```
      Where Alph, the sacred river, ran
```

```
      Through caverns measureless to man
```

```
      Down to a sunless sea.
```

Note that, so far, our client (and server) are not very sophisticated:

- The protocol and address information are hard-wired into the code.
- The client makes more remote procedure calls than strictly necessary; with minor redesign of the Slice definitions, many of these calls can be avoided.

We will see how to address these shortcomings in our discussions of [IceGrid](#) and [object life cycle](#).

Server-Side Slice-to-C-Sharp Mapping

The mapping for Slice data types to C# is identical on the client side and server side. This means that everything in the [Client-Side Slice-to-C-Sharp Mapping](#) also applies to the server side. However, for the server side, there are a few additional things you need to know — specifically, how to:

- Initialize and finalize the server-side run time
- Implement servants
- Pass parameters and throw exceptions
- Create servants and register them with the Ice run time.

Because the mapping for Slice data types is identical for clients and servers, the server-side mapping only adds a few additional mechanisms to the client side: a small API to initialize and finalize the run time, plus a few rules for how to derive servant classes from skeletons and how to register servants with the server-side run time.

Although the examples we present in this chapter are very simple, they accurately reflect the basics of writing an Ice server. Of course, for more sophisticated servers, you will be using [additional APIs](#), for example, to improve performance or scalability. However, these APIs are all described in Slice, so, to use these APIs, you need not learn any C# mapping rules beyond those described here.

The Server-Side main Method in C-Sharp

On this page:

- [A Basic Main Method in C#](#)
- [The Ice.Application Class in C#](#)
 - [Using Ice.Application on the Client Side in C#](#)
 - [Catching Signals in C#](#)
 - [Ice.Application and Properties in C#](#)
 - [Limitations of Ice.Application in C#](#)

A Basic Main Method in C#

The main entry point to the Ice run time is represented by the local interface `Ice::Communicator`. As for the client side, you must initialize the Ice run time by calling `Ice.Util.initialize` before you can do anything else in your server. `Ice.Util.initialize` returns a reference to an instance of an `Ice.Communicator`:

C#

```

using System;

public class Server
{
    public static void Main(string[] args)
    {
        int status = 0;
        Ice.Communicator communicator = null;

        try {
            communicator = Ice.Util.initialize(ref args);
            // ...
        } catch (Exception ex) {
            Console.Error.WriteLine(ex);
            status = 1;
        }
        // ...
    }
}

```

`Ice.Util.initialize` accepts the argument vector that is passed to `Main` by the operating system. The method scans the argument vector for any [command-line options](#) that are relevant to the Ice run time; any such options are removed from the argument vector so, when `Ice.Util.initialize` returns, the only options and arguments remaining are those that concern your application. If anything goes wrong during initialization, `initialize` throws an exception.

Before leaving your `Main` method, you *must* call `Communicator.destroy`. The `destroy` operation is responsible for finalizing the Ice run time. In particular, `destroy` waits for any operation implementations that are still executing in the server to complete. In addition, `destroy` ensures that any outstanding threads are joined with and reclaims a number of operating system resources, such as file descriptors and memory. Never allow your `Main` method to terminate without calling `destroy` first; doing so has undefined behavior.

The general shape of our server-side `Main` method is therefore as follows:

C#

```

using System;

public class Server
{
    public static void Main(string[] args)
    {
        int status = 0;
        Ice.Communicator communicator = null;

        try {
            communicator = Ice.Util.initialize(ref args);
            // ...
        } catch (Exception ex) {
            Console.Error.WriteLine(ex);
            status = 1;
        }
        if (communicator != null) {
            try {
                communicator.destroy();
            } catch (Exception ex) {
                Console.Error.WriteLine(ex);
                status = 1;
            }
        }
        Environment.Exit(status);
    }
}

```

Note that the code places the call to `Ice.Util.initialize` into a `try` block and takes care to return the correct exit status to the operating system. Also note that an attempt to destroy the communicator is made only if the initialization succeeded.

A simpler version of the `Main` method employs a `using` statement to automatically dispose of the communicator:

C#

```

using System;

public class Server
{
    public static void Main(string[] args)
    {
        int status = 0;

        try {
            using(Ice.Communicator
communicator = Ice.Util.initialize(ref args)) {
                // ...
            }
        } catch (Exception ex) {
            Console.Error.WriteLine(ex);
            status = 1;
        }
        Environment.Exit(status);
    }
}

```

Communicator objects implement `IDisposable`, and calling `Dispose` on a communicator is equivalent to invoking `destroy`.

The `Ice.Application` Class in C#

The preceding structure for the `Main` method is so common that Ice offers a class, `Ice.Application`, that encapsulates all the correct initialization and finalization activities. The synopsis of the class is as follows (with some detail omitted for now):

C#

```
namespace Ice
{
    public abstract class Application
    {
        public abstract int run(string[] args);

        public Application();

        public Application(SignalPolicy signalPolicy);

        public int main(string[] args);
        public int main(string[] args, string configFile);
        public int main(string[] args, InitializationData init);

        public static string appName();

        public static Communicator communicator();
    }
}
```

The intent of this class is that you specialize `Ice.Application` and implement the abstract `run` method in your derived class. Whatever code you would normally place in `Main` goes into the `run` method instead. Using `Ice.Application`, our program looks as follows:

C#

```

using System;

public class Server
{
    class App : Ice.Application
    {
        public override int run(string[] args)
        {
            // Server code here...

            return 0;
        }
    }

    public static void Main(string[] args)
    {
        App app = new App();
        Environment.Exit(app.main(args));
    }
}

```

Note that `Application.main` is overloaded: you can pass an optional file name or an `InitializationData` structure.

If you pass a [configuration file name](#) to `main`, the property settings in this file are overridden by settings in a file identified by the `ICE_CONFIG` environment variable (if defined). Property settings supplied on the [command line](#) take precedence over all other settings.

The `Application.main` method does the following:

1. It installs an exception handler for `System.Exception`. If your code fails to handle an exception, `Application.main` prints the name of the exception and a stack trace on `Console.Error` before returning with a non-zero return value.
2. It initializes (by calling `Ice.Util.initialize`) and finalizes (by calling `Communicator.destroy`) a communicator. You can get access to the communicator for your server by calling the static `communicator` accessor.
3. It scans the argument vector for options that are relevant to the Ice run time and removes any such options. The argument vector that is passed to your `run` method therefore is free of Ice-related options and only contains options and arguments that are specific to your application.
4. It provides the name of your application via the static `appName` method. You can get at the application name from anywhere in your code by calling `Ice.Application.appName` (which is usually required for error messages).
5. It installs a signal handler that properly destroys the communicator.
6. It installs a [per-process logger](#) if the application has not already configured one. The per-process logger uses the value of the `Ice.ProgramName` property as a prefix for its messages and sends its output to the standard error channel. An application can also specify an [alternate logger](#).

Using `Ice.Application` ensures that your program properly finalizes the Ice run time, whether your server terminates normally or in response to an exception. We recommend that all your programs use this class; doing so makes your life easier. In addition, `Ice.Application` also provides features for signal handling and configuration that you do not have to implement yourself when you use this class.

Using Ice.Application on the Client Side in C#

You can use `Ice.Application` for your clients as well: simply implement a class that derives from `Ice.Application` and place the client code into its `run` method. The advantage of this approach is the same as for the server side: `Ice.Application` ensures that the communicator is destroyed correctly even in the presence of exceptions.

Catching Signals in C#

The simple server we developed in [Hello World Application](#) had no way to shut down cleanly: we simply interrupted the server from the command line to force it to exit. Terminating a server in this fashion is unacceptable for many real-life server applications: typically, the server has to perform some cleanup work before terminating, such as flushing database buffers or closing network connections. This is particularly important on receipt of a signal or keyboard interrupt to prevent possible corruption of database files or other persistent data.

To make it easier to deal with signals, `Ice.Application` encapsulates the low-level signal handling tasks, allowing you to cleanly shut down on receipt of a signal.

```

C#

namespace Ice
{
    public abstract class Application
    {
        // ...

        public static void destroyOnInterrupt();
        public static void shutdownOnInterrupt();
        public static void ignoreInterrupt();
        public static void callbackOnInterrupt();
        public static void holdInterrupt();
        public static void releaseInterrupt();

        public static bool interrupted();

        public virtual void interruptCallback(int sig);
    }
}
```

The methods behave as follows:

- `destroyOnInterrupt`
This method installs a handler that destroys the communicator if it is interrupted. This is the default behavior.
- `shutdownOnInterrupt`
This method installs a handler that shuts down the communicator if it is interrupted.
- `ignoreInterrupt`
This method causes signals to be ignored.
- `callbackOnInterrupt`
This method configures `Ice.Application` to invoke `interruptCallback` when a signal occurs, thereby giving the subclass responsibility for handling the signal.
- `holdInterrupt`
This method temporarily blocks signal delivery.
- `releaseInterrupt`
This method restores signal delivery to the previous disposition. Any signal that arrives after `holdInterrupt` was called is delivered when you call `releaseInterrupt`.
- `interrupted`
This method returns `true` if a signal caused the communicator to shut down, `false` otherwise. This allows us to distinguish intentional shutdown from a forced shutdown that was caused by a signal. This is useful, for example, for logging purposes.
- `interruptCallback`
A subclass overrides this method to respond to signals. The method may be called concurrently with any other thread and must not raise exceptions.

By default, `Ice.Application` behaves as if `destroyOnInterrupt` was invoked, therefore our server `Main` method requires no change to ensure that the program terminates cleanly on receipt of a signal. (You can disable the signal-handling functionality of `Ice.Application` by passing the enumerator `NoSignalHandling` to the constructor. In that case, signals retain their default behavior, that is, terminate the process.) However, we add a diagnostic to report the occurrence, so our `run` method now looks like:

```

C#

using System;

public class Server
{
    class App : Ice.Application
    {
        public override int run(string[] args)
        {
            // Server code here...

            if (interrupted())
                Console.Error.WriteLine(appName() + ": terminating");

            return 0;
        }
    }

    public static void Main(string[] args)
    {
        App app = new App();
        Environment.Exit(app.main(args));
    }
}

```

Ice.Application and Properties in C#

Apart from the functionality shown in this section, `Ice.Application` also takes care of initializing the Ice run time with property values. [Properties](#) allow you to configure the run time in various ways. For example, you can use properties to control things such as the thread pool size or port number for a server. The `main` method of `Ice.Application` is overloaded; the second version allows you to specify the name of a configuration file that will be processed during initialization.

Limitations of Ice.Application in C#

`Ice.Application` is a singleton class that creates a single communicator. If you are using multiple communicators, you cannot use `Ice.Application`. Instead, you must structure your code as we saw in [Hello World Application](#) (taking care to always destroy the communicator).

Server-Side C-Sharp Mapping for Interfaces

The server-side mapping for interfaces provides an up-call API for the Ice run time: by implementing methods in a servant class, you provide the hook that gets the thread of control from the Ice server-side run time into your application code.

On this page:

- [Skeleton Classes in C#](#)
- [Servant Classes in C#](#)
 - [Server-Side Normal and idempotent Operations in C#](#)

Skeleton Classes in C#

On the client side, interfaces map to [proxy classes](#). On the server side, interfaces map to *skeleton* classes. A skeleton is a class that has an abstract method for each operation on the corresponding interface. For example, consider our [Slice definition](#) for the `Node` interface:

```

Slice

```
module Filesystem {
 interface Node {
 idempotent string name();
 };
 // ...
};
```

```

The Slice compiler generates the following definition for this interface:

C#

```

namespace Filesystem
{
    public interface NodeOperations_
    {
        string name(Ice.Current __current);
    }

    public interface NodeOperationsNC_
    {
        string name();
    }

    public interface Node : Ice.Object,
NodeOperations_, NodeOperationsNC_
    {
    }

    public abstract class NodeDisp_ : Ice.ObjectImpl, Node
    {
        public string name()
        {
            return name(new Ice.Current());
        }

        public abstract string name(Ice.Current __current);

        // Mapping-internal code here...
    }
}

```

The important points to note here are:

- As for the client side, Slice modules are mapped to C# namespaces with the same name, so the skeleton class definitions are part of the `Filesystem` namespace.
- For each Slice interface `<interface-name>`, the compiler generates C# interfaces `<interface-name>Operations_` and `<interface-name>OperationsNC_` (`NodeOperations_` and `NodeOperationsNC_` in this example). These interfaces contain a method for each operation in the Slice interface. (You can ignore the `Ice.Current` parameter for the now.)
- For each Slice interface `<interface-name>`, the compiler generates a C# interface `<interface-name>` (`Node` in this example). That interface extends `Ice.Object` and the two operations interfaces.
- For each Slice interface `<interface-name>`, the compiler generates an abstract class `<interface-name>Disp_` (`NodeDisp_` in this example). This abstract class is the actual skeleton class; it is the base class from which you derive your servant class.

Servant Classes in C#

In order to provide an implementation for an Ice object, you must create a servant class that inherits from the corresponding skeleton class. For example, to create a servant for the `Node` interface, you could write:

C#

```

public class NodeI : NodeDisp_
{
    public NodeI(string name)
    {
        _name = name;
    }

    public override string name(Ice.Current current)
    {
        return _name;
    }

    private string _name;
}

```

By convention, servant classes have the name of their interface with an `I`-suffix, so the servant class for the `Node` interface is called `NodeI`. (This is a convention only: as far as the Ice run time is concerned, you can choose any name you prefer for your servant classes.) Note that `NodeI` extends `NodeDisp_`, that is, it derives from its skeleton class.

As far as Ice is concerned, the `NodeI` class must implement only a single method: the abstract `name` method that it inherits from its skeleton. This makes the servant class a concrete class that can be instantiated. You can add other methods and data members as you see fit to support your implementation. For example, in the preceding definition, we added a `_name` member and a constructor. (Obviously, the constructor initializes the `_name` member and the `name` method returns its value.)

Server-Side Normal and idempotent Operations in C#

Whether an operation is an ordinary operation or an `idempotent` operation has no influence on the way the operation is mapped. To illustrate this, consider the following interface:

Slice

```

interface Example {
    void          normalOp();
    idempotent void idempotentOp();
};

```

The operations class for this interface looks like this:

C#

```

public interface ExampleOperations_
{
    void normalOp(Ice.Current __current);
    void idempotentOp(Ice.Current __current);
}

```

Note that the signatures of the methods are unaffected by the `idempotent` qualifier.

Parameter Passing in C-Sharp

Parameter Passing in C#

For each parameter of a Slice operation, the C# mapping generates a corresponding parameter for the corresponding method in the *<interface-name>Operations_* interface. In addition, every operation has an additional, trailing parameter of type `Ice.Current`. For example, the `name` operation of the `Node` interface has no parameters, but the `name` method of the `NodeOperations_` interface has a single parameter of type `Ice.Current`. We will ignore this parameter for now.

Parameter passing on the server side follows the rules for the [client side](#). To illustrate the rules, consider the following interface that passes string parameters in all possible directions:

Slice
<pre> module M { interface Example { string op(string sin, out string sout); }; }; </pre>

The generated method for `op` looks as follows:

C#
<pre> public interface ExampleOperations_ { string op(string sin, out string sout, Ice.Current __current); } </pre>

As you can see, there are no surprises here. For example, we could implement `op` as follows:

C#
<pre> using System; public class ExampleI : ExampleDisp_ { public override string op(string sin, out string sout, Ice.Current current) { Console.WriteLine(sin); // In params are initialized sout = "Hello World!"; // Assign out param return "Done"; } } </pre>

This code is in no way different from what you would normally write if you were to pass strings to and from a method; the fact that remote

procedure calls are involved does not affect your code in any way. The same is true for parameters of other types, such as proxies, classes, or dictionaries: the parameter passing conventions follow normal C# rules and do not require special-purpose API calls.

Raising Exceptions in C-Sharp

To throw an exception from an operation implementation, you simply instantiate the exception, initialize it, and throw it. For example:

```

C#

```

// ...
public override void write(string[] text, Ice.Current current)
{
 try
 {
 // Try to write file contents here...
 }
 catch(System.Exception ex)
 {
 GenericError e = new GenericError("cannot write file", ex);
 e.reason = "Exception during write operation";
 throw e;
 }
}

```

```

Note that, for this example, we have supplied the [optional second parameter](#) to the `GenericError` constructor. This parameter sets the `InnerException` member of `System.Exception` and preserves the original cause of the error for later diagnosis.

If you throw an arbitrary C# run-time exception (such as an `InvalidCastException`), the Ice run time catches the exception and then returns an `UnknownException` to the client. Similarly, if you throw an "impossible" user exception (a user exception that is not listed in the exception specification of the operation), the client receives an `UnknownUserException`.

If you throw an Ice run-time exception, such `MemoryLimitException`, the client receives an `UnknownLocalException`. For that reason, you should never throw system exceptions from operation implementations. If you do, all the client will see is an `UnknownLocalException`, which does not tell the client anything useful.

Three run-time exceptions are [treated specially](#) and not changed to `UnknownLocalException` when returned to the client: `ObjectNotExistException`, `OperationNotExistException`, and `FacetNotExistException`.

Tie Classes in C-Sharp

The mapping to [skeleton classes](#) requires the servant class to inherit from its skeleton class. Occasionally, this creates a problem: some class libraries require you to inherit from a base class in order to access functionality provided by the library; because C# does not support multiple implementation inheritance, this means that you cannot use such a class library to implement your servants because your servants cannot inherit from both the library class and the skeleton class simultaneously.

To allow you to still use such class libraries, Ice provides a way to write servants that replaces inheritance with delegation. This approach is supported by *tie classes*. The idea is that, instead of inheriting from the skeleton class, you simply create a class (known as an *implementation class* or *delegate class*) that contains methods corresponding to the operations of an interface. You use the `--tie` option with the `slice2cs` compiler to create a tie class. For example, the `--tie` option causes the compiler to create exactly the same code for the [Node interface](#) as we saw previously, but to also emit an additional tie class. For an interface `<interface-name>`, the generated tie class has the name `<interface-name>Tie_`:

```

C#

public class NodeTie_ : NodeDisp_, Ice.TieBase
{
    public NodeTie_()
    {
    }

    public NodeTie_(NodeOperations_ del)
    {
        _ice_delegate = del;
    }

    public object ice_delegate()
    {
        return _ice_delegate;
    }

    public void ice_delegate(object del)
    {
        _ice_delegate = (NodeOperations_)del;
    }

    public override int GetHashCode()
    {
        return _ice_delegate == null ? 0 : _ice_delegate.GetHashCode();
    }

    public override bool Equals(object rhs)
    {
        if (object.ReferenceEquals(this, rhs))
        {
            return true;
        }
        if (!(rhs is NodeTie_))
        {
            return false;
        }
    }
}

```

```
    if (_ice_delegate == null)
    {
        return ((NodeTie_)rhs)._ice_delegate == null;
    }
    return _ice_delegate.Equals(((NodeTie_)rhs)._ice_delegate);
}

public override string name(Ice.Current __current)
{
    return _ice_delegate.name(__current);
}
```

```

    private NodeOperations_ _ice_delegate;
}

```

This looks a lot worse than it is: in essence, the generated tie class is simply a servant class (it extends `NodeDisp_`) that delegates each invocation of a method that corresponds to a Slice operation to your implementation class:

A skeleton class, tie class, and implementation class.

The `Ice.TieBase` interface defines the `ice_delegate` methods that allow you to get and set the delegate.

Given this machinery, we can create an implementation class for our `Node` interface as follows:

```

C#

public class NodeI : NodeOperations_
{
    public NodeI(string name)
    {
        _name = name;
    }

    public override string name(Ice.Current current)
    {
        return _name;
    }

    private string _name;
}

```

Note that this class is identical to our previous implementation, except that it implements the `NodeOperations_` interface and does not extend `NodeDisp_` (which means that you are now free to extend any other class to support your implementation).

To create a servant, you instantiate your implementation class and the tie class, passing a reference to the implementation instance to the tie constructor:

```

C#

NodeI fred = new NodeI("Fred");           // Create implementation
NodeTie_ servant = new NodeTie_(fred);    // Create tie

```

Alternatively, you can also default-construct the tie class and later set its delegate instance by calling `ice_delegate`:

C#

```

NodeTie_ servant = new NodeTie_();      // Create tie
// ...
NodeI fred = new NodeI("Fred");       // Create implementation
// ...
servant.ice_delegate(fred);           // Set delegate

```

When using tie classes, it is important to remember that the tie instance is the servant, not your delegate. Furthermore, you must not use a tie instance to [incarnate](#) an Ice object until the tie has a delegate. Once you have set the delegate, you must not change it for the lifetime of the tie; otherwise, undefined behavior results.

You should use the tie approach only if you need to, that is, if you need to extend some base class in order to implement your servants: using the tie approach is more costly in terms of memory because each Ice object is incarnated by two C# objects (the tie and the delegate) instead of just one. In addition, call dispatch for ties is marginally slower than for ordinary servants because the tie forwards each operation to the delegate, that is, each operation invocation requires two function calls instead of one.

Also note that, unless you arrange for it, there is no way to get from the delegate back to the tie. If you need to navigate back to the tie from the delegate, you can store a reference to the tie in a member of the delegate. (The reference can, for example, be initialized by the constructor of the delegate.)

Object Incarnation in C-Sharp

Having created a servant class such as the rudimentary `NodeI` class, you can instantiate the class to create a concrete servant that can receive invocations from a client. However, merely instantiating a servant class is insufficient to incarnate an object. Specifically, to provide an implementation of an Ice object, you must take the following steps:

1. Instantiate a servant class.
2. Create an identity for the Ice object incarnated by the servant.
3. Inform the Ice run time of the existence of the servant.
4. Pass a proxy for the object to a client so the client can reach it.

On this page:

- [Instantiating a C# Servant](#)
- [Creating an Identity in C#](#)
- [Activating a C# Servant](#)
- [UUIDs as Identities in C#](#)
- [Creating Proxies in C#](#)
 - [Proxies and Servant Activation in C#](#)
 - [Direct Proxy Creation in C#](#)

Instantiating a C# Servant

Instantiating a servant means to allocate an instance:

C#

```
Node servant = new NodeI("Fred");
```

This code creates a new `NodeI` instance and assigns its address to a reference of type `Node`. This works because `NodeI` is derived from `Node`, so a `Node` reference can refer to an instance of type `NodeI`. However, if we want to invoke a method of the `NodeI` class at this point, we must use a `NodeI` reference:

C#

```
NodeI servant = new NodeI("Fred");
```

Whether you use a `Node` or a `NodeI` reference depends purely on whether you want to invoke a method of the `NodeI` class: if not, a `Node` reference works just as well as a `NodeI` reference.

Creating an Identity in C#

Each Ice object requires an identity. That identity must be unique for all servants using the same object adapter.

The Ice object model assumes that all objects (regardless of their adapter) have a [globally unique identity](#).

An Ice object identity is a structure with the following Slice definition:

Slice

```
module Ice {
    struct Identity {
        string name;
        string category;
    };
    // ...
};
```

The full identity of an object is the combination of both the `name` and `category` fields of the `Identity` structure. For now, we will leave the `category` field as the empty string and simply use the `name` field. (The `category` field is most often used in conjunction with `servant locators`.)

To create an identity, we simply assign a key that identifies the servant to the `name` field of the `Identity` structure:

C#

```
Ice.Identity id = new Ice.Identity();
id.name = "Fred"; // Not unique, but good enough for now
```

Activating a C# Servant

Merely creating a servant instance does nothing: the Ice run time becomes aware of the existence of a servant only once you explicitly tell the object adapter about the servant. To activate a servant, you invoke the `add` operation on the object adapter. Assuming that we have access to the object adapter in the `_adapter` variable, we can write:

C#

```
_adapter.add(servant, id);
```

Note the two arguments to `add`: the servant and the object identity. Calling `add` on the object adapter adds the servant and the servant's identity to the adapter's servant map and links the proxy for an Ice object to the correct servant instance in the server's memory as follows:

1. The proxy for an Ice object, apart from addressing information, contains the identity of the Ice object. When a client invokes an operation, the object identity is sent with the request to the server.
2. The object adapter receives the request, retrieves the identity, and uses the identity as an index into the servant map.
3. If a servant with that identity is active, the object adapter retrieves the servant from the servant map and dispatches the incoming request into the correct method on the servant.

Assuming that the object adapter is in the `active state`, client requests are dispatched to the servant as soon as you call `add`.

UUIDs as Identities in C#

The Ice object model assumes that object identities are globally unique. One way of ensuring that uniqueness is to use UUIDs (Universally Unique Identifiers) as identities. .NET provides a helper function that we can use to create such identities:

C#

```
public class Example
{
    public static void Main(string[] args)
    {
        System.Console.WriteLine(System.Guid.NewGuid().ToString());
    }
}
```

When executed, this program prints a unique string such as 5029a22c-e333-4f87-86b1-cd5e0fccc509. Each call to `NewGuid` creates a string that differs from all previous ones.

You can use a UUID such as this to create object identities. For convenience, the object adapter has an operation `addWithUUID` that generates a UUID and adds a servant to the servant map in a single step. Using this operation, we can create an identity and register a servant with that identity in a single step as follows:

C#

```
_adapter.addWithUUID(new NodeI("Fred"));
```

Creating Proxies in C#

Once we have activated a servant for an Ice object, the server can process incoming client requests for that object. However, clients can only access the object once they hold a proxy for the object. If a client knows the server's address details and the object identity, it can create a proxy from a string, as we saw in our first example in [Hello World Application](#). However, creation of proxies by the client in this manner is usually only done to allow the client access to initial objects for bootstrapping. Once the client has an initial proxy, it typically obtains further proxies by invoking operations.

The object adapter contains all the details that make up the information in a proxy: the addressing and protocol information, and the object identity. The Ice run time offers a number of ways to create proxies. Once created, you can pass a proxy to the client as the return value or as an out-parameter of an operation invocation.

Proxies and Servant Activation in C#

The `add` and `addWithUUID` servant activation operations on the object adapter return a proxy for the corresponding Ice object. This means we can write:

C#

```
NodePrx proxy = NodePrxHelper.uncheckedCast(_adapter.addWithUUID(new NodeI("Fred")));
```

Here, `addWithUUID` both activates the servant and returns a proxy for the Ice object incarnated by that servant in a single step.

Note that we need to use an `uncheckedCast` here because `addWithUUID` returns a proxy of type `Ice.ObjectPrx`.

Direct Proxy Creation in C#

The object adapter offers an operation to create a proxy for a given identity:

Slice

```

module Ice {
    local interface ObjectAdapter {
        Object* createProxy(Identity id);
        // ...
    };
};

```

Note that `createProxy` creates a proxy for a given identity whether a servant is activated with that identity or not. In other words, proxies have a life cycle that is quite independent from the life cycle of servants:

C#

```

Ice.Identity id = new Ice.Identity();
id.name = System.Guid.NewGuid().ToString();
Ice.ObjectPrx o = _adapter.createProxy(id);

```

This creates a proxy for an Ice object with the identity returned by `NewGuid`. Obviously, no servant yet exists for that object so, if we return the proxy to a client and the client invokes an operation on the proxy, the client will receive an `ObjectNotExistException`. (We examine these life cycle issues in more detail in [Object Life Cycle](#).)

Asynchronous Method Dispatch (AMD) in C-Sharp

The number of simultaneous synchronous requests a server is capable of supporting is determined by the number of threads in the server's [thread pool](#). If all of the threads are busy dispatching long-running operations, then no threads are available to process new requests and therefore clients may experience an unacceptable lack of responsiveness.

Asynchronous Method Dispatch (AMD), the server-side equivalent of [AMI](#), addresses this scalability issue. Using AMD, a server can receive a request but then suspend its processing in order to release the dispatch thread as soon as possible. When processing resumes and the results are available, the server sends a response explicitly using a callback object provided by the Ice run time.

AMD is transparent to the client, that is, there is no way for a client to distinguish a request that, in the server, is processed synchronously from a request that is processed asynchronously.

In practical terms, an AMD operation typically queues the request data (i.e., the callback object and operation arguments) for later processing by an application thread (or thread pool). In this way, the server minimizes the use of dispatch threads and becomes capable of efficiently supporting thousands of simultaneous clients.

An alternate use case for AMD is an operation that requires further processing after completing the client's request. In order to minimize the client's delay, the operation returns the results while still in the dispatch thread, and then continues using the dispatch thread for additional work.

On this page:

- [Enabling AMD with Metadata in C#](#)
- [AMD Mapping in C#](#)
 - [Callback Interface for AMD](#)
 - [Dispatch Method for AMD](#)
- [AMD Exceptions in C#](#)
- [AMD Example in C#](#)

Enabling AMD with Metadata in C#

To enable asynchronous dispatch, you must add an ["amd"] metadata directive to your Slice definitions. The directive applies at the interface and the operation level. If you specify ["amd"] at the interface level, all operations in that interface use asynchronous dispatch; if you specify ["amd"] for an individual operation, only that operation uses asynchronous dispatch. In either case, the metadata directive replaces synchronous dispatch, that is, a particular operation implementation must use synchronous or asynchronous dispatch and cannot use both.

Consider the following Slice definitions:

Slice

```

["amd"] interface I {
    bool isValid();
    float computeRate();
};

interface J {
    ["amd"] void startProcess();
    int endProcess();
};

```

In this example, both operations of interface `I` use asynchronous dispatch, whereas, for interface `J`, `startProcess` uses asynchronous dispatch and `endProcess` uses synchronous dispatch.

Specifying metadata at the operation level (rather than at the interface or class level) minimizes the amount of generated code and, more importantly, minimizes complexity: although the asynchronous model is more flexible, it is also more complicated to use. It is therefore in your best interest to limit the use of the asynchronous model to those operations that need it, while using the simpler synchronous model for the rest.

AMD Mapping in C#

The C# mapping emits the following code for each AMD operation:

1. [Callback interface](#)
2. [Dispatch method](#)

Callback Interface for AMD

A callback interface is used by the implementation to notify the Ice run time about the completion of an operation. The name of this interface is formed using the pattern `AMD_class_op`. For example, an operation named `foo` defined in interface `I` results in an interface named `AMD_I_foo`. The interface is generated in the same scope as the interface or class containing the operation. Two methods are provided:

```

C#

---

public void ice_response(<params>);
```

The `ice_response` method allows the server to report the successful completion of the operation. If the operation has a non-void return type, the first parameter to `ice_response` is the return value. Parameters corresponding to the operation's `out` parameters follow the return value, in the order of declaration.

```

C#

---

public void ice_exception(System.Exception ex);
```

The `ice_exception` method allows the server to raise an exception. Although any exception type could conceivably be passed to `ice_exception`, the Ice run time [validates](#) the exception value using the same semantics as for synchronous dispatch.

Neither `ice_response` nor `ice_exception` throw any exceptions to the caller.

Dispatch Method for AMD

The dispatch method, whose name has the suffix `_async`, has a `void` return type. The first parameter is a reference to an instance of the callback interface described above. The remaining parameters comprise the `in` parameters of the operation, in the order of declaration.

For example, suppose we have defined the following operation:

```

Slice

---

interface I {
    ["amd"] int foo(short s, out long l);
};
```

The callback interface generated for operation `foo` is shown below:

C#

```
public interface AMD_I_foo
{
    void ice_response(int __ret, long l);
    void ice_exception(System.Exception ex);
}
```

The dispatch method for asynchronous invocation of operation `foo` is generated as follows:

C#

```
public abstract void foo_async(AMD_I_foo __cb, short s,
    Ice.Current __current);
```

AMD Exceptions in C#

There are two processing contexts in which the logical implementation of an AMD operation may need to report an exception: the dispatch thread (the thread that receives the invocation), and the response thread (the thread that sends the response).

These are not necessarily two different threads: it is legal to send the response from the dispatch thread.

Although we recommend that the callback object be used to report all exceptions to the client, it is legal for the implementation to raise an exception instead, but only from the dispatch thread.

As you would expect, an exception raised from a response thread cannot be caught by the Ice run time; the application's run time environment determines how such an exception is handled. Therefore, a response thread must ensure that it traps all exceptions and sends the appropriate response using the callback object. Otherwise, if a response thread is terminated by an uncaught exception, the request may never be completed and the client might wait indefinitely for a response.

Whether raised in a dispatch thread or reported via the callback object, user exceptions are validated as described in [User Exceptions](#), and local exceptions may undergo the translation described in [Run-Time Exceptions](#).

AMD Example in C#

To demonstrate the use of AMD in Ice, let us define the Slice interface for a simple computational engine:

Slice

```

module Demo {
    sequence<float> Row;
    sequence<Row> Grid;

    exception RangeError {};

    interface Model {
        ["amd"] Grid interpolate(Grid data, float factor)
            throws RangeError;
    };
};

```

Given a two-dimensional grid of floating point values and a factor, the `interpolate` operation returns a new grid of the same size with the values interpolated in some interesting (but unspecified) way.

Our servant class derives from `Demo._ModelDisp` and supplies a definition for the `interpolate_async` method that creates a `Job` to hold the callback object and arguments, and adds the `Job` to a queue. The method uses a `lock` statement to guard access to the queue:

C#

```

public class ModelI : Demo.ModelDisp_
{
    public override void interpolate_async(
        Demo.AMD_Model_interpolate cb,
        float[][] data,
        float factor,
        Ice.Current current)
    {
        lock(this)
        {
            _jobs.Add(new Job(cb, data, factor));
        }
    }

    private System.Collections.ArrayList _jobs
    = new System.Collections.ArrayList();
}

```

After queuing the information, the operation returns control to the Ice run time, making the dispatch thread available to process another request. An application thread removes the next `Job` from the queue and invokes `execute`, which uses `interpolateGrid` (not shown) to perform the computational work:

C#

```

public class Job {
    public Job(Demo.AMD_Model_interpolate cb,
float[][] grid, float factor)
    {
        _cb = cb;
        _grid = grid;
        _factor = factor;
    }

    public void execute()
    {
        if (!interpolateGrid()) {
            _cb.ice_exception(new Demo.RangeError());
            return;
        }
        _cb.ice_response(_grid);
    }

    private boolean interpolateGrid()
    {
        // ...
    }

    private Demo.AMD_Model_interpolate _cb;
    private float[][] _grid;
    private float _factor;
}

```

If `interpolateGrid` returns `false`, then `ice_exception` is invoked to indicate that a range error has occurred. The `return` statement following the call to `ice_exception` is necessary because `ice_exception` does not throw an exception; it only marshals the exception argument and sends it to the client.

If interpolation was successful, `ice_response` is called to send the modified grid back to the client.

Example of a File System Server in C-Sharp

This page presents the source code for a C# server that implements our [file system](#) and communicates with the [client](#) we wrote earlier. The code is fully functional, apart from the required interlocking for threads.

The server is free of code that relates to distribution: most of the server code is simply application logic that would be present just the same for a non-distributed version. Again, this is one of the major advantages of Ice: distribution concerns are kept away from application code so that you can concentrate on developing application logic instead of networking infrastructure.

The server code shown here is not quite correct as it stands: if two clients access the same file in parallel, each via a different thread, one thread may read the `_lines` data member while another thread updates it. Obviously, if that happens, we may write or return garbage or, worse, crash the server. However, it is trivial to make the `read` and `write` operations thread-safe. We discuss thread safety in [The Ice Threading Model](#).

On this page:

- [Implementing a File System Server in C#](#)
- [Server Main Program in C#](#)
- [FileI Servant Class in C#](#)
- [DirectoryI Servant Class in C#](#)

 - [DirectoryI Constructor](#)
 - [DirectoryI Methods](#)

Implementing a File System Server in C#

We have now seen enough of the server-side C# mapping to implement a server for our [file system](#). (You may find it useful to review these [Slice definitions](#) before studying the source code.)

Our server is composed of three source files:

- `Server.cs`
This file contains the server main program.
- `DirectoryI.cs`
This file contains the implementation for the `Directory` servants.
- `FileI.cs`
This file contains the implementation for the `File` servants.

Server Main Program in C#

Our server main program, in the file `Server.cs`, uses the `Ice.Application` class. The `run` method installs a signal handler, creates an object adapter, instantiates a few servants for the directories and files in the file system, and then activates the adapter. This leads to a main program as follows:

C#

```

using Filesystem;
using System;

public class Server
{
    class App : Ice.Application
    {
        public override int run(string[] args)
        {
            // Terminate cleanly on receipt of a signal

```

```

//
shutdownOnInterrupt();

// Create an object adapter (stored in the _adapter
// static members)
//
Ice.ObjectAdapter adapter
= communicator().createObjectAdapterWithEndpoints(
    "SimpleFilesystem", "default -p 10000");
DirectoryI._adapter = adapter;
FileI._adapter = adapter;

// Create the root directory (with name "/" and no
// parent)
//
DirectoryI root = new DirectoryI("/", null);

// Create a file called "README" in the root directory
//
File file = new FileI("README", root);
string[] text;
text = new string[] {
    "This file system contains a collection of poetry."
};
try {
    file.write(text);
} catch (GenericError e) {
    Console.Error.WriteLine(e.reason);
}

// Create a directory called "Coleridge"
// in the root directory
//
DirectoryI coleridge = new DirectoryI("Coleridge", root);

// Create a file called "Kubla_Khan"
// in the Coleridge directory
//
file = new FileI("Kubla_Khan", coleridge);
text = new string[] { "In Xanadu did Kubla Khan",
    "A stately pleasure-dome decree:",
    "Where Alph, the sacred river, ran",
    "Through caverns measureless to man",
    "Down to a sunless sea." };
try {
    file.write(text);
} catch (GenericError e) {
    Console.Error.WriteLine(e.reason);
}

```

```
        // All objects are created, allow client requests now
        //
        adapter.activate();

        // Wait until we are done
        //
        communicator().waitForShutdown();

        if (interrupted())
            Console.Error.WriteLine(appName() + ": terminating");

        return 0;
    }
}

public static void Main(string[] args)
{
    App app = new App();
    Environment.Exit(app.main(args));
}
```

```

    }
}

```

The code uses a `using` directive for the `Filesystem` namespace. This avoids having to continuously use fully-qualified identifiers with a `Filesystem.` prefix.

The next part of the source code is the definition of the `Server` class, which includes a nested class that derives from `Ice.Application` and contains the main application logic in its `run` method. Much of this code is boiler plate that we saw previously: we create an object adapter, and, towards the end, activate the object adapter and call `waitForShutdown`.

The interesting part of the code follows the adapter creation: here, the server instantiates a few nodes for our file system to create the structure shown below:

A small file system.

As we will see shortly, the servants for our directories and files are of type `DirectoryI` and `FileI`, respectively. The constructor for either type of servant accepts two parameters, the name of the directory or file to be created and a reference to the servant for the parent directory. (For the root directory, which has no parent, we pass a null parent.) Thus, the statement

```

C#
DirectoryI root = new DirectoryI("/", null);

```

creates the root directory, with the name `" / "` and no parent directory.

Here is the code that establishes the structure in the above illustration:

C#

```

// Create the root directory (with name "/" and no parent)
//
DirectoryI root = new DirectoryI("/", null);

// Create a file called "README" in the root directory
//
File file = new FileI("README", root);
string[] text;
text = new string[] {
    "This file system contains a collection of poetry."
};
try {
    file.write(text);
} catch (GenericError e) {
    Console.Error.WriteLine(e.reason);
}

// Create a directory called "Coleridge"
// in the root directory
//
DirectoryI coleridge = new DirectoryI("Coleridge", root);

// Create a file called "Kubla_Khan"
// in the Coleridge directory
//
file = new FileI("Kubla_Khan", coleridge);
text = new string[] { "In Xanadu did Kubla Khan",
    "A stately pleasure-dome decree:",
    "Where Alph, the sacred river, ran",
    "Through caverns measureless to man",
    "Down to a sunless sea." };
try {
    file.write(text);
} catch (GenericError e) {
    Console.Error.WriteLine(e.reason);
}

```

We first create the root directory and a file `README` within the root directory. (Note that we pass a reference to the root directory as the parent when we create the new node of type `FileI`.)

The next step is to fill the file with text:

C#

```

string[] text;
text = new string[] {
    "This file system contains a collection of poetry."
};
try {
    file.write(text);
} catch (GenericError e) {
    Console.Error.WriteLine(e.reason);
}

```

Recall that [Slice sequences](#) by default map to C# arrays. The Slice type `Lines` is simply an array of strings; we add a line of text to our REA DME file by initializing the `text` array to contain one element.

Finally, we call the Slice `write` operation on our `FileI` servant by writing:

C#

```
file.write(text);
```

This statement is interesting: the server code invokes an operation on one of its own servants. Because the call happens via a reference to the servant (of type `FileI`) and not via a proxy (of type `FilePrx`), the Ice run time does not know that this call is even taking place — such a direct call into a servant is not mediated by the Ice run time in any way and is dispatched as an ordinary C# method call.

In similar fashion, the remainder of the code creates a subdirectory called `Coleridge` and, within that directory, a file called `Kubla_Khan` to complete the structure in the above illustration.

FileI Servant Class in C#

Our `FileI` servant class has the following basic structure:

C#

```

using FileSystem;
using System;

public class FileI : FileDisp_
{
    // Constructor and operations here...

    public static Ice.ObjectAdapter _adapter;
    private string _name;
    private DirectoryI _parent;
    private string[] _lines;
}

```

The class has a number of data members:

- `_adapter`
This static member stores a reference to the single object adapter we use in our server.
- `_name`
This member stores the name of the file incarnated by the servant.
- `_parent`
This member stores the reference to the servant for the file's parent directory.
- `_lines`
This member holds the contents of the file.

The `_name` and `_parent` data members are initialized by the constructor:

```

C#

public FileI(string name, DirectoryI parent)
{
    _name = name;
    _parent = parent;

    Debug.Assert(_parent != null);

    // Create an identity
    //
    Ice.Identity myID = new Ice.Identity();
    myID.name = System.Guid.NewGuid().ToString();

    // Add the identity to the object adapter
    //
    _adapter.add(this, myID);

    // Create a proxy for the new node and
    // add it as a child to the parent
    //
    NodePrx thisNode = NodePrxHelper.uncheckedCast(_adapter.createP
roxy(myID));
    _parent.addChild(thisNode);
}

```

After initializing the `_name` and `_parent` members, the code verifies that the reference to the parent is not null because every file must have a parent directory. The constructor then generates an identity for the file by calling `NewGuid` and adds itself to the servant map by calling `ObjectAdapter.add`. Finally, the constructor creates a proxy for this file and calls the `addChild` method on its parent directory. `addChild` is a helper function that a child directory or file calls to add itself to the list of descendant nodes of its parent directory. We will see the implementation of this function in [DirectoryI Methods](#).

The remaining methods of the `FileI` class implement the Slice operations we defined in the `Node` and `File` Slice interfaces:

C#

```

// Slice Node::name() operation

public override string name(Ice.Current current)
{
    return _name;
}

// Slice File::read() operation

public override string[] read(Ice.Current current)
{
    return _lines;
}

// Slice File::write() operation

public override void write(string[] text, Ice.Current current)
{
    _lines = text;
}

```

The `name` method is inherited from the generated `Node` interface (which is a base interface of the `_FileDisp` class from which `FileI` is derived). It simply returns the value of the `_name` member.

The `read` and `write` methods are inherited from the generated `File` interface (which is a base interface of the `_FileDisp` class from which `FileI` is derived) and simply return and set the `_lines` member.

DirectoryI Servant Class in C#

The `DirectoryI` class has the following basic structure:

C#

```
using Filesystem;
using System;
using System.Collections;

public class DirectoryI : DirectoryDisp_
{
    // Constructor and operations here...

    public static Ice.ObjectAdapter _adapter;
    private string _name;
    private DirectoryI _parent;
    private ArrayList _contents = new ArrayList();
}
```

DirectoryI Data Members

As for the `FileI` class, we have data members to store the object adapter, the name, and the parent directory. (For the root directory, the `_parent` member holds a null reference.) In addition, we have a `_contents` data member that stores the list of child directories. These data members are initialized by the constructor:

C#

```

public DirectoryI(string name, DirectoryI parent)
{
    _name = name;
    _parent = parent;

    // Create an identity. The
    // parent has the fixed identity "RootDir"
    //
    Ice.Identity myID = new Ice.Identity();
    myID.name = _parent != null ? System.Guid.NewGuid().ToString()
: "RootDir";

    // Add the identity to the object adapter
    //
    _adapter.add(this, myID);

    // Create a proxy for the new node and
    // add it as a child to the parent
    //
    NodePrx thisNode = NodePrxHelper.uncheckedCast(_adapter.createP
roxy(myID));
    if (_parent != null)
        _parent.addChild(thisNode);
}

```

DirectoryI Constructor

The constructor creates an identity for the new directory by calling `NewGuid`. (For the root directory, we use the fixed identity "RootDir".) The servant adds itself to the servant map by calling `ObjectAdapter.add` and then creates a proxy to itself and passes it to the `addChild` helper function.

DirectoryI Methods

`addChild` simply adds the passed reference to the `_contents` list:

C#

```

public void addChild(NodePrx child)
{
    _contents.Add(child);
}

```

The remainder of the operations, `name` and `list`, are trivial:

C#

```
public override string name(Ice.Current current)
{
    return _name;
}

public override NodePrx[] list(Ice.Current current)
{
    return (NodePrx[])_contents.ToArray(typeof(NodePrx));
}
```

Note that the `_contents` member is of type `System.Collections.ArrayList`, which is convenient for the implementation of the `addChild` method. However, this requires us to convert the list into a C# array in order to return it from the `list` operation.

The .NET Utility Library

Ice for .Net includes a number of utility APIs in the `Ice.Util` class. This appendix summarizes the contents of these APIs for your reference.

On this page:

- [Communicator Initialization Methods](#)
- [Identity Conversion](#)
- [Per-Process Logger Methods](#)
- [Property Creation Methods](#)
- [Proxy Comparison Methods](#)
- [Stream Creation](#)
- [Version Information](#)

Communicator Initialization Methods

`Ice.Util` provides a number of overloaded `initialize` methods that [create a communicator](#).

Identity Conversion

`Ice.Util` contains two methods to [convert object identities](#) of type `Ice.Identity` to and from strings.

Per-Process Logger Methods

`Ice.Util` provides methods for getting and setting the [per-process logger](#).

Property Creation Methods

`Ice.Util` provides a number of overloaded `createProperties` methods that [create property sets](#).

Proxy Comparison Methods

Two methods, `proxyIdentityCompare` and `proxyIdentityAndFacetCompare`, allow you to [compare object identities](#) that are stored in proxies (either ignoring the facet or taking the facet into account).

Stream Creation

The methods `createInputStream`, `wrapInputStream` and `createOutputStream` create [streams](#) for use with dynamic invocation.

Version Information

The `stringVersion` and `intVersion` methods return the version of the Ice run time:

```

C#

public static string stringVersion();
public static int intVersion();
```

The `stringVersion` method returns the Ice version in the form `<major>.<minor>.<patch>`, for example, `3.4.2`. For beta releases, the version is `<major>.<minor>b`, for example, `3.4b`.

The `intVersion` method returns the Ice version in the form `AABBCC`, where `AA` is the major version number, `BB` is the minor version

number, and *CC* is patch level, for example, 30402 for version 3.4.2. For beta releases, the patch level is set to 51 so, for example, for version 3.4b, the value is 30451.

Client-Side Slice-to-Java Mapping

In this section, we present the client-side Slice-to-Java mapping. The client-side Slice-to-Java mapping defines how Slice data types are translated to Java types, and how clients invoke operations, pass parameters, and handle errors. Much of the Java mapping is intuitive. For example, Slice sequences map to Java arrays, so there is essentially nothing new you have to learn in order to use Slice sequences in Java.

The Java API to the Ice run time is fully thread-safe. Obviously, you must still synchronize access to data from different threads. For example, if you have two threads sharing a sequence, you cannot safely have one thread insert into the sequence while another thread is iterating over the sequence. However, you only need to concern yourself with concurrent access to your own data — the Ice run time itself is fully thread safe, and none of the Ice API calls require you to acquire or release a lock before you safely can make the call.

Much of what appears in this chapter is reference material. We suggest that you skim the material on the initial reading and refer back to specific sections as needed. However, we recommend that you read at least the mappings for [exceptions](#), [interfaces](#), and [operations](#) in detail because these sections cover how to call operations from a client, pass parameters, and handle exceptions.

In order to use the Java mapping, you should need no more than the Slice definition of your application and knowledge of the Java mapping rules. In particular, looking through the generated code in order to discern how to use the Java mapping is likely to be inefficient, due to the amount of detail. Of course, occasionally, you may want to refer to the generated code to confirm a detail of the mapping, but we recommend that you otherwise use the material presented here to see how to write your client-side code.

The Ice Package

All of the APIs for the Ice run time are nested in the `Ice` package, to avoid clashes with definitions for other libraries or applications. Some of the contents of the `Ice` package are generated from Slice definitions; other parts of the `Ice` package provide special-purpose definitions that do not have a corresponding Slice definition. We will incrementally cover the contents of the `Ice` package throughout the remainder of the manual.

Java Mapping for Identifiers

A Slice [identifier](#) maps to an identical Java identifier. For example, the Slice identifier `clock` becomes the Java identifier `clock`. There is one exception to this rule: if a Slice identifier is the same as a Java keyword or is an identifier reserved by the Ice run time (such as `checkedCast`), the corresponding Java identifier is prefixed with an underscore. For example, the Slice identifier `while` is mapped as `_while`.

You should try to [avoid such identifiers](#) as much as possible.

A single Slice identifier often results in several Java identifiers. For example, for a Slice interface named `Foo`, the generated Java code uses the identifiers `Foo` and `FooPrx` (among others). If the interface has the name `while`, the generated identifiers are `_while` and `whilePrx` (*not* `_whilePrx`), that is, the underscore prefix is applied only to those generated identifiers that actually require it.

- [Java Mapping for Exceptions](#)

Java Mapping for Modules

A Slice `module` maps to a Java package with the same name as the Slice module. The mapping preserves the nesting of the Slice definitions. For example:

Slice
<pre> // Definitions at global scope here... module M1 { // Definitions for M1 here... module M2 { // Definitions for M2 here... }; }; // ... module M1 { // Reopen M1 // More definitions for M1 here... }; </pre>

This definition maps to the corresponding Java definitions:

Java
<pre> package M1; // Definitions for M1 here... package M1.M2; // Definitions for M2 here... package M1; // Definitions for M1 here... </pre>

Note that these definitions appear in the appropriate source files; source files for definitions in module `M1` are generated in directory `M1` underneath the top-level directory, and source files for definitions for module `M2` are generated in directory `M1/M2` underneath the top-level directory. You can set the top-level output directory using the `--output-dir` option with `slice2java`.

Java Mapping for Built-In Types

The Slice built-in types are mapped to Java types as follows:

Slice	Java
bool	boolean
byte	byte
short	short
int	int
long	long
float	float
double	double
string	String

Mapping of Slice built-in types to Java.

Java Mapping for Enumerations

A Slice enumeration maps to the corresponding enumeration in Java. For example:

Slice
<pre>enum Fruit { Apple, Pear, Orange };</pre>

The Java mapping for `Fruit` is shown below:

Java
<pre>public enum Fruit implements java.io.Serializable { Apple, Pear, Orange; public int value(); public static Fruit valueOf(int v); // ... }</pre>

Given the above definitions, we can use enumerated values as follows:

Java
<pre>Fruit f1 = Fruit.Apple; Fruit f2 = Fruit.Orange; if (f1 == Fruit.Apple) // Compare with constant // ... if (f1 == f2) // Compare two enums // ... switch (f2) { // Switch on enum case Fruit.Apple: // ... break; case Fruit.Pear: // ... break; case Fruit.Orange: // ... break; }</pre>

The Java mapping includes two methods of interest. The `value` method returns the Slice value of an enumerator, which is not necessarily the same as its ordinal value. The `valueOf` method translates a Slice value into its corresponding enumerator, or returns `null` if no match is found. Note that the generated class contains a number of other members, which we have not shown. These members are internal to the Ice run time and you must not use them in your application code (because they may change from release to release).

In the `Fruit` definition above, the Slice value of each enumerator matches its ordinal value. This will not be true if we modify the definition to include a [custom enumerator value](#):

```
Slice  
enum Fruit { Apple, Pear = 3, Orange };
```

The table below shows the new relationship between ordinal value and Slice value:

Enumerator	Ordinal	Slice
Apple	0	0
Pear	1	3
Orange	2	4

Java enumerated types inherit implicitly from `java.lang.Enum`, which defines methods such as `ordinal` and `compareTo` that operate on the *ordinal* value of an enumerator, not its Slice value.

Java Mapping for Structures

On this page:

- [Basic Java Mapping for Structures](#)
- [Java Default Constructors for Structures](#)

Basic Java Mapping for Structures

A Slice [structure](#) maps to a Java class with the same name. For each Slice data member, the Java class contains a corresponding public data member. For example, here is our [Employee](#) structure once more:

Slice
<pre>struct Employee { long number; string firstName; string lastName; };</pre>

The Slice-to-Java compiler generates the following definition for this structure:

Java

```

public final class Employee implements java.lang.Cloneable,
java.io.Serializable {
    public long number;
    public String firstName;
    public String lastName;

    public Employee() {}

    public Employee(long number, String firstName, String lastName) {
        this.number = number;
        this.firstName = firstName;
        this.lastName = lastName;
    }

    public boolean equals(java.lang.Object rhs) {
        // ...
    }

    public int hashCode() {
        // ...
    }

    public java.lang.Object clone()
        java.lang.Object o;
        try
        {
            o = super.clone();
        }
        catch(java.lang.CloneNotSupportedException ex)
        {
            assert false; // impossible
        }
        return o;
    }
}

```

For each data member in the Slice definition, the Java class contains a corresponding public data member of the same name. Note that you can optionally [customize the mapping](#) for data members to use getters and setters instead.

The `equals` member function compares two structures for equality. Note that the generated class also provides the usual `hashCode` and `clone` methods. (`clone` has the default behavior of making a shallow copy.)

Java Default Constructors for Structures

Structures have a default constructor that initializes data members as follows:

Data Member Type	Default Value
string	Empty string

enum	First enumerator in enumeration
struct	Default-constructed value
Numeric	Zero
bool	False
sequence	Null
dictionary	Null
class/interface	Null

The constructor won't explicitly initialize a data member if the default Java behavior for that type produces the desired results.

If you wish to ensure that data members of primitive and enumerated types are initialized to specific values, you can declare default values in your [Slice definition](#). The default constructor initializes each of these data members to its declared value instead.

Structures also have a second constructor that has one parameter for each data member. This allows you to construct and initialize an instance in a single statement (instead of first having to construct the instance and then assign to its members).

- [Java Mapping for Sequences](#)
- [Java Mapping for Dictionaries](#)
- [Customizing the Java Mapping](#)

Java Mapping for Sequences

A Slice [sequence](#) maps to a Java array. This means that the Slice-to-Java compiler does not generate a separate named type for a Slice sequence.

For example:

```

Slice

```
sequence<Fruit> FruitPlatter;
```

```

This definition simply corresponds to the Java type `Fruit[]`. Naturally, because Slice sequences are mapped to Java arrays, you can take advantage of all the array functionality provided by Java, such as initialization, assignment, cloning, and the `length` member. For example:

```

Java

```
Fruit[] platter = { Fruit.Apple, Fruit.Pear };
assert(platter.length == 2);
```

```

Alternate mappings for sequence types are also possible.

- [Customizing the Java Mapping](#)

Java Mapping for Dictionaries

Here is the definition of our `EmployeeMap` once more:

Slice
<pre>dictionary<long, Employee> EmployeeMap;</pre>

As for sequences, the Java mapping does not create a separate named type for this definition. Instead, the dictionary is simply an instance of the generic type `java.util.Map<K, V>`, where `K` is the mapping of the key type and `V` is the mapping of the value type. In the example above, `EmployeeMap` is mapped to the Java type `java.util.Map<Long, Employee>`. The following code demonstrates how to allocate and use an instance of `EmployeeMap`:

Java
<pre>java.util.Map<Long, Employee> em = new java.util.HashMap<Long, Employee>(); Employee e = new Employee(); e.number = 31; e.firstName = "James"; e.lastName = "Gosling"; em.put(e.number, e);</pre>

The type-safe nature of the mapping makes iterating over the dictionary quite convenient:

Java
<pre>for (java.util.Map.Entry<Long, Employee> i : em.entrySet()) { long num = i.getKey(); Employee emp = i.getValue(); System.out.println(emp.firstName + " was employee #" + num); }</pre>

Alternate mappings for dictionary types are also possible.

Java Mapping for Constants

Here are the sample constant definitions once more:

Slice	
<code>const bool</code>	<code>AppendByDefault = true;</code>
<code>const byte</code>	<code>LowerNibble = 0x0f;</code>
<code>const string</code>	<code>Advice = "Don't Panic!";</code>
<code>const short</code>	<code>TheAnswer = 42;</code>
<code>const double</code>	<code>PI = 3.1416;</code>
<code>enum Fruit { Apple, Pear, Orange };</code>	
<code>const Fruit</code>	<code>FavoriteFruit = Pear;</code>

Here are the generated definitions for these constants:

Java	
<code>public interface AppendByDefault {</code>	<code> boolean value = true;</code>
<code>}</code>	
<code>public interface LowerNibble {</code>	<code> byte value = 15;</code>
<code>}</code>	
<code>public interface Advice {</code>	<code> String value = "Don't Panic!";</code>
<code>}</code>	
<code>public interface TheAnswer {</code>	<code> short value = 42;</code>
<code>}</code>	
<code>public interface PI {</code>	<code> double value = 3.1416;</code>
<code>}</code>	
<code>public interface FavoriteFruit {</code>	<code> Fruit value = Fruit.Pear;</code>
<code>}</code>	

As you can see, each Slice constant is mapped to a Java interface with the same name as the constant. The interface contains a member named `value` that holds the value of the constant.

Slice string literals that contain non-ASCII characters or universal character names are mapped to Java string literals with universal character names. For example:

Slice

```
const string Egg = "æuf";
const string Heart = "c\u0153ur";
const string Banana = "\U0001F34C";
```

is mapped to:

Java

```
public interface Egg {
    String value = "\u0153uf";
}

public interface Heart {
    String value = "c\u0153ur";
}

public interface Banana {
    String value = "\ud83c\udf4c";
}
```

Java Mapping for Exceptions

On this page:

- [Java Mapping for User Exceptions](#)
- [Java Constructors for User Exceptions](#)
- [Java Mapping for Run-Time Exceptions](#)

Java Mapping for User Exceptions

Here is a fragment of the Slice definition for our world time server once more:

Slice
<pre>exception GenericError { string reason; }; exception BadTimeVal extends GenericError {}; exception BadZoneName extends GenericError {};</pre>

These exception definitions map as follows:

Java
<pre>public class GenericError extends Ice.UserException { public String reason; public GenericError() {} public GenericError(Throwable cause) { super(cause); } public GenericError(String reason) { this.reason = reason; } public GenericError(String reason, Throwable cause) { super(cause); this.reason = reason; } public String ice_name() { return "GenericError"; } }</pre>

```
}

public class BadTimeVal extends GenericError {
    public BadTimeVal() {}

    public BadTimeVal(Throwable cause)
    {
        super(cause);
    }

    public BadTimeVal(String reason)
    {
        super(reason);
    }

    public BadTimeVal(String reason, Throwable cause)
    {
        super(reason, cause);
    }

    public String ice_name()
    {
        return "BadTimeVal";
    }
}

public class BadZoneName extends GenericError {
    public BadZoneName() {}

    public BadZoneName(Throwable cause)
    {
        super(cause);
    }

    public BadZoneName(String reason)
    {
        super(reason);
    }

    public BadZoneName(String reason, Throwable cause)
    {
        super(reason, cause);
    }

    public String ice_name()
    {
        return "BadZoneName";
    }
}
```

```

    }
}

```

Each Slice exception is mapped to a Java class with the same name. For each data member, the corresponding class contains a public data member. (Obviously, because `BadTimeVal` and `BadZoneName` do not have members, the generated classes for these exceptions also do not have members.) A [JavaBean-style API](#) is used for optional data members, and you can [customize the mapping](#) to force required members to use this same API.

The inheritance structure of the Slice exceptions is preserved for the generated classes, so `BadTimeVal` and `BadZoneName` inherit from `GenericError`.

Each exception also defines the `ice_name` member function, which returns the name of the exception.

All user exceptions are derived from the base class `Ice.UserException`. This allows you to catch all user exceptions generically by installing a handler for `Ice.UserException`. `Ice.UserException`, in turn, derives from `java.lang.Exception`.

`Ice.UserException` implements a `clone` method that is inherited by its derived exceptions, so you can make memberwise shallow copies of exceptions.

Note that the generated exception classes contain other member functions that are not shown. However, those member functions are internal to the Java mapping and are not meant to be called by application code.

Java Constructors for User Exceptions

Exceptions have a default constructor that initializes data members as follows:

Data Member Type	Default Value
<code>string</code>	Empty string
<code>enum</code>	First enumerator in enumeration
<code>struct</code>	Default-constructed value
<code>Numeric</code>	Zero
<code>bool</code>	False
<code>sequence</code>	Null
<code>dictionary</code>	Null
<code>class/interface</code>	Null

The constructor won't explicitly initialize a data member if the default Java behavior for that type produces the desired results.

If you wish to ensure that data members of primitive and enumerated types are initialized to specific values, you can declare default values in your [Slice definition](#). The default constructor initializes each of these data members to its declared value instead.

If an exception declares or inherits any data members, the generated class provides a second constructor that accepts one parameter for each data member so that you can construct and initialize an instance in a single statement (instead of first having to construct the instance and then assign to its members). For a derived exception, this constructor accepts one argument for each base exception member, plus one argument for each derived exception member, in base-to-derived order.

The generated class may include an additional constructor if the exception declares or inherits any [optional data members](#).

The Slice compiler generates overloaded versions of all constructors that accept a trailing `Throwable` argument for preserving an exception chain.

Java Mapping for Run-Time Exceptions

The Ice run time throws run-time exceptions for a number of pre-defined error conditions. All run-time exceptions directly or indirectly derive from `Ice.LocalException` (which, in turn, derives from `java.lang.RuntimeException`).

`Ice.LocalException` implements a `clone` method that is inherited by its derived exceptions, so you can make memberwise shallow copies of exceptions.

Recall the [inheritance diagram](#) for user and run-time exceptions. By catching exceptions at the appropriate point in the hierarchy, you can handle exceptions according to the category of error they indicate:

- `Ice.LocalException`
This is the root of the inheritance tree for run-time exceptions.
- `Ice.UserException`
This is the root of the inheritance tree for user exceptions.
- `Ice.TimeoutException`
This is the base exception for both operation-invocation and connection-establishment timeouts.
- `Ice.ConnectTimeoutException`
This exception is raised when the initial attempt to establish a connection to a server times out.

For example, a `ConnectTimeoutException` can be handled as `ConnectTimeoutException`, `TimeoutException`, `LocalException`, or `java.lang.Exception`.

You will probably have little need to catch run-time exceptions as their most-derived type and instead catch them as `LocalException`; the fine-grained error handling offered by the remainder of the hierarchy is of interest mainly in the implementation of the Ice run time. Exceptions to this rule are the exceptions related to [facet](#) and [object](#) life cycles, which you may want to catch explicitly. These exceptions are `FacetNotExistException` and `ObjectNotExistException`, respectively.

Java Mapping for Interfaces

The mapping of Slice [interfaces](#) revolves around the idea that, to invoke a remote operation, you call a member function on a local class instance that is a [proxy](#) for the remote object. This makes the mapping easy and intuitive to use because making a remote procedure call is no different from making a local procedure call (apart from error semantics).

On this page:

- [Java Classes Generated for an Interface](#)
- [Proxy Interfaces in Java](#)
- [The Ice.ObjectPrx Interface in Java](#)
- [Proxy Helpers in Java](#)
- [Using Proxy Methods in Java](#)
- [Object Identity and Proxy Comparison in Java](#)
- [Deserializing Proxies in Java](#)

Java Classes Generated for an Interface

The compiler generates quite a few source files for each Slice interface. In general, for an interface `<interface-name>`, the following source files are created by the compiler:

- `<interface-name>.java`
This source file declares the `<interface-name>` Java interface.
- `<interface-name>Holder.java`
This source file defines a [holder type](#) for the interface.
- `<interface-name>Prx.java`
This source file defines the [proxy interface](#) `<interface-name>Prx`.
- `<interface-name>PrxHelper.java`
This source file defines the [helper type](#) for the interface's proxy.
- `<interface-name>PrxHolder.java`
This source file defines the [holder type](#) for the interface's proxy.
- `_<interface-name>Operations.java`
`_<interface-name>OperationsNC.java`
These source files each define an interface that contains the operations corresponding to the Slice interface. The `Operations` interface is used for [tie classes](#).

These are the files that contain code that is relevant to the client side. The compiler also generates a file that is specific to the server side, plus three additional files:

- `_<interface-name>Disp.java`
This file contains the definition of the [server-side skeleton class](#).
- `_<interface-name>Del.java`
- `_<interface-name>DelD.java`
- `_<interface-name>DelM.java`
These files contain code that is internal to the Java mapping; they do not contain any functions of relevance to application programmers.

Proxy Interfaces in Java

On the client side, a Slice interface maps to a Java interface with methods that correspond to the operations on that interface. Consider the following simple interface:

Slice
<pre>interface Simple { void op(); };</pre>

The Slice compiler generates the following definition for use by the client:

```

Java

public interface SimplePrx extends Ice.ObjectPrx {
    public void op();
    public void op(java.util.Map<String, String> __context);
}

```

As you can see, the compiler generates a *proxy interface* `SimplePrx`. In general, the generated name is `<interface-name>Prx`. If an interface is nested in a module `M`, the generated class is part of package `M`, so the fully-qualified name is `M.<interface-name>Prx`.

In the client's address space, an instance of `SimplePrx` is the local ambassador for a remote instance of the `Simple` interface in a server and is known as a proxy instance. All the details about the server-side object, such as its address, what protocol to use, and its object identity are encapsulated in that instance.

Note that `SimplePrx` inherits from `Ice.ObjectPrx`. This reflects the fact that all Ice interfaces implicitly inherit from `Ice::Object`.

For each operation in the interface, the proxy class has a method of the same name. For the preceding example, we find that the operation `op` has been mapped to the method `op`. Also note that `op` is overloaded: the second version of `op` has a parameter `__context` of type `java.util.Map<String, String>`. This parameter is for use by the Ice run time to store information about how to deliver a request. You normally do not need to use it. (We examine the `__context` parameter in detail in [Request Contexts](#). The parameter is also used by `IceStor`.)

Because all the `<interface-name>Prx` types are interfaces, you cannot instantiate an object of such a type. Instead, proxy instances are always instantiated on behalf of the client by the Ice run time, so client code never has any need to instantiate a proxy directly. The proxy references handed out by the Ice run time are always of type `<interface-name>Prx`; the concrete implementation of the interface is part of the Ice run time and does not concern application code.

A value of `null` denotes the null proxy. The null proxy is a dedicated value that indicates that a proxy points "nowhere" (denotes no object).

The `Ice.ObjectPrx` Interface in Java

All Ice objects have `Object` as the ultimate ancestor type, so all proxies inherit from `Ice.ObjectPrx`. `ObjectPrx` provides a number of methods:

```

Java

package Ice;

public interface ObjectPrx {
    boolean equals(java.lang.Object r);
    Identity ice_getIdentity();
    boolean ice_isA(String __id);
    boolean ice_isA(String __id, java.util.Map<String, String> ctx);
    String[] ice_ids();
    String[] ice_ids(java.util.Map<String, String> ctx);
    String ice_id();
    String ice_id(java.util.Map<String, String> ctx);
    void ice_ping();
    void ice_ping(java.util.Map<String, String> ctx);
    // ...
}

```

The methods behave as follows:

- **equals**

This operation compares two proxies for equality. Note that all aspects of proxies are compared by this operation, such as the communication endpoints for the proxy. This means that, in general, if two proxies compare unequal, that does *not* imply that they denote different objects. For example, if two proxies denote the same Ice object via different transport endpoints, `equals` returns `false` even though the proxies denote the same object.

- **ice_getIdentity**

This method returns the identity of the object denoted by the proxy. The identity of an Ice object has the following Slice type:

```

Slice
module Ice {
    struct Identity {
        string name;
        string category;
    };
};

```

To see whether two proxies denote the same object, first obtain the identity for each object and then compare the identities:

```

Java
Ice.ObjectPrx o1 = ...;
Ice.ObjectPrx o2 = ...;
Ice.Identity i1 = o1.ice_getIdentity();
Ice.Identity i2 = o2.ice_getIdentity();

if (i1.equals(i2))
    // o1 and o2 denote the same object
else
    // o1 and o2 denote different objects

```

- **ice_isA**

The `ice_isA` method determines whether the object denoted by the proxy supports a specific interface. The argument to `ice_isA` is a *type ID*. For example, to see whether a proxy of type `ObjectPrx` denotes a `Printer` object, we can write:

```

Java
Ice.ObjectPrx o = ...;
if (o != null && o.ice_isA("::Printer"))
    // o denotes a Printer object
else
    // o denotes some other type of object

```

Note that we are testing whether the proxy is null before attempting to invoke the `ice_isA` method. This avoids getting a `NullPointerException` if the proxy is null.

- **ice_ids**

The `ice_ids` method returns an array of strings representing all of the type IDs that the object denoted by the proxy supports.

- **ice_id**

The `ice_id` method returns the type ID of the object denoted by the proxy. Note that the type returned is the type of the actual object, which may be more derived than the static type of the proxy. For example, if we have a proxy of type `BasePrx`, with a static type ID of `::Base`, the return value of `ice_id` might be `::Base`, or it might something more derived, such as `::Derived`.

- **ice_ping**

The `ice_ping` method provides a basic reachability test for the object. If the object can physically be contacted (that is, the object exists and its server is running and reachable), the call completes normally; otherwise, it throws an exception that indicates why the object could not be reached, such as `ObjectNotExistException` or `ConnectTimeoutException`.

The `ice_isA`, `ice_ids`, `ice_id`, and `ice_ping` methods are remote operations and therefore support an additional overloading that accepts a [request context](#). Also note that there are [other methods](#) in `ObjectPrx`, not shown here. These methods provide different ways to dispatch a call and also provide access to an object's [facets](#).

Proxy Helpers in Java

For each Slice interface, apart from the proxy interface, the Slice-to-Java compiler creates a helper class: for an interface `Simple`, the name of the generated helper class is `SimplePrxHelper`. The helper class provides methods that support down-casting and type discovery:

```

Java

public final class SimplePrxHelper
extends Ice.ObjectPrxHelper implements SimplePrx {
    public static SimplePrx checkedCast(Ice.ObjectPrx b) {
        // ...
    }

    public static SimplePrx checkedCast(Ice.ObjectPrx b,
Ice.Context ctx) {
        // ...
    }

    public static SimplePrx uncheckedCast(Ice.ObjectPrx b) {
        // ...
    }

    public static String ice_staticId() {
        // ...
    }

    // ...
}

```

For `checkedCast`, if the passed proxy is for an object of type `Simple`, or a proxy for an object with a type derived from `Simple`, the cast returns a non-null reference to a proxy of type `SimplePrx`; otherwise, if the passed proxy denotes an object of a different type (or if the passed proxy is null), the cast returns a null reference.

Given a proxy of any type, you can use a `checkedCast` to determine whether the corresponding object supports a given type, for example:

Java

```
Ice.ObjectPrx obj = ...;           // Get a proxy from somewhere...

SimplePrx simple = SimplePrxHelper.checkedCast(obj);
if (simple != null)
    // Object supports the Simple interface...
else
    // Object is not of type Simple...
```

Note that a `checkedCast` contacts the server. This is necessary because only the implementation of an object in the server has definite knowledge of the type of an object. As a result, a `checkedCast` may throw a `ConnectTimeoutException` or an `ObjectNotExistException`. (This also explains the need for the helper class: the Ice run time must contact the server, so we cannot use a Java down-cast.)

In contrast, an `uncheckedCast` does not contact the server and unconditionally returns a proxy of the requested type. However, if you do use an `uncheckedCast`, you must be certain that the proxy really does support the type you are casting to; otherwise, if you get it wrong, you will most likely get a run-time exception when you invoke an operation on the proxy. The most likely error for such a type mismatch is `OperationNotExistException`. However, other exceptions, such as a marshaling exception are possible as well. And, if the object happens to have an operation with the correct name, but different parameter types, no exception may be reported at all and you simply end up sending the invocation to an object of the wrong type; that object may do rather nonsensical things. To illustrate this, consider the following two interfaces:

Slice

```
interface Process {
    void launch(int stackSize, int dataSize);
};

// ...

interface Rocket {
    void launch(float xCoord, float yCoord);
};
```

Suppose you expect to receive a proxy for a `Process` object and use an `uncheckedCast` to down-cast the proxy:

Java

```
Ice.ObjectPrx obj = ...;           // Get proxy...
ProcessPrx process
= ProcessPrxHelper.uncheckedCast(obj); // No worries...
process.launch(40, 60);           // Oops...
```

If the proxy you received actually denotes a `Rocket` object, the error will go undetected by the Ice run time: because `int` and `float` have the same size and because the Ice protocol does not tag data with its type on the wire, the implementation of `Rocket::launch` will simply misinterpret the passed integers as floating-point numbers.

In fairness, this example is somewhat contrived. For such a mistake to go unnoticed at run time, both objects must have an operation with the same name and, in addition, the run-time arguments passed to the operation must have a total marshaled size that matches the number of bytes that are expected by the unmarshaling code on the server side. In practice, this is extremely rare and an incorrect `uncheckedCast` typically results in a run-time exception.

A final warning about down-casts: you must use either a `checkedCast` or an `uncheckedCast` to down-cast a proxy. If you use a Java cast, the behavior is undefined.

Another method defined by every helper class is `ice_staticId`, which returns the `type ID` string corresponding to the interface. As an example, for the Slice interface `Simple` in module `M`, the string returned by `ice_staticId` is `"::M::Simple"`.

Using Proxy Methods in Java

The base proxy class `ObjectPrx` supports a variety of [methods for customizing a proxy](#). Since proxies are immutable, each of these "factory methods" returns a copy of the original proxy that contains the desired modification. For example, you can obtain a proxy configured with a ten second timeout as shown below:

```
Java
```

```
Ice.ObjectPrx proxy = communicator.stringToProxy(...);
proxy = proxy.ice_timeout(10000);
```

A factory method returns a new proxy object if the requested modification differs from the current proxy, otherwise it returns the current proxy. With few exceptions, factory methods return a proxy of the same type as the current proxy, therefore it is generally not necessary to repeat a `checkedCast` or `uncheckedCast` after using a factory method. However, a regular cast is still required, as shown in the example below:

```
Java
```

```
Ice.ObjectPrx base = communicator.stringToProxy(...);
HelloPrx hello = HelloPrxHelper.checkedCast(base);
hello = (HelloPrx)hello.ice_timeout(10000); # Type is preserved
hello.sayHello();
```

The only exceptions are the factory methods `ice_facet` and `ice_identity`. Calls to either of these methods may produce a proxy for an object of an unrelated type, therefore they return a base proxy that you must subsequently down-cast to an appropriate type.

Object Identity and Proxy Comparison in Java

Proxies provide an `equals` method that compares proxies:

```
Java
```

```
interface ObjectPrx {
    boolean equals(java.lang.Object r);
}
```

Note that proxy comparison with `equals` uses *all* of the information in a proxy for the comparison. This means that not only the object identity must match for a comparison to succeed, but other details inside the proxy, such as the protocol and endpoint information, must be the same. In other words, comparison with `equals` tests for *proxy* identity, *not* object identity. A common mistake is to write code along the following lines:

Java

```
Ice.ObjectPrx p1 = ...;           // Get a proxy...
Ice.ObjectPrx p2 = ...;           // Get another proxy...

if (!p1.equals(p2)) {
    // p1 and p2 denote different objects           // WRONG!
} else {
    // p1 and p2 denote the same object             // Correct
}
```

Even though `p1` and `p2` differ, they may denote the same Ice object. This can happen because, for example, both `p1` and `p2` embed the same object identity, but each use a different protocol to contact the target object. Similarly, the protocols may be the same, but denote different endpoints (because a single Ice object can be contacted via several different transport endpoints). In other words, if two proxies compare equal with `equals`, we know that the two proxies denote the same object (because they are identical in all respects); however, if two proxies compare unequal with `equals`, we know absolutely nothing: the proxies may or may not denote the same object.

To compare the object identities of two proxies, you can use a helper function in the `Ice.Util` class:

Java

```
package Ice;

public final class Util {
    public static int proxyIdentityCompare(ObjectPrx lhs,
    ObjectPrx rhs);
    public static int proxyIdentityAndFacetCompare(ObjectPrx lhs,
    ObjectPrx rhs);
    // ...
}
```

`proxyIdentityCompare` allows you to correctly compare proxies for identity:

Java

```
Ice.ObjectPrx p1 = ...;           // Get a proxy...
Ice.ObjectPrx p2 = ...;           // Get another proxy...

if (Ice.Util.proxyIdentityCompare(p1, p2) != 0) {
    // p1 and p2 denote different objects           // Correct
} else {
    // p1 and p2 denote the same object             // Correct
}
```

The function returns 0 if the identities are equal, -1 if `p1` is less than `p2`, and 1 if `p1` is greater than `p2`. (The comparison uses `name` as the major and `category` as the minor sort key.)

The `proxyIdentityAndFacetCompare` function behaves similarly, but compares both the identity and the [facet name](#).

In addition, the Java mapping provides two wrapper classes that allow you to wrap a proxy for use as the key of a hashed collection:

Java

```
package Ice;

public class ProxyIdentityKey {
    public ProxyIdentityKey(Ice.ObjectPrx proxy);
    public int hashCode();
    public boolean equals(java.lang.Object obj);
    public Ice.ObjectPrx getProxy();
}

public class ProxyIdentityFacetKey {
    public ProxyIdentityFacetKey(Ice.ObjectPrx proxy);
    public int hashCode();
    public boolean equals(java.lang.Object obj);
    public Ice.ObjectPrx getProxy();
}
```

The constructor caches the identity and the hash code of the passed proxy, so calls to `hashCode` and `equals` can be evaluated efficiently. The `getProxy` method returns the proxy that was passed to the constructor.

As for the comparison functions, `ProxyIdentityKey` only uses the proxy's identity, whereas `ProxyIdentityFacetKey` also includes the facet name.

Deserializing Proxies in Java

Proxy objects implement the `java.io.Serializable` interface that enables serialization of proxies to and from a byte stream. You can use the standard class `java.io.ObjectInputStream` to deserialize all Slice types *except* proxies; proxies are a special case because they must be created by a communicator.

To supply a communicator for use in deserializing proxies, an application must use the class `Ice.ObjectInputStream`:

Java

```
package Ice;

public class ObjectInputStream extends java.io.ObjectInputStream
{
    public ObjectInputStream(Communicator communicator,
        java.io.InputStream stream)
        throws java.io.IOException;

    public Communicator getCommunicator();
}
```

The code shown below demonstrates how to use this class:

Java

```
Ice.Communicator communicator = ...
byte[] bytes = ... // data to be deserialized
java.io.ByteArrayInputStream byteStream =
new java.io.ByteArrayInputStream(bytes);
Ice.ObjectInputStream in =
new Ice.ObjectInputStream(communicator, byteStream);
Ice.ObjectPrx proxy = (Ice.ObjectPrx)in.readObject();
```

Ice raises `java.io.IOException` if an application attempts to deserialize a proxy without supplying a communicator.

Basic Java Mapping for Operations

As we saw in the [mapping for interfaces](#), for each [operation](#) on an interface, the proxy class contains a corresponding member function with the same name. To invoke an operation, you call it via the proxy. For example, here is part of the definitions for our [file system](#):

Slice

```

module Filesystem {
    interface Node {
        idempotent string name();
    };
    // ...
};

```

The `name` operation returns a value of type `string`. Given a proxy to an object of type `Node`, the client can invoke the operation as follows:

Java

```

NodePrx node = ...;           // Initialize proxy
String name = node.name();    // Get name via RPC

```

This illustrates the typical pattern for receiving return values: return values are returned by reference for complex types, and by value for simple types (such as `int` or `double`).

Normal and idempotent Operations in Java

You can add an `idempotent` qualifier to a Slice operation. As far as the signature for the corresponding proxy method is concerned, `idempotent` has no effect. For example, consider the following interface:

Slice

```

interface Example {
    string op1();
    idempotent string op2();
};

```

The proxy interface for this is:

```
Java
```

```
public interface ExamplePrx extends Ice.ObjectPrx {
    public String op1();
    public String op2();
}
```

Because `idempotent` affects an aspect of call dispatch, not interface, it makes sense for the two methods to be mapped the same.

Passing Parameters in Java

In-Parameters in Java

The parameter passing rules for the Java mapping are very simple: parameters are passed either by value (for simple types) or by reference (for complex types and type `string`). Semantically, the two ways of passing parameters are identical: it is guaranteed that the value of a parameter will not be changed by the invocation.

Here is an interface with operations that pass parameters of various types from client to server:

```
Slice
```

```
struct NumberAndString {
    int x;
    string str;
};

sequence<string> StringSeq;

dictionary<long, StringSeq> StringTable;

interface ClientToServer {
    void op1(int i, float f, bool b, string s);
    void op2(NumberAndString ns, StringSeq ss, StringTable st);
    void op3(ClientToServer* proxy);
};
```

The Slice compiler generates the following proxy for these definitions:

Java

```
public interface ClientToServerPrx extends Ice.ObjectPrx {
    public void op1(int i, float f, boolean b, String s);
    public void op2(NumberAndString ns, String[] ss, java.util.Map st);
    public void op3(ClientToServerPrx proxy);
}
```

Given a proxy to a `ClientToServer` interface, the client code can pass parameters as in the following example:

Java

```
ClientToServerPrx p = ...; // Get proxy...

p.op1(42, 3.14f, true, "Hello world!"); // Pass simple literals

int i = 42;
float f = 3.14f;
boolean b = true;
String s = "Hello world!";
p.op1(i, f, b, s); // Pass simple variables

NumberAndString ns = new NumberAndString();
ns.x = 42;
ns.str = "The Answer";
String[] ss = { "Hello world!" };
java.util.HashMap st = new java.util.HashMap();
st.put(new Long(0), ns);
p.op2(ns, ss, st); // Pass complex variables

p.op3(p); // Pass proxy
```

Out-Parameters in Java

Java does not have pass-by-reference: parameters are always passed by value. For a function to modify one of its arguments, we must pass a reference (by value) to an object; the called function can then modify the object's contents via the passed reference.

To permit the called function to modify a parameter, the Java mapping uses *holder* classes. For example, for each of the built-in Slice types, such as `int` and `string`, the `Ice` package contains a corresponding holder class. Here are the definitions for the holder classes `Ice.IntHolder` and `Ice.StringHolder`:

Java

```

package Ice;

public final class IntHolder {
    public IntHolder() {}
    public IntHolder(int value) {
        this.value = value;
    }
    public int value;
}

public final class StringHolder {
    public StringHolder() {}
    public StringHolder(String value) {
        this.value = value;
    }
    public String value;
}

```

A holder class has a public `value` member that stores the value of the parameter; the called function can modify the value by assigning to that member. The class also has a default constructor and a constructor that accepts an initial value.

For user-defined types, such as structures, the Slice-to-Java compiler generates a corresponding holder type. For example, here is the generated holder type for the `NumberAndString` structure we defined earlier:

Java

```

public final class NumberAndStringHolder {
    public NumberAndStringHolder() {}

    public NumberAndStringHolder(NumberAndString value) {
        this.value = value;
    }

    public NumberAndString value;
}

```

This looks exactly like the holder classes for the built-in types: we get a default constructor, a constructor that accepts an initial value, and the public `value` member.

Note that holder classes are generated for *every* Slice type you define. For example, for sequences, such as the `FruitPlatter` sequence, the compiler does not generate a special Java `FruitPlatter` type because sequences map to Java arrays. However, the compiler does generate a `FruitPlatterHolder` class, so we can pass a `FruitPlatter` array as an out-parameter.

To pass an out-parameter to an operation, we simply pass an instance of a holder class and examine the `value` member of each out-parameter when the call completes. Here are the same Slice definitions we saw earlier, but this time with all parameters being passed in the out direction:

Slice

```

struct NumberAndString {
    int x;
    string str;
};

sequence<string> StringSeq;

dictionary<long, StringSeq> StringTable;

interface ServerToClient {
    void op1(out int i, out float f, out bool b, out string s);
    void op2(out NumberAndString ns,
             out StringSeq ss,
             out StringTable st);
    void op3(out ServerToClient* proxy);
};

```

The Slice compiler generates the following code for these definitions:

Java

```

public interface ClientToServerPrx extends Ice.ObjectPrx {
    public void op1(Ice.IntHolder i, Ice.FloatHolder f,
                   Ice.BooleanHolder b, Ice.StringHolder s);
    public void op2(NumberAndStringHolder ns,
                   StringSeqHolder ss, StringTableHolder st);
    public void op3(ClientToServerPrxHolder proxy);
}

```

Given a proxy to a `ServerToClient` interface, the client code can pass parameters as in the following example:

Java

```

ClientToServerPrx p = ...;           // Get proxy...

Ice.IntHolder ih = new Ice.IntHolder();
Ice.FloatHolder fh = new Ice.FloatHolder();
Ice.BooleanHolder bh = new Ice.BooleanHolder();
Ice.StringHolder sh = new Ice.StringHolder();
p.op1(ih, fh, bh, sh);

NumberAndStringHolder nsh = new NumberAndString();
StringSeqHolder ssh = new StringSeqHolder();
StringTableHolder sth = new StringTableHolder();
p.op2(nsh, ssh, sth);

ServerToClientPrxHolder stch = new ServerToClientPrxHolder();
p.op3(stch);

System.out.println(ih.value); // Show one of the values

```

Again, there are no surprises in this code: the various holder instances contain values once the operation invocation completes and the `value` member of each instance provides access to those values.

Null Parameters in Java

Some Slice types naturally have "empty" or "not there" semantics. Specifically, sequences, dictionaries, and strings all can be `null`, but the corresponding Slice types do not have the concept of a null value. To make life with these types easier, whenever you pass `null` as a parameter or return value of type sequence, dictionary, or string, the Ice run time automatically sends an empty sequence, dictionary, or string to the receiver.

This behavior is useful as a convenience feature: especially for deeply-nested data types, members that are sequences, dictionaries, or strings automatically arrive as an empty value at the receiving end. This saves you having to explicitly initialize, for example, every string element in a large sequence before sending the sequence in order to avoid `NullPointerException`. Note that using null parameters in this way does *not* create null semantics for Slice sequences, dictionaries, or strings. As far as the object model is concerned, these do not exist (only *empty* sequences, dictionaries, and strings do). For example, whether you send a string as `null` or as an empty string makes no difference to the receiver: either way, the receiver sees an empty string.

Optional Parameters in Java

The Java mapping uses the generic class `Ice.Optional` to encapsulate **optional parameters**. All Slice types (including `string`) that map to Java reference types use the `Ice.Optional` generic class. To minimize garbage, the mapping also defines several non-generic classes to hold the unboxed primitive types `boolean`, `byte`, `short`, `int`, `long`, `float`, and `double`. For example, an optional `boolean` parameter maps to the `Ice.BooleanOptional` class.

Optional return values and output parameters are mapped to instances of `Ice.Optional` or one of the primitive wrapper classes, depending on their types. For operations with optional *input* parameters, the proxy provides a set of overloaded methods that accept them as optional values, and another set of methods that accept them as required values. Consider the following operation:

Slice

```
optional(1) int execute(optional(2) string params, out optional(3) float
value);
```

The default Java mapping for this operation is shown below:

Java

```
Ice.IntOptional execute(String params, Ice.FloatOptional value, ...);
Ice.IntOptional execute(Ice.Optional<String> params, Ice.FloatOptional
value, ...);
```

For cases where you are passing values for all optional input parameters, it is more efficient to use the required mapping and avoid creating temporary optional values.

A client can invoke `execute` as shown below:

Java

```
Ice.IntOptional i;
Ice.FloatOptional v = new Ice.FloatOptional();

i = proxy.execute("--file log.txt", v); //
required mapping
i = proxy.execute(new Ice.Optional<String>("--file log.txt"), v); //
optional mapping
i = proxy.execute((Ice.Optional<String>)null, v); //
params is unset

if(v.isSet())
    System.out.println("value = " + v.get());
```

Passing `null` where an `Ice.Optional` value is expected is equivalent to passing an `Ice.Optional` instance whose value is unset. For optional parameters of reference types, passing an explicit `null` requires a cast as shown in the last call to `execute` above.

Whereas the mapping for required output parameters uses `Holder` classes to transfer their values from the Ice run time to the caller, the optional mapping uses `Optional` values. When invoking a proxy operation, the client must pass an instance of the appropriate `Optional` type for each output parameter. The Ice run time invokes `clear` on the client's `Optional` value if the server does not supply a value for an output parameter, therefore it is safe to pass an `Optional` instance that already has a value.

A well-behaved program must not assume that an optional parameter always has a value. Calling `get` on an `Optional` instance for which no value is set raises `java.lang.IllegalStateException`.

Exception Handling in Java

Any operation invocation may throw a [run-time exception](#) and, if the operation has an exception specification, may also throw [user exceptions](#). Suppose we have the following simple interface:

Slice

```
exception Tantrum {
    string reason;
};

interface Child {
    void askToCleanUp() throws Tantrum;
};
```

Slice exceptions are thrown as Java exceptions, so you can simply enclose one or more operation invocations in a try-catch block:

Java

```
ChildPrx child = ...; // Get child proxy...

try {
    child.askToCleanUp();
} catch (Tantrum t) {
    System.out.write("The child says: ");
    System.out.println(t.reason);
}
```

Typically, you will catch only a few exceptions of specific interest around an operation invocation; other exceptions, such as unexpected run-time errors, will typically be handled by exception handlers higher in the hierarchy. For example:

Java

```

public class Client {
    static void run() {
        ChildPrx child = ...;    // Get child proxy...
        try {
            child.askToCleanUp();
        } catch (Tantrum t) {
            System.out.print("The child says: ");
            System.out.println(t.reason);
            child.scold();        // Recover from error...
        }
        child.praise();          // Give positive feedback...
    }

    public static void
    main(String[] args)
    {
        try {
            // ...
            run();
            // ...
        } catch (Ice.LocalException e) {
            e.printStackTrace();
        } catch (Ice.UserException e) {
            System.err.println(e.getMessage());
        }
    }
}

```

This code handles a specific exception of local interest at the point of call and deals with other exceptions generically. (This is also the strategy we used for our [first simple application](#).)

Exceptions and Out-Parameters

The Ice run time makes no guarantees about the state of out-parameters when an operation throws an exception: the parameter may still have its original value or may have been changed by the operation's implementation in the target object. In other words, for out-parameters, Ice provides the weak exception guarantee [1] but does not provide the strong exception guarantee.

This is done for reasons of efficiency: providing the strong exception guarantee would require more overhead than can be justified.

Java Mapping for Classes

On this page:

- [Basic Java Mapping for Classes](#)
- [Operations Interfaces in Java](#)
- [Inheritance from Ice.Object in Java](#)
- [Class Data Members in Java](#)
- [Class Operations in Java](#)
- [Class Factories in Java](#)
- [Class Constructors in Java](#)

Basic Java Mapping for Classes

A Slice `class` is mapped to a Java class with the same name. The generated class contains a public data member for each Slice data member (just as for structures and exceptions), and a member function for each operation. Consider the following class definition:

Slice
<pre>class TimeOfDay { short hour; // 0 - 23 short minute; // 0 - 59 short second; // 0 - 59 string format(); // Return time as hh:mm:ss };</pre>

The Slice compiler generates the following code for this definition:

Java
<pre>public interface _TimeOfDayOperations { String format(Ice.Current current); } public interface _TimeOfDayOperationsNC { String format(); } public abstract class TimeOfDay extends Ice.ObjectImpl implements _TimeOfDayOperations, _TimeOfDayOperationsNC { public short hour; public short minute; public short second; public TimeOfDay(); public TimeOfDay(short hour, short minute, short second); // ... }</pre>

There are a number of things to note about the generated code:

1. The compiler generates "operations interfaces" called `_TimeOfDayOperations` and `_TimeOfDayOperationsNC`. These interfaces contain a method for each Slice operation of the class.
2. The generated class `TimeOfDay` inherits (indirectly) from `Ice.Object`. This means that all classes implicitly inherit from `Ice.Object`, which is the ultimate ancestor of all classes. Note that `Ice.Object` is *not* the same as `Ice.ObjectPrx`. In other words, you *cannot* pass a class where a proxy is expected and vice versa. If a class has only data members, but no operations, the compiler generates a non-abstract class.
3. The generated class contains a public member for each Slice data member.
4. The generated class inherits member functions for each Slice operation from the operations interfaces.
5. The generated class contains two constructors.

There is quite a bit to discuss here, so we will look at each item in turn.

Operations Interfaces in Java

The methods in the `<interface-name>Operations` interface have an additional trailing parameter of type `Ice.Current`, whereas the methods in the `<interface-name>OperationsNC` interface lack this additional trailing parameter. The methods without the `Current` parameter simply forward to the methods with a `Current` parameter, supplying a default `Current`. For now, you can ignore this parameter and pretend it does not exist.

If a class has only data members, but no operations, the compiler omits generating the `<interface-name>Operations` and `<interface-name>OperationsNC` interfaces.

Inheritance from `Ice.Object` in Java

Like interfaces, classes implicitly inherit from a common base class, `Ice.Object`. However, as shown in the illustration below, classes inherit from `Ice.Object` instead of `Ice.ObjectPrx` (which is at the base of the inheritance hierarchy for proxies). As a result, you cannot pass a class where a proxy is expected (and vice versa) because the base types for classes and proxies are not compatible.

Inheritance from `Ice.ObjectPrx` and `Ice.Object`.

`Ice.Object` contains a number of member functions:

Java

```

package Ice;

public interface Object
{
    boolean ice_isA(String s);
    boolean ice_isA(String s, Current current);

    void ice_ping();
    void ice_ping(Current current);

    String[] ice_ids();
    String[] ice_ids(Current current);

    String ice_id();
    String ice_id(Current current);

    void ice_preMarshal();
    void ice_postUnmarshal();

    DispatchStatus ice_dispatch(Request request,
    DispatchInterceptorAsyncCallback cb);
}

```

The member functions of `Ice.Object` behave as follows:

- `ice_isA`
This function returns `true` if the object supports the given [type ID](#), and `false` otherwise.
- `ice_ping`
As for interfaces, `ice_ping` provides a basic reachability test for the class.
- `ice_ids`
This function returns a string sequence representing all of the [type IDs](#) supported by this object, including `::Ice::Object`.
- `ice_id`
This function returns the actual run-time [type ID](#) for a class. If you call `ice_id` through a reference to a base instance, the returned type id is the actual (possibly more derived) type ID of the instance.
- `ice_preMarshal`
The Ice run time invokes this function prior to marshaling the object's state, providing the opportunity for a subclass to validate its declared data members.
- `ice_postUnmarshal`
The Ice run time invokes this function after unmarshaling an object's state. A subclass typically overrides this function when it needs to perform additional initialization using the values of its declared data members.
- `ice_dispatch`
This function dispatches an incoming request to a servant. It is used in the implementation of [dispatch interceptors](#).

Note that the generated class does not override `hashCode` and `equals`. This means that classes are compared using shallow reference equality, not value equality (as is used for structures).

All Slice classes derive from `Ice.Object` via the `Ice.ObjectImpl` abstract base class. `ObjectImpl` implements the `java.io.Serializable` interface to support Java's [serialization](#) facility. `ObjectImpl` also supplies an implementation of `clone` that returns a shallow memberwise copy.

Class Data Members in Java

By default, data members of classes are mapped exactly as for structures and exceptions: for each data member in the Slice definition, the generated class contains a corresponding public data member. A [JavaBean-style API](#) is used for optional data members, and you can [customize the mapping](#) to force required members to use this same API.

If you wish to restrict access to a data member, you can modify its visibility using the `protected` metadata directive. The presence of this directive causes the Slice compiler to generate the data member with protected visibility. As a result, the member can be accessed only by the class itself or by one of its subclasses. For example, the `TimeOfDay` class shown below has the `protected` metadata directive applied to each of its data members:

Slice
<pre>class TimeOfDay { ["protected"] short hour; // 0 - 23 ["protected"] short minute; // 0 - 59 ["protected"] short second; // 0 - 59 string format(); // Return time as hh:mm:ss };</pre>

The Slice compiler produces the following generated code for this definition:

Java
<pre>public abstract class TimeOfDay extends Ice.ObjectImpl implements _TimeOfDayOperations, _TimeOfDayOperationsNC { protected short hour; protected short minute; protected short second; public TimeOfDay(); public TimeOfDay(short hour, short minute, short second); // ... }</pre>

For a class in which all of the data members are protected, the metadata directive can be applied to the class itself rather than to each member individually. For example, we can rewrite the `TimeOfDay` class as follows:

Slice

```
["protected"] class TimeOfDay {
    short hour;          // 0 - 23
    short minute;       // 0 - 59
    short second;       // 0 - 59
    string format();    // Return time as hh:mm:ss
};
```

Note that you can optionally [customize the mapping](#) for data members to use getters and setters instead.

Class Operations in Java

Operations of classes are mapped to abstract member functions in the generated class. This means that, if a class contains operations (such as the `format` operation of our `TimeOfDay` class), you must provide an implementation of the operation in a class that is derived from the generated class. For example:

Java

```
public class TimeOfDayI extends TimeOfDay {
    public String format(Ice.Current current) {
        DecimalFormat df = (DecimalFormat)DecimalFormat.getInstance();
        df.setMinimumIntegerDigits(2);
        return new String(df.format(hour) + ":" +
            df.format(minute) + ":" +
                df.format(second));
    }
}
```

Class Factories in Java

Having created a class such as `TimeOfDayI`, we have an implementation and we can instantiate the `TimeOfDayI` class, but we cannot receive it as the return value or as an out-parameter from an operation invocation. To see why, consider the following simple interface:

Slice

```
interface Time {
    TimeOfDay get();
};
```

When a client invokes the `get` operation, the Ice run time must instantiate and return an instance of the `TimeOfDay` class. However, `TimeOfDay` is an abstract class that cannot be instantiated. Unless we tell it, the Ice run time cannot magically know that we have created a `TimeOfDayI` class that implements the abstract `format` operation of the `TimeOfDay` abstract class. In other words, we must provide the Ice run time with a factory that knows that the `TimeOfDay` abstract class has a `TimeOfDayI` concrete implementation. The `Ice::CommunicatorI` interface provides us with the necessary operations:

Slice

```

module Ice {
    local interface ObjectFactory {
        Object create(string type);
        void destroy();
    };

    local interface Communicator {
        void addObjectFactory(ObjectFactory factory, string id);
        ObjectFactory findObjectFactory(string id);
        // ...
    };
};

```

To supply the Ice run time with a factory for our `TimeOfDayI` class, we must implement the `ObjectFactory` interface:

Java

```

class ObjectFactory implements Ice.ObjectFactory {
    public Ice.Object create(String type) {
        if (type.equals(M.TimeOfDay.ice_staticId())) {
            return new TimeOfDayI();
        }
        assert(false);
        return null;
    }

    public void destroy() {
        // Nothing to do
    }
}

```

The object factory's `create` method is called by the Ice run time when it needs to instantiate a `TimeOfDay` class. The factory's `destroy` method is called by the Ice run time when its communicator is destroyed.

The `create` method is passed the **type ID** of the class to instantiate. For our `TimeOfDay` class, the type ID is `"::M::TimeOfDay"`. Our implementation of `create` checks the type ID: if it matches, the method instantiates and returns a `TimeOfDayI` object. For other type IDs, the method asserts because it does not know how to instantiate other types of objects.

Note that we used the `ice_staticId` method to obtain the type ID rather than embedding a literal string. Using a literal type ID string in your code is discouraged because it can lead to errors that are only detected at run time. For example, if a Slice class or one of its enclosing modules is renamed and the literal string is not changed accordingly, a receiver will fail to unmarshal the object and the Ice run time will raise `NoObjectFactoryException`. By using `ice_staticId` instead, we avoid any risk of a misspelled or obsolete type ID, and we can discover at compile time if a Slice class or module has been renamed.

Given a factory implementation, such as our `ObjectFactory`, we must inform the Ice run time of the existence of the factory:

Java

```
Ice.Communicator ic = ...;
ic.addObjectFactory(new ObjectFactory(), M.TimeOfDay.ice_staticId());
```

Now, whenever the Ice run time needs to instantiate a class with the type ID `"::M::TimeOfDay"`, it calls the `create` method of the registered `ObjectFactory` instance.

The `destroy` operation of the object factory is invoked by the Ice run time when the communicator is destroyed. This gives you a chance to clean up any resources that may be used by your factory. Do not call `destroy` on the factory while it is registered with the communicator — if you do, the Ice run time has no idea that this has happened and, depending on what your `destroy` implementation is doing, may cause undefined behavior when the Ice run time tries to next use the factory.

The run time guarantees that `destroy` will be the last call made on the factory, that is, `create` will not be called concurrently with `destroy`, and `create` will not be called once `destroy` has been called. However, calls to `create` can be made concurrently.

Note that you cannot register a factory for the same type ID twice: if you call `addObjectFactory` with a type ID for which a factory is registered, the Ice run time throws an `AlreadyRegisteredException`.

Finally, keep in mind that if a class has only data members, but no operations, you need not create and register an object factory to transmit instances of such a class. Only if a class has operations do you have to define and register an object factory.

Class Constructors in Java

Classes have a default constructor that initializes data members as follows:

Data Member Type	Default Value
<code>string</code>	Empty string
<code>enum</code>	First enumerator in enumeration
<code>struct</code>	Default-constructed value
Numeric	Zero
<code>bool</code>	False
<code>sequence</code>	Null
<code>dictionary</code>	Null
<code>class/interface</code>	Null

The constructor won't explicitly initialize a data member if the default Java behavior for that type produces the desired results.

If you wish to ensure that data members of primitive and enumerated types are initialized to specific values, you can declare default values in your [Slice definition](#). The default constructor initializes each of these data members to its declared value instead.

The generated class also contains a second constructor that accepts one argument for each member of the class. This allows you to create and initialize a class in a single statement, for example:

Java

```
TimeOfDayI tod = new TimeOfDayI(14, 45, 00); // 14:45pm
```

For derived classes, the constructor requires an argument for every member of the class, including inherited members. For example, consider the the definition from [Class Inheritance](#) once more:

Slice

```
class TimeOfDay {
    short hour;          // 0 - 23
    short minute;       // 0 - 59
    short second;       // 0 - 59
};

class DateTime extends TimeOfDay {
    short day;          // 1 - 31
    short month;        // 1 - 12
    short year;         // 1753 onwards
};
```

The constructors for the generated classes are as follows:

Java

```

public class TimeOfDay extends Ice.ObjectImpl {
    public TimeOfDay() {}

    public TimeOfDay(short hour, short minute, short second)
    {
        this.hour = hour;
        this.minute = minute;
        this.second = second;
    }

    // ...
}

public class DateTime extends TimeOfDay
{
    public DateTime()
    {
        super();
    }

    public DateTime(short hour, short minute, short second,
                    short day, short month, short year)
    {
        super(hour, minute, second);
        this.day = day;
        this.month = month;
        this.year = year;
    }

    // ...
}

```

If you want to instantiate and initialize a `DateTime` instance, you must either use the default constructor or provide values for all of the data members of the instance, including data members of any base classes.

Overview of Java Mapping for Optional Data Members

The Java mapping for [optional data members](#) in [Slice classes](#) and [exceptions](#) uses a [JavaBean-style API](#) that provides methods to get, set, and clear a member's value, and test whether a value is set. Consider the following Slice definition:

Slice
<pre>class C { string name; optional(2) string alternateName; optional(5) bool active; };</pre>

The generated Java code provides the following API:

Java

```
public class C ...
{
    public C();
    public C(String name);
    public C(String name, String alternateName, boolean active);

    public String name;

    public String getAlternateName();
    public void setAlternateName(String v);
    public boolean hasAlternateName();
    public void clearAlternateName();
    public void optionalAlternateName(Ice.Optional<String> v);
    public Ice.Optional<String> optionalAlternateName();

    public boolean getActive();
    public void setActive(boolean v);
    public boolean isActive();
    public boolean hasActive();
    public void clearActive();
    public void optionalActive(Ice.BooleanOptional v);
    public Ice.BooleanOptional optionalActive();

    ...
}
```

If a class or exception declares any required data members, the generated class includes an overloaded constructor that accepts values for just the required members; optional members remain unset unless their Slice definitions specify a default value. Another overloaded constructor accepts values for all data members.

The `has` method allows you to test whether a member's value has been set, and the `clear` method removes any existing value for a member.

Calling a `get` method when the member's value has not been set raises `java.lang.IllegalStateException`.

The `optional` methods provide an alternate API that uses an `Optional` object to encapsulate the value, as discussed below.

Java Helper Classes for Optional Values

Ice defines the following classes to encapsulate optional values of primitive types:

- `Ice.BooleanOptional`
- `Ice.ByteOptional`
- `Ice.DoubleOptional`
- `Ice.FloatOptional`
- `Ice.IntOptional`
- `Ice.LongOptional`
- `Ice.ShortOptional`

These classes all share the same API for getting, setting, and testing an optional value. We'll use the `IntOptional` class as an example:

Java

```
public class IntOptional
{
    public IntOptional();           // Value is unset
    public IntOptional(int v);     // Value is set
    public IntOptional(IntOptional opt); // Copies the state of the
argument
    public int get();              // Raises IllegalStateException
if unset
    public void set(int v);        // Value is set
    public void set(IntOptional opt); // Copies the state of the
argument
    public boolean isSet();
    public void clear();

    ...
}
```

The `Ice.Optional` generic class encapsulates values of reference types and offers an identical API:

Java

```

public class Optional<T>
{
    public Optional();           // Value is unset
    public Optional(T v);       // Value is set
    public Optional(Optional<T> opt); // Copies the state of the
argument
    public T get();             // Raises IllegalStateException if
unset
    public void set(T v);       // Value is set
    public void set(Optional<T> opt); // Copies the state of the
argument
    public boolean isSet();
    public void clear();

    public static <T> Optional<T> O(T v);
    public static BooleanOptional O(boolean v);
    public static ByteOptional O(byte v);
    public static ShortOptional O(short v);
    public static IntOptional O(int v);
    public static LongOptional O(long v);
    public static FloatOptional O(float v);
    public static DoubleOptional O(double v);

    ...
}

```

To improve the readability of code that creates optional values, the `Optional` class defines overloaded `O` methods that simplify the creation of these objects:

Java

```

import static Ice.Optional.O;

C obj = ...;
Ice.Optional<C> opt = O(obj);

Ice.IntOptional i = O(5);

```

Serializable Objects in Java

In Java terminology, a *serializable object* typically refers to an object that implements the `java.io.Serializable` interface and therefore supports serialization to and from a byte stream. All Java classes generated from Slice definitions implement the `java.io.Serializable` interface.

In addition to serializing Slice types, applications may also need to incorporate foreign types into their Slice definitions. Ice allows you to pass Java *serializable objects* directly as operation parameters or as fields of another data type. For example:

```

Slice

["java:serializable:SomePackage.JavaClass"]
sequence<byte> JavaObj;
struct MyStruct {
    int i;
    JavaObj o;
};

interface Example {
    void op(JavaObj inObj, MyStruct s, out JavaObj outObj);
};

```

The generated code for `MyStruct` contains a member `i` of type `int` and a member `o` of type `SomePackage.JavaClass`:

```

Java

public final class MyStruct implements java.lang.Cloneable {
    public int i;
    public SomePackage.JavaClass o;

    // ...
}

```

Similarly, the signature for `op` has parameters of type `JavaClass` and `MyStruct` for the in-parameters, and `Ice.Holder<SomePackage.JavaClass>` for the out-parameter. (Out-parameters are always passed as `Ice.Holder<Class>`.)

```

Java

void op(SomePackage.JavaClass inObj,
        MyStruct s,
        Ice.Holder<SomePackage.JavaClass> outObj);

```

Of course, your client and server code must have an implementation of `JavaClass` that derives from `java.io.Serializable`:

Java

```
package SomePackage;  
  
public class JavaClass implements java.io.Serializable {  
    // ...  
}
```

You can implement this class in any way you see fit — the Ice run time does not place any other requirements on the implementation.

Customizing the Java Mapping

You can customize the code that the Slice-to-Java compiler produces by annotating your Slice definitions with `metadata`. This section describes how metadata influences several aspects of the generated Java code.

On this page:

 - [JavaBean Metadata](#)
- [Overriding serialVersionUID](#)

Java Packages

By default, the scope of a Slice definition determines the package of its mapped Java construct. A Slice type defined in a module hierarchy is mapped to a type residing in the equivalent Java package.

There are times when applications require greater control over the packaging of generated Java classes. For instance, a company may have software development guidelines that require all Java classes to reside in a designated package. One way to satisfy this requirement is to modify the Slice module hierarchy so that the generated code uses the required package by default. In the example below, we have enclosed the original definition of `Workflow::Document` in the modules `com::acme` so that the compiler will create the class in the `com.acme` package:

Slice

```

module com {
  module acme {
    module Workflow {
      class Document {
        // ...
      };
    };
  };
};

```

There are two problems with this workaround:

1. It incorporates the requirements of an implementation language into the application's interface specification.
2. Developers using other languages, such as C++, are also affected.

The Slice-to-Java compiler provides a better way to control the packages of generated code through the use of [global metadata](#). The example above can be converted as follows:

Slice

```

[[ "java:package:com.acme" ]]
module Workflow {
    class Document {
        // ...
    };
};

```

The global metadata directive `java:package:com.acme` instructs the compiler to generate all of the classes resulting from definitions in this Slice file into the Java package `com.acme`. The net effect is the same: the class for `Document` is generated in the package `com.acme.Workflow`. However, we have addressed the two shortcomings of the first solution by reducing our impact on the interface specification: the Slice-to-Java compiler recognizes the package metadata directive and modifies its actions accordingly, whereas the compilers for other language mappings simply ignore it.

Java Package Configuration Properties

Using global metadata to alter the default package of generated classes has ramifications for the Ice run time when unmarshaling [exceptions](#) and [concrete class types](#). The Ice run time dynamically loads generated classes by translating their Slice type ids into Java class names. For example, the Ice run time translates the Slice type id `::Workflow::Document` into the class name `Workflow.Document`.

However, when the generated classes are placed in a user-specified package, the Ice run time can no longer rely on the direct translation of a Slice type id into a Java class name, and therefore requires additional configuration so that it can successfully locate the generated classes. Two configuration properties are supported:

- `Ice.Package.Module=package`
Associates a top-level Slice module with the package in which it was generated.

Only top-level module names are allowed; the semantics of global metadata prevent a nested module from being generated into a different package than its enclosing module.

- `Ice.Default.Package=package`
Specifies a default package to use if other attempts to load a class have failed.

The behavior of the Ice run time when unmarshaling an exception or concrete class is described below:

1. Translate the Slice type id into a Java class name and attempt to load the class.
2. If that fails, extract the top-level module from the type id and check for an `Ice.Package` property with a matching module name. If found, prepend the specified package to the class name and try to load the class again.
3. If that fails, check for the presence of `Ice.Default.Package`. If found, prepend the specified package to the class name and try to load the class again.
4. If the class still cannot be loaded, the instance may be [sliced](#).

Continuing our example from the previous section, we can define the following property:

```
Ice.Package.Workflow=com.acme
```

Alternatively, we could achieve the same result with this property:

```
Ice.Default.Package=com.acme
```

Custom Types in Java

One of the more powerful applications of metadata is the ability to tailor the Java mapping for sequence and dictionary types to match the needs of your application.

Metadata in Java

The metadata for specifying a custom type has the following format:

```
java:type:instance-type[:formal-type]
```

The formal type is optional; the compiler uses a default value if one is not defined. The instance type must satisfy an is-A relationship with the formal type: either the same class is specified for both types, or the instance type must be derived from the formal type.

The Slice-to-Java compiler generates code that uses the formal type for all occurrences of the modified Slice definition except when the generated code must instantiate the type, in which case the compiler uses the instance type instead.

The compiler performs no validation on your custom types. Misspellings and other errors will not be apparent until you compile the generated code.

Defining a Custom Sequence Type in Java

Although the default mapping of a sequence type to a native Java array is efficient and typesafe, it is not always the most convenient representation of your data. To use a different representation, specify the type information in a metadata directive, as shown in the following example:

```

Slice
[ "java:type:java.util.LinkedList<String>" ]
sequence<string> StringList;

```

It is your responsibility to use a type parameter for the Java class (`String` in the example above) that is the correct mapping for the sequence's element type.

The compiler requires the formal type to implement `java.util.List<E>`, where `E` is the Java mapping of the element type. If you do not specify a formal type, the compiler uses `java.util.List<E>` by default.

Note that extra care must be taken when defining custom types that contain nested generic types, such as a custom sequence whose element type is also a custom sequence. The Java compiler strictly enforces type safety, therefore any compatibility issues in the custom type metadata will be apparent when the generated code is compiled.

Defining a Custom Dictionary Type in Java

The default instance type for a dictionary is `java.util.HashMap<K, V>`, where `K` is the Java mapping of the key type and `V` is the Java mapping of the value type. If the semantics of a `HashMap` are not suitable for your application, you can specify an alternate type using metadata as shown in the example below:

Slice

```
[ "java:type:java.util.TreeMap<String, String>" ]
dictionary<string, string> StringMap;
```

It is your responsibility to use type parameters for the Java class (`String` in the example above) that are the correct mappings for the dictionary's key and value types.

The compiler requires the formal type to implement `java.util.Map<K, V>`. If you do not specify a formal type, the compiler uses this type by default.

Note that extra care must be taken when defining dictionary types that contain nested generic types, such as a dictionary whose element type is a custom sequence. The Java compiler strictly enforces type safety, therefore any compatibility issues in the custom type metadata will be apparent when the generated code is compiled.

Using Custom Type Metadata in Java

You can define custom type metadata in a variety of situations. The simplest scenario is specifying the metadata at the point of definition:

Slice

```
[ "java:type:java.util.LinkedList<String>" ]
sequence<string> StringList;
```

Defined in this manner, the Slice-to-Java compiler uses `java.util.List<String>` (the default formal type) for all occurrences of `StringList`, and `java.util.LinkedList<String>` when it needs to instantiate `StringList`.

You may also specify a custom type more selectively by defining metadata for a data member, parameter or return value. For instance, the mapping for the original Slice definition might be sufficient in most situations, but a different mapping is more convenient in particular cases. The example below demonstrates how to override the sequence mapping for the data member of a structure as well as for several operations:

Slice

```
sequence<string> StringSeq;

struct S {
    ["java:type:java.util.LinkedList<String>"] StringSeq seq;
};

interface I {
    ["java:type:java.util.ArrayList<String>"] StringSeq
    modifiedReturnValue();

    void modifiedInParam(["java:type:java.util.ArrayList<String>"] Stri
ngSeq seq);

    void modifiedOutParam(out ["java:type:java.util.ArrayList<String>"]
StringSeq seq);
};
```

As you might expect, modifying the mapping for an operation's parameters or return value may require the application to manually convert values from the original mapping to the modified mapping. For example, suppose we want to invoke the `modifiedInParam` operation. The signature of its proxy operation is shown below:

Java

```
void modifiedInParam(java.util.List<String> seq, Ice.Current curr)
```

The metadata changes the mapping of the `seq` parameter to `java.util.List`, which is the default formal type. If a caller has a `StringSeq` value in the original mapping, it must convert the array as shown in the following example:

Java

```
String[] seq = new String[2];
seq[0] = "hi";
seq[1] = "there";
IPrx proxy = ...;
proxy.modifiedInParam(java.util.Arrays.asList(seq));
```

Although we specified the instance type `java.util.ArrayList<String>` for the parameter, we are still able to pass the result of `asList` because its return type (`java.util.List<String>`) is compatible with the parameter's formal type declared by the proxy method. In the case of an operation parameter, the instance type is only relevant to a servant implementation, which may need to make assumptions about the actual type of the parameter.

Mapping for Modified Out Parameters in Java

The mapping for an `out` parameter uses a generated "holder" class to convey the `parameter value`. If you modify the mapping of an `out` parameter, as discussed in the previous section, it is possible that the holder class for the parameter's unmodified type is no longer compatible with the custom type you have specified. The holder class generated for `StringSeq` is shown below:

```
Java
```

```
public final class StringSeqHolder
{
    public
    StringSeqHolder()
    {
    }

    public
    StringSeqHolder(String[] value)
    {
        this.value = value;
    }

    public String[] value;
}
```

An `out` parameter of type `StringSeq` would normally map to a proxy method that used `StringSeqHolder` to hold the parameter value. When the parameter is modified, as is the case with the `modifiedOutParam` operation, the Slice-to-Java compiler cannot use `StringSeqHolder` to hold an instance of `java.util.List<String>`, because `StringSeqHolder` is only appropriate for the default mapping to a native array.

As a result, the compiler handles these situations using instances of the generic class `Ice.Holder<T>`, where `T` is the parameter's formal type. Consider the following example:

```
Slice
```

```
sequence<string> StringSeq;

interface I {
    void modifiedOutParam(out ["java:type:java.util.ArrayList<String>"]
StringSeq seq);
};
```

The compiler generates the following mapping for the `modifiedOutParam` proxy method:

```
Java
```

```
void modifiedOutParam(Ice.Holder<java.util.List<java.lang.String> > seq,
Ice.Current curr)
```

The formal type of the parameter is `java.util.List<String>`, therefore the holder class becomes `Ice.Holder<java.util.List<String>>`.

Buffer Types in Java

As of Ice 3.6, you can annotate sequences of certain primitive types with the `java:buffer` metadata tag to change the mapping to use subclasses of `java.nio.Buffer`. This mapping provides several benefits:

- You can pass a buffer to a Slice API instead of creating and filling a temporary array
- If you need to pass a portion of an existing array, you can wrap it with a buffer and avoid an extra copy
- Receiving buffers during a Slice operation also avoids copying by directly referencing the data in Ice's unmarshaling buffer

To use buffers safely, applications must disable caching by setting `Ice.CacheMessageBuffers` to zero.

The following table lists each supported Slice primitive type with its corresponding mapped class:

Primitive	Mapping
byte	<code>java.nio.ByteBuffer</code>
short	<code>java.nio.ShortBuffer</code>
int	<code>java.nio.IntBuffer</code>
long	<code>java.nio.LongBuffer</code>
float	<code>java.nio.FloatBuffer</code>
double	<code>java.nio.DoubleBuffer</code>

The `java:buffer` tag can be applied to the initial definition of a sequence, in which case the mapping uses the buffer type for all occurrences of that sequence type:

```

Slice

["java:buffer"] sequence<int> Values;

struct Observation {
    int x;
    int y;
    Values measurements;
};

```

We can construct an `Observation` as follows:

```

Java

Observation obs = new Observation();
obs.x = 5;
obs.y = 9;
obs.measurements = java.nio.IntBuffer.allocate(10);
for(int i = 0; i < obs.measurements.capacity(); ++i)
    obs.measurements.put(i, ...);

```

The `java:buffer` tag can also be applied in more limited situations to override a sequence's normal mapping:

```

Slice

sequence<byte> ByteSeq; // Maps to byte[]

struct Page {
    int offset;
    ["java:buffer"] ByteSeq data; // Maps to java.nio.ByteBuffer
};

interface Decoder {
    ["java:buffer"] ByteSeq decode(ByteSeq data);
};

```

In this example, `ByteSeq` maps by default to a `byte` array, but we've overridden the mapping to use a buffer when this type is used as a data member in `Page` and as the return value of the `decode` operation; the input parameter to `decode` uses the default array mapping.

JavaBean Mapping

The Java mapping optionally generates JavaBean-style methods for the data members of class, structure, and exception types.

JavaBean Generated Methods

For each data member `val` of type `T`, the mapping generates the following methods:

```

Java

public T getVal();
public void setVal(T v);

```

The mapping generates an additional method if `T` is the `bool` type:

```

Java

public boolean isVal();

```

Finally, if `T` is a sequence type with an element type `E`, two methods are generated to provide direct access to elements:

```

Java

public E getVal(int index);
public void setVal(int index, E v);

```

Note that these element methods are only generated for sequence types that use the default mapping.

The Slice-to-Java compiler considers it a fatal error for a JavaBean method of a class data member to conflict with a declared operation of the class. In this situation, you must rename the operation or the data member, or disable the generation of JavaBean methods for the data member in question.

JavaBean Metadata

The JavaBean methods are generated for a data member when the member or its enclosing type is annotated with the `java:getset` meta data. The following example demonstrates both styles of usage:

Slice
<pre> sequence<int> IntSeq; class C { ["java:getset"] int i; double d; }; ["java:getset"] struct S { bool b; string str; }; ["java:getset"] exception E { IntSeq seq; }; </pre>

JavaBean methods are generated for all members of struct `S` and exception `E`, but for only one member of class `C`. Relevant portions of the generated code are shown below:

Java
<pre> public class C extends Ice.ObjectImpl { ... public int i; public int getI() { return i; } public void setI(int _i) </pre>

```

    {
        i = _i;
    }

    public double d;
}

public final class S implements java.lang.Cloneable
{
    public boolean b;

    public boolean
    getB()
    {
        return b;
    }

    public void
    setB(boolean _b)
    {
        b = _b;
    }

    public boolean
    isB()
    {
        return b;
    }

    public String str;

    public String
    getStr()
    {
        return str;
    }

    public void
    setStr(String _str)
    {
        str = _str;
    }

    ...
}

public class E extends Ice.UserException
{
    ...
}

```

```
public int[] seq;

public int[]
getSeq()
{
    return seq;
}

public void
setSeq(int[] _seq)
{
    seq = _seq;
}

public int
getSeq(int _index)
{
    return seq[_index];
}

public void
setSeq(int _index, int _val)
{
    seq[_index] = _val;
}
```

```

    ...
}

```

Overriding `serialVersionUID`

The Slice-to-Java compiler computes a default value for the `serialVersionUID` member of Slice classes, exceptions and structures. If you prefer, you can override this value using the `java:serialVersionUID` metadata, as shown below:

Slice

```

["java:serialVersionUID:571254925"]
struct Identity
{
    ...
};

```

The specified value will be used in place of the default value in the generated code:

Java

```

public class Identity
{
    ...

    public static final long serialVersionUID = 571254925L;
}

```

By using this metadata, the application assumes responsibility for updating the UID whenever changes to the Slice definition affect the serializable state of the type.

Asynchronous Method Invocation (AMI) in Java

Asynchronous Method Invocation (AMI) is the term used to describe the client-side support for the asynchronous programming model. AMI supports both oneway and twoway requests, but unlike their synchronous counterparts, AMI requests never block the calling thread. When a client issues an AMI request, the Ice run time hands the message off to the local transport buffer or, if the buffer is currently full, queues the request for later delivery. The application can then continue its activities and poll or wait for completion of the invocation, or receive a callback when the invocation completes.

AMI is transparent to the server: there is no way for the server to tell whether a client sent a request synchronously or asynchronously.

Basic Asynchronous API in Java

Consider the following simple Slice definition:

Slice

```

module Demo {
    interface Employees {
        string getName(int number);
    };
};

```

Asynchronous Proxy Methods in Java

Besides the synchronous proxy methods, `slice2java` generates the following asynchronous proxy methods:

Java

```
public interface EmployeesPrx extends Ice.ObjectPrx
{
    // ...

    public Ice.AsyncResult begin_getName(int number);
    public Ice.AsyncResult begin_getName(int number,
    java.util.Map<String, String> __ctx);

    public String end_getName(Ice.AsyncResult __result);
}
```

Four additional overloads of `begin_getName` are generated for use with [generic completion callbacks](#) and [type-safe completion callbacks](#).

As you can see, the single `getName` operation results in `begin_getName` and `end_getName` methods. (The `begin_` method is overloaded so you can pass a [per-invocation context](#).)

- The `begin_getName` method sends (or queues) an invocation of `getName`. This method does not block the calling thread.
- The `end_getName` method collects the result of the asynchronous invocation. If, at the time the calling thread calls `end_getName`, the result is not yet available, the calling thread blocks until the invocation completes. Otherwise, if the invocation completed some time before the call to `end_getName`, the method returns immediately with the result.

A client could call these methods as follows:

Java

```
EmployeesPrx e = ...;
Ice.AsyncResult r = e.begin_getName(99);

// Continue to do other things here...

String name = e.end_getName(r);
```

Because `begin_getName` does not block, the calling thread can do other things while the operation is in progress.

Note that `begin_getName` returns a value of type `AsyncResult`. This value contains the state that the Ice run time requires to keep track of the asynchronous invocation. You must pass the `AsyncResult` that is returned by the `begin_` method to the corresponding `end_` method.

The `begin_` method has one parameter for each in-parameter of the corresponding Slice operation. Similarly, the `end_` method has one out-parameter for each out-parameter of the corresponding Slice operation (plus the `AsyncResult` parameter). For example, consider the following operation:

Slice

```
double op(int inp1, string inp2, out bool outp1, out long outp2);
```

The `begin_op` and `end_op` methods have the following signature:

Java

```
Ice.AsyncResult begin_op(int inp1, String inp2);
Ice.AsyncResult begin_op(int inp1, String inp2,
    java.util.Map<String, String> __ctx);
double end_op(Ice.BooleanHolder outp1, Ice.LongHolder outp2,
    Ice.AsyncResult r);
```

Asynchronous Exception Semantics in Java

If an invocation raises an exception, the exception is thrown by the `end_` method, even if the actual error condition for the exception was encountered during the `begin_` method ("on the way out"). The advantage of this behavior is that all exception handling is located with the code that calls the `end_` method (instead of being present twice, once where the `begin_` method is called, and again where the `end_` method is called).

There is one exception to the above rule: if you destroy the communicator and then make an asynchronous invocation, the `begin_` method throws `CommunicatorDestroyedException`. This is necessary because, once the run time is finalized, it can no longer throw an exception from the `end_` method.

The only other exception that is thrown by the `begin_` and `end_` methods is `java.lang.IllegalArgumentException`. This exception indicates that you have used the API incorrectly. For example, the `begin_` method throws this exception if you call an operation that has a return value or out-parameters on a oneway proxy. Similarly, the `end_` method throws this exception if you use a different proxy to call the `end_` method than the proxy you used to call the `begin_` method, or if the `AsyncResult` you pass to the `end_` method was obtained by calling the `begin_` method for a different operation.

AsyncResult Interface in Java

The `AsyncResult` that is returned by the `begin_` method encapsulates the state of the asynchronous invocation:

Java

```

public interface AsyncResult {
    public void cancel();

    public Communicator getCommunicator();
    public Connection getConnection();
    public ObjectPrx getProxy();
    public String getOperation();

    public boolean isCompleted();
    public void waitForCompleted();

    public boolean isSent();
    public void waitForSent();

    public void throwLocalException();

    public boolean sentSynchronously();
}

```

The methods have the following semantics:

- `void cancel()`
This method prevents a queued invocation from being sent or, if the invocation has already been sent, ignores a reply if the server sends one. `cancel` is a local operation and has no effect on the server. A canceled invocation is considered to be completed, meaning `isCompleted` returns true, and the result of the invocation is an `Ice.InvocationCanceledException`.
- `Communicator getCommunicator()`
This method returns the communicator that sent the invocation.
- `Connection getConnection()`
This method returns the connection that was used for the invocation. Note that, for typical asynchronous proxy invocations, this method returns a nil value because the possibility of automatic retries means the connection that is currently in use could change unexpectedly. The `getConnection` method only returns a non-nil value when the `AsyncResult` object is obtained by calling `begin_flushBatchRequests` on a `Connection` object.
- `ObjectPrx getProxy()`
This method returns the proxy that was used to call the `begin_` method, or nil if the `AsyncResult` object was not obtained via an asynchronous proxy invocation.
- `String getOperation()`
This method returns the name of the operation.
- `boolean isCompleted()`
This method returns true if, at the time it is called, the result of an invocation is available, indicating that a call to the `end_` method will not block the caller. Otherwise, if the result is not yet available, the method returns false.
- `void waitForCompleted()`
This method blocks the caller until the result of an invocation becomes available.
- `boolean isSent()`
When you call the `begin_` method, the Ice run time attempts to write the corresponding request to the client-side transport. If the transport cannot accept the request, the Ice run time queues the request for later transmission. `isSent` returns true if, at the time it is called, the request has been written to the local transport (whether it was initially queued or not). Otherwise, if the request is still queued or an exception occurred before the request could be sent, `isSent` returns false.
- `void waitForSent()`

This method blocks the calling thread until a request has been written to the client-side transport, or an exception occurs. After `waitForSent` returns, `isSent` returns true if the request was successfully written to the client-side transport, or false if an exception occurred. In the case of a failure, you can call the corresponding `end_` method or `throwLocalException` to obtain the exception.

- `void throwLocalException()`
This method throws the local exception that caused the invocation to fail. If no exception has occurred yet, `throwLocalException` does nothing.
- `boolean sentSynchronously()`
This method returns true if a request was written to the client-side transport without first being queued. If the request was initially queued, `sentSynchronously` returns false (independent of whether the request is still in the queue or has since been written to the client-side transport).

Polling for Completion in Java

The `AsyncResult` methods allow you to poll for call completion. Polling is useful in a variety of cases. As an example, consider the following simple interface to transfer files from client to server:

Slice

```
interface FileTransfer
{
    void send(int offset, ByteSeq bytes);
};
```

The client repeatedly calls `send` to send a chunk of the file, indicating at which offset in the file the chunk belongs. A naïve way to transmit a file would be along the following lines:

Java

```
FileHandle file = open(...);
FileTransferPrx ft = ...;
int chunkSize = ...;
int offset = 0;
while (!file.eof()) {
    byte[] bs;
    bs = file.read(chunkSize); // Read a chunk
    ft.send(offset, bs);      // Send the chunk
    offset += bs.length;
}
```

This works, but not very well: because the client makes synchronous calls, it writes each chunk on the wire and then waits for the server to receive the data, process it, and return a reply before writing the next chunk. This means that both client and server spend much of their time doing nothing — the client does nothing while the server processes the data, and the server does nothing while it waits for the client to send the next chunk.

Using asynchronous calls, we can improve on this considerably:

Java

```

FileHandle file = open(...);
FileTransferPrx ft = ...;
int chunkSize = ...;
int offset = 0;

LinkedList<Ice.AsyncResult> results = new LinkedList<Ice.AsyncResult>();
int numRequests = 5;

while (!file.eof()) {
    byte[] bs;
    bs = file.read(chunkSize);

    // Send up to numRequests + 1 chunks asynchronously.
    Ice.AsyncResult r = ft.begin_send(offset, bs);
    offset += bs.length;

    // Wait until this request has been passed to the transport.
    r.waitForSent();
    results.add(r);

    // Once there are more than numRequests, wait for the least
    // recent one to complete.
    while (results.size() > numRequests) {
        Ice.AsyncResult r = results.getFirst();
        results.removeFirst();
        r.waitForCompleted();
    }
}

// Wait for any remaining requests to complete.
while (results.size() > 0) {
    Ice.AsyncResult r = results.getFirst();
    results.removeFirst();
    r.waitForCompleted();
}

```

With this code, the client sends up to `numRequests + 1` chunks before it waits for the least recent one of these requests to complete. In other words, the client sends the next request without waiting for the preceding request to complete, up to the limit set by `numRequests`. In effect, this allows the client to "keep the pipe to the server full of data": the client keeps sending data, so both client and server continuously do work.

Obviously, the correct chunk size and value of `numRequests` depend on the bandwidth of the network as well as the amount of time taken by the server to process each request. However, with a little testing, you can quickly zoom in on the point where making the requests larger or queuing more requests no longer improves performance. With this technique, you can realize the full bandwidth of the link to within a percent or two of the theoretical bandwidth limit of a native socket connection.

Generic Completion Callbacks in Java

The `begin_` method is overloaded to allow you to provide completion callbacks. Here are the corresponding methods for the `getName` operation:

```
Java
```

```
Ice.AsyncResult begin_getName(int number, Ice.Callback __cb);

Ice.AsyncResult begin_getName(int number,
                               java.util.Map<String, String> __ctx,
                               Ice.Callback __cb);
```

The second version of `begin_getName` lets you override the default context. Following the in-parameters, the `begin_` method accepts a parameter of type `Ice.Callback`, which is a callback class with a `completed` method that you must provide. The Ice run time invokes the `completed` method when an asynchronous operation completes. For example:

```
Java
```

```
public class MyCallback extends Ice.Callback
{
    public void completed(Ice.AsyncResult r)
    {
        EmployeesPrx e = (EmployeesPrx)r.getProxy();
        try {
            String name = e.end_getName(r);
            System.out.println("Name is: " + name);
        } catch (Ice.LocalException ex) {
            System.err.println("Exception is: " + ex);
        }
    }
}
```

Note that your callback class must derive from `Ice.Callback`. The implementation of your callback method must call the `end_` method. The proxy for the call is available via the `getProxy` method on the `AsyncResult` that is passed by the Ice run time. The return type of `getProxy` is `Ice.ObjectPrx`, so you must down-cast the proxy to its correct type.

Your callback method should catch and handle any exceptions that may be thrown by the `end_` method. If an operation can throw user exceptions, this means that you need an additional catch handler for `Ice.UserException` (or catch all possible user exceptions explicitly). If you allow an exception to escape from the callback method, the Ice run time produces a log entry by default and ignores the exception. (You can disable the log message by setting the property `Ice.Warn.AMICallback` to zero.)

To inform the Ice run time that you want to receive a callback for the completion of the asynchronous call, you pass the callback instance to the `begin_` method:

Java

```

EmployeesPrx e = ...;

MyCallback cb = new MyCallback();
e.begin_getName(99, cb);

```

This is often written using an anonymous class instead:

Java

```

EmployeesPrx e = ...;

e.begin_getName(
    99,
    new Ice.Callback()
    {
        public void completed(Ice.AsyncResult r)
        {
            EmployeesPrx p = (EmployeesPrx)r.getProxy();
            try {
                String name = p.end_getName(r);
                System.out.println("Name is: " + name);
            } catch (Ice.LocalException ex) {
                System.err.println("Exception: " + ex);
            }
        }
    }
);

```

An anonymous class is especially useful for callbacks that do only a small amount of work because the code that starts the call and the code that processes the results are physically close together.

Sharing State Between `begin_` and `end_` Methods in Java

It is common for the `end_` method to require access to some state that is established by the code that calls the `begin_` method. As an example, consider an application that asynchronously starts a number of operations and, as each operation completes, needs to update different user interface elements with the results. In this case, the `begin_` method knows which user interface element should receive the update, and the `end_` method needs access to that element.

Assuming that we have a `Widget` class that designates a particular user interface element, you could pass different widgets by storing the widget to be used as a member of your callback class:

Java

```
public class MyCallback extends Ice.Callback
{
    public MyCallback(Widget w)
    {
        _w = w;
    }

    private Widget _w;

    public void completed(Ice.AsyncResult r)
    {
        EmployeesPrx e = (EmployeesPrx)r.getProxy();
        try {
            String name = e.end_getName(r);
            _w.writeString(name);
        } catch (Ice.LocalException ex) {
            System.err.println("Exception is: " + ex);
        }
    }
}
```

For this example, we assume that widgets have a `writeString` method that updates the relevant UI element.

When you call the `begin_` method, you pass the appropriate callback instance to inform the `end_` method how to update the display:

Java

```
EmployeesPrx e = ...;
Widget widget1 = ...;
Widget widget2 = ...;

// Invoke the getName operation with different widget callbacks.
e.begin_getName(99, new MyCallback(widget1));
e.begin_getName(24, new MyCallback(widget2));
```

The callback class provides a simple and effective way for you to pass state between the point where an operation is invoked and the point where its results are processed. Moreover, if you have a number of operations that share common state, you can pass the same callback instance to multiple invocations. (If you do this, your callback methods may need to use synchronization.)

Type-Safe Completion Callbacks in Java

The [generic callback API](#) is not entirely type-safe:

- You must down-cast the return value of `getProxy` to the correct proxy type before you can call the `end_` method.
- You must call the correct `end_` method to match the operation called by the `begin_` method.

- You must remember to catch exceptions when you call the `end_` method; if you forget to do this, you will not know that the operation failed.

`slice2java` generates an additional type-safe API that takes care of these chores for you. To use type-safe callbacks, you can either implement a callback class or use lambda functions (in Java 8).

Type-Safe Callback Classes in Java

A callback class must define two callback methods:

- a `response` method that is called if the operation succeeds
- an `exception` method that is called if the operation raises an exception

The class must derive from the base class that is generated by `slice2java`. The name of this base class is `<module>.Callback_<interface>_<operation>`. Here is a callback class for an invocation of the `getName` operation:

```

Java

public class MyCallback extends Demo.Callback_Employees_getName
{
    public void response(String name)
    {
        System.out.println("Name is: " + name);
    }

    public void exception(Ice.LocalException ex)
    {
        System.err.println("Exception is: " + ex);
    }
}

```

The `response` callback parameters depend on the operation signature. If the operation has non-void return type, the first parameter of the `response` callback is the return value. The return value (if any) is followed by a parameter for each out-parameter of the corresponding Slice operation, in the order of declaration.

The `exception` callback is invoked if the invocation fails because of an Ice run time exception. If the Slice operation can also raise user exceptions, your callback class must supply an additional overloading of `exception` that accepts an argument of type `Ice.UserException`.

The proxy methods are overloaded to accept this callback instance:

```

Java

Ice.AsyncResult begin_getName(int number,
                              Callback_Employees_getName __cb);

Ice.AsyncResult begin_getName(int number,
                              java.util.Map<String, String> __ctx,
                              Callback_Employees_getName __cb);

```

You pass the callback to an invocation as you would with the generic API:

Java

```

EmployeesPrx e = ...;

MyCallback cb = new MyCallback();
e.begin_getName(99, cb);

```

Type-Safe Lambda Functions in Java

If you're using Java 8, you can implement your type-safe callbacks using in-line lambda functions. The proxy methods are overloaded to accept these functions:

Java

```

Ice.AsyncResult begin_getName(int number,

IceInternal.Functional_GenericCallback1<String> __responseCb,

IceInternal.Functional_GenericCallback1<Ice.Exception> __exceptionCb);

Ice.AsyncResult begin_getName(int number,
                               java.util.Map<String, String> __ctx,

IceInternal.Functional_GenericCallback1<String> __responseCb,

IceInternal.Functional_GenericCallback1<Ice.Exception> __exceptionCb);

```

The names of the internal interfaces used in the API are not important; what matters are their parameterized types, which tell you the arguments that your lambda functions must accept. For example, we can call `begin_getName` as follows:

Java

```

EmployeesPrx e = ...;

e.begin_getName(99,
  (String name) -> {
    System.out.println("Name is: " + name);
  },
  (Ice.Exception ex) -> {
    System.err.println("Exception is: " + ex);
  });

```

Asynchronous Oneway Invocations in Java

You can invoke operations via oneway proxies asynchronously, provided the operation has `void` return type, does not have any out-parameters, and does not raise user exceptions. If you call the `begin_` method on a oneway proxy for an operation that returns values or raises a user exception, the `begin_` method throws an `IllegalArgumentException`.

The callback methods looks exactly as for a twoway invocation. For the generic API, the Ice run time does not call the `completed` callback method unless the invocation raised an exception during the `begin_` method ("on the way out"). For the type-safe API, the `response` method is never called.

Flow Control in Java

Asynchronous method invocations never block the thread that calls the `begin_` method: the Ice run time checks to see whether it can write the request to the local transport. If it can, it does so immediately in the caller's thread. (In that case, `AsyncResult.sentSynchronously` returns true.) Alternatively, if the local transport does not have sufficient buffer space to accept the request, the Ice run time queues the request internally for later transmission in the background. (In that case, `AsyncResult.sentSynchronously` returns false.)

This creates a potential problem: if a client sends many asynchronous requests at the time the server is too busy to keep up with them, the requests pile up in the client-side run time until, eventually, the client runs out of memory.

The API provides a way for you to implement flow control by counting the number of requests that are queued so, if that number exceeds some threshold, the client stops invoking more operations until some of the queued operations have drained out of the local transport.

For the [generic API](#), you can override the `sent` method:

```

Java

```

public class MyCallback extends Ice.Callback
{
 public void completed(Ice.AsyncResult r)
 {
 // ...
 }

 public void sent(Ice.AsyncResult r)
 {
 // ...
 }
}

```

```

You inform the Ice run time that you want to be informed when a call has been passed to the local transport as usual:

```

Java

```

e.begin_getName(99, new MyCallback());

```

```

If the Ice run time can immediately pass the request to the local transport, it does so and invokes the `sent` method from the thread that calls the `begin_` method. On the other hand, if the run time has to queue the request, it calls the `sent` method from a different thread once it has written the request to the local transport. In addition, you can find out from the `AsyncResult` that is returned by the `begin_` method whether the request was sent synchronously or was queued, by calling `sentSynchronously`.

For the [generic API](#), the `sent` method has the following signature:

Java

```
void sent(Ice.AsyncResult r);
```

For the **type-safe API**, the signature is:

Java

```
void sent(boolean sentSynchronously);
```

For the generic API, you can find out whether the request was sent synchronously by calling `sentSynchronously` on the `AsyncResult`. For the type-safe API, the boolean `sentSynchronously` parameter provides the same information.

The `sent` methods allow you to limit the number of queued requests by counting the number of requests that are queued and decrementing the count when the Ice run time passes a request to the local transport.

Asynchronous Batch Requests in Java

Applications that send [batched requests](#) can either flush a batch explicitly or allow the Ice run time to flush automatically. The proxy method `ice_flushBatchRequests` performs an immediate flush using the synchronous invocation model and may block the calling thread until the entire message can be sent. Ice also provides asynchronous versions of this method so you can flush batch requests asynchronously.

`begin_ice_flushBatchRequests` and `end_ice_flushBatchRequests` are proxy methods that flush any batch requests queued by that proxy.

In addition, similar methods are available on the communicator and the `Connection` object that is returned by `AsyncResult.getConnection`. These methods flush batch requests sent via the same communicator and via the same connection, respectively.

Concurrency Semantics for AMI in Java

The Ice run time always invokes your callback methods from a separate thread, with one exception: it calls the `sent` callback from the thread calling the `begin_` method if the request could be sent synchronously. In the `sent` callback, you know which thread is calling the callback by looking at the `sentSynchronously` member or parameter.

Using the Slice Compiler for Java

Redirection Notice

This page will redirect to [slice2java Command-Line Options](#) in about one second.

slice2java Command-Line Options

The Slice-to-Java compiler, `slice2java`, offers the following command-line options in addition to the [standard options](#):

- `--tie`
Generate [tie classes](#).
- `--impl`
Generate sample implementation files. This option will not overwrite an existing file.
- `--impl-tie`
Generate sample implementation files using [tie classes](#). This option will not overwrite an existing file.
- `--checksum CLASS`
Generate [checksums](#) for Slice definitions into the class `CLASS`. The given class name may optionally contain a package specifier. The generated class contains checksums for all of the Slice files being translated by this invocation of the compiler. For example, the command below causes `slice2java` to generate the file `Checksums.java` containing the checksums for the Slice definitions in `File1.ice` and `File2.ice`:

```
slice2java --checksum Checksums File1.ice File2.ice
```

- `--stream`
Generate [streaming helper methods](#) for Slice types.
- `--meta META`
Define the global metadata directive `META`. Using this option is equivalent to defining the global metadata `META` in each named Slice file, as well as in any file included by a named Slice file. Global metadata specified with `--meta` overrides any corresponding global metadata directive in the files being compiled.
- `--list-generated`
Emit a list of generated files in XML format.

Using Slice Checksums in Java

The Slice compilers can optionally generate `checksums` of Slice definitions. For `slice2java`, the `--checksum` option causes the compiler to generate a new Java class that adds checksums to a static map member. Assuming we supplied the option `--checksum Checksums` to `slice2java`, the generated class `Checksums.java` looks like this:

```

Java
public class Checksums {
    public static java.util.Map<String, String> checksums;
}

```

The read-only map `checksums` is initialized automatically prior to first use; no action is required by the application.

In order to verify a server's checksums, a client could simply compare the dictionaries using the `equals` method. However, this is not feasible if it is possible that the server might return a superset of the client's checksums. A more general solution is to iterate over the local checksums as demonstrated below:

```

Java
java.util.Map<String, String> serverChecksums = ...
java.util.Iterator<java.util.Map.Entry<String, String>> i =
    Checksums.checksums.entrySet().iterator();
while(i.hasNext()) {
    java.util.Map.Entry<String, String> e = i.next();
    String id = e.getKey();
    String checksum = e.getValue();
    String serverChecksum = serverChecksums.get(id);
    if (serverChecksum == null) {
        // No match found for type id!
    } else if (!checksum.equals(serverChecksum)) {
        // Checksum mismatch!
    }
}
}

```

In this example, the client first verifies that the server's dictionary contains an entry for each Slice type ID, and then it proceeds to compare the checksums.

Example of a File System Client in Java

This page presents the source code for a very simple client to access a server that implements the file system we developed in [Slice for a Simple File System](#). The Java code hardly differs from the code you would write for an ordinary Java program. This is one of the biggest advantages of using Ice: accessing a remote object is as easy as accessing an ordinary, local Java object. This allows you to put your effort where you should, namely, into developing your application logic instead of having to struggle with arcane networking APIs. This is true for the [server side](#) as well, meaning that you can develop distributed applications easily and efficiently.

We now have seen enough of the client-side Java mapping to develop a complete client to access our remote file system. For reference, here is the Slice definition once more:

```

Slice

module Filesystem {
    interface Node {
        idempotent string name();
    };

    exception GenericError {
        string reason;
    };

    sequence<string> Lines;

    interface File extends Node {
        idempotent Lines read();
        idempotent void write(Lines text) throws GenericError;
    };

    sequence<Node*> NodeSeq;

    interface Directory extends Node {
        idempotent NodeSeq list();
    };
};
```

To exercise the file system, the client does a recursive listing of the file system, starting at the root directory. For each node in the file system, the client shows the name of the node and whether that node is a file or directory. If the node is a file, the client retrieves the contents of the file and prints them.

The body of the client code looks as follows:

```

Java

import Filesystem.*;

public class Client {

    // Recursively print the contents of directory "dir" in
    // tree fashion. For files, show the contents of each file.
    // The "depth" parameter is the current nesting level
```

```

// (for indentation).

static void
listRecursive(DirectoryPrx dir, int depth)
{
    char[] indentCh = new char[++depth];
    java.util.Arrays.fill(indentCh, '\t');
    String indent = new String(indentCh);

    NodePrx[] contents = dir.list();

    for (int i = 0; i < contents.length; ++i) {
        DirectoryPrx subdir
= DirectoryPrxHelper.checkedCast(contents[i]);
        FilePrx file = FilePrxHelper.uncheckedCast(contents[i]);
        System.out.println(indent + contents[i].name() +
            (subdir != null ? " (directory):" : " (file):"));
        if (subdir != null) {
            listRecursive(subdir, depth);
        } else {
            String[] text = file.read();
            for (int j = 0; j < text.length; ++j)
                System.out.println(indent + "\t" + text[j]);
        }
    }
}

public static void
main(String[] args)
{
    int status = 0;
    Ice.Communicator ic = null;
    try {
        // Create a communicator
        //
        ic = Ice.Util.initialize(args);

        // Create a proxy for the root directory
        //
        Ice.ObjectPrx base
= ic.stringToProxy("RootDir:default -p 10000");
        if (base == null)
            throw new RuntimeException("Cannot create proxy");

        // Down-cast the proxy to a Directory proxy
        //
        DirectoryPrx rootDir = DirectoryPrxHelper.checkedCast(base);
        if (rootDir == null)
            throw new RuntimeException("Invalid proxy");
    }
}

```

```
        // Recursively list the contents of the root directory
        //
        System.out.println("Contents of root directory:");
        listRecursive(rootDir, 0);
    } catch (Ice.LocalException e) {
        e.printStackTrace();
        status = 1;
    } catch (Exception e) {
        System.err.println(e.getMessage());
        status = 1;
    }
    if (ic != null) {
        // Clean up
        //
        try {
            ic.destroy();
        } catch (Exception e) {
            System.err.println(e.getMessage());
            status = 1;
        }
    }
    System.exit(status);
```

```

    }
}

```

After importing the `Filesystem` package, the `Client` class defines two methods: `listRecursive`, which is a helper function to print the contents of the file system, and `main`, which is the main program. Let us look at `main` first:

1. The structure of the code in `main` follows what we saw in [Hello World Application](#). After initializing the run time, the client creates a proxy to the root directory of the file system. For this example, we assume that the server runs on the local host and listens using the default protocol (TCP/IP) at port 10000. The object identity of the root directory is known to be `RootDir`.
2. The client down-casts the proxy to `DirectoryPrx` and passes that proxy to `listRecursive`, which prints the contents of the file system.

Most of the work happens in `listRecursive`. The function is passed a proxy to a directory to list, and an indent level. (The indent level increments with each recursive call and allows the code to print the name of each node at an indent level that corresponds to the depth of the tree at that node.) `listRecursive` calls the `list` operation on the directory and iterates over the returned sequence of nodes:

1. The code does a `checkedCast` to narrow the `Node` proxy to a `Directory` proxy, as well as an `uncheckedCast` to narrow the `Node` proxy to a `File` proxy. Exactly one of those casts will succeed, so there is no need to call `checkedCast` twice: if the `Node` is a `Directory`, the code uses the `DirectoryPrx` returned by the `checkedCast`; if the `checkedCast` fails, we *know* that the `Node` is a `File` and, therefore, an `uncheckedCast` is sufficient to get a `FilePrx`.
In general, if you know that a down-cast to a specific type will succeed, it is preferable to use an `uncheckedCast` instead of a `checkedCast` because an `uncheckedCast` does not incur any network traffic.
2. The code prints the name of the file or directory and then, depending on which cast succeeded, prints "`(directory)`" or "`(file)`" following the name.
3. The code checks the type of the node:
 - If it is a directory, the code recurses, incrementing the indent level.
 - If it is a file, the code calls the `read` operation on the file to retrieve the file contents and then iterates over the returned sequence of lines, printing each line.

Assume that we have a small file system consisting of two files and a directory as follows:

A small file system.

The output produced by the client for this file system is:

```
Contents of root directory:
```

```
  README (file):
```

```
    This file system contains a collection of poetry.
```

```
  Coleridge (directory):
```

```
    Kubla_Khan (file):
```

```
      In Xanadu did Kubla Khan
```

```
      A stately pleasure-dome decree:
```

```
      Where Alph, the sacred river, ran
```

```
      Through caverns measureless to man
```

```
      Down to a sunless sea.
```

Note that, so far, our client (and server) are not very sophisticated:

- The protocol and address information are hard-wired into the code.
- The client makes more remote procedure calls than strictly necessary; with minor redesign of the Slice definitions, many of these calls can be avoided.

We will see how to address these shortcomings in our discussions of [IceGrid](#) and [object life cycle](#).

Server-Side Slice-to-Java Mapping

The mapping for Slice data types to Java is identical on the client side and server side. This means that everything in [Client-Side Slice-to-Java Mapping](#) also applies to the server side. However, for the server side, there are a few additional things you need to know — specifically how to:

- Initialize and finalize the server-side run time
- Implement servants
- Pass parameters and throw exceptions
- Create servants and register them with the Ice run time

Because the mapping for Slice data types is identical for clients and servers, the server-side mapping only adds a few additional mechanisms to the client side: a small API to initialize and finalize the run time, plus a few rules for how to derive servant classes from skeletons and how to register servants with the server-side run time.

Although the examples we present are very simple, they accurately reflect the basics of writing an Ice server. Of course, for more sophisticated servers, you will be using [additional APIs](#), for example, to improve performance or scalability. However, these APIs are all described in [Slice](#), so, to use these APIs, you need not learn any Java mapping rules beyond those we described here.

The Server-Side main Method in Java

On this page:

- [A Basic main Method in Java](#)
- [The Ice.Application Class in Java](#)
 - [Using Ice.Application on the Client Side in Java](#)
 - [Catching Signals in Java](#)
 - [Ice.Application and Properties in Java](#)
 - [Limitations of Ice.Application in Java](#)

A Basic main Method in Java

The main entry point to the Ice run time is represented by the local Slice interface `Ice::Communicator`. As for the client side, you must initialize the Ice run time by calling `Ice.Util.initialize` before you can do anything else in your server. `Ice.Util.initialize` returns a reference to an instance of an `Ice.Communicator`:

Java

```

public class Server {
    public static void
    main(String[] args)
    {
        int status = 0;
        Ice.Communicator ic = null;
        try {
            ic = Ice.Util.initialize(args);
            // ...
        } catch (Exception e) {
            e.printStackTrace();
            status = 1;
        }
        // ...
    }
}

```

`Ice.Util.initialize` accepts the argument vector that is passed to `main` by the operating system. The function scans the argument vector for any [command-line options](#) that are relevant to the Ice run time, but does not remove those options. If anything goes wrong during initialization, `initialize` throws an exception.

The semantics of Java arrays prevents `Ice.Util.initialize` from modifying the size of the argument vector. However, [another overloading](#) of `Ice.Util.initialize` is provided that allows the application to obtain a new argument vector with the Ice options removed.

Before leaving your `main` function, you *must* call `Communicator.destroy`. The `destroy` operation is responsible for finalizing the Ice run time. In particular, `destroy` waits for any operation implementations that are still executing in the server to complete. In addition, `destroy` ensures that any outstanding threads are joined with and reclaims a number of operating system resources, such as file descriptors and memory. Never allow your `main` function to terminate without calling `destroy` first; doing so has undefined behavior.

The general shape of our server-side `main` function is therefore as follows:

Java

```

public class Server {
    public static void
    main(String[] args)
    {
        int status = 0;
        Ice.Communicator ic = null;
        try {
            ic = Ice.Util.initialize(args);
            // ...
        } catch (Exception e) {
            e.printStackTrace();
            status = 1;
        }
        if (ic != null) {
            try {
                ic.destroy();
            } catch (Exception e) {
                e.printStackTrace();
                status = 1;
            }
        }
        System.exit(status);
    }
}

```

Note that the code places the call to `Ice.Util.initialize` into a `try` block and takes care to return the correct exit status to the operating system. Also note that an attempt to destroy the communicator is made only if the initialization succeeded.

The `Ice.Application` Class in Java

The preceding structure for the `main` function is so common that Ice offers a class, `Ice.Application`, that encapsulates all the correct initialization and finalization activities. The synopsis of the class is as follows (with some detail omitted for now):

Java

```
package Ice;

public enum SignalPolicy { HandleSignals, NoSignalHandling }

public abstract class Application {
    public Application()

        public Application(SignalPolicy signalPolicy)

        public final int main(String appName, String[] args)

        public final int main(String appName, String[] args,
String configFile)

        public final int main(String appName, String[] args,
InitializationData initData)

        public abstract int run(String[] args)

        public static String appName()

        public static Communicator communicator()

        // ...
}
```

The intent of this class is that you specialize `Ice.Application` and implement the abstract `run` method in your derived class. Whatever code you would normally place in `main` goes into the `run` method instead. Using `Ice.Application`, our program looks as follows:

Java

```
public class Server extends Ice.Application {
    public int
    run(String[] args)
    {
        // Server code here...

        return 0;
    }

    public static void
    main(String[] args)
    {
        Server app = new Server();
        int status = app.main("Server", args);
        System.exit(status);
    }
}
```

Note that `Application.main` is overloaded: you can pass an optional file name or an `InitializationData` structure.

If you pass a [configuration file name](#) to `main`, the property settings in this file are overridden by settings in a file identified by the `ICE_CONFIG` environment variable (if defined). Property settings supplied on the [command line](#) take precedence over all other settings.

The `Application.main` function does the following:

1. It installs an exception handler for `java.lang.Exception`. If your code fails to handle an exception, `Application.main` prints the name of an exception and a stack trace on `System.err` before returning with a non-zero return value.
2. It initializes (by calling `Ice.Util.initialize`) and finalizes (by calling `Communicator.destroy`) a communicator. You can get access to the communicator for your server by calling the static `communicator` accessor.
3. It scans the argument vector for options that are relevant to the Ice run time and removes any such options. The argument vector that is passed to your `run` method therefore is free of Ice-related options and only contains options and arguments that are specific to your application.
4. It provides the name of your application via the static `appName` member function. The return value from this call is the first argument in the call to `Application.main`, so you can get at this name from anywhere in your code by calling `Ice.Application.appName` (which is usually required for error messages). In the example above, the return value from `appName` would be `Server`.
5. It installs a shutdown hook that properly shuts down the communicator.
6. It installs a [per-process logger](#) if the application has not already configured one. The per-process logger uses the value of the `Ice.ProgramName` property as a prefix for its messages and sends its output to the standard error channel. An application can also specify an [alternate logger](#).

Using `Ice.Application` ensures that your program properly finalizes the Ice run time, whether your server terminates normally or in response to an exception. We recommend that all your programs use this class; doing so makes your life easier. In addition, `Ice.Application` also provides features for signal handling and configuration that you do not have to implement yourself when you use this class.

Using Ice.Application on the Client Side in Java

You can use `Ice.Application` for your clients as well: simply implement a class that derives from `Ice.Application` and place the client code into its `run` method. The advantage of this approach is the same as for the server side: `Ice.Application` ensures that the communicator is destroyed correctly even in the presence of exceptions.

Catching Signals in Java

The simple server we developed in [Hello World Application](#) had no way to shut down cleanly: we simply interrupted the server from the command line to force it to exit. Terminating a server in this fashion is unacceptable for many real-life server applications: typically, the

server has to perform some cleanup work before terminating, such as flushing database buffers or closing network connections. This is particularly important on receipt of a signal or keyboard interrupt to prevent possible corruption of database files or other persistent data.

Java does not provide direct support for signals, but it does allow an application to register a *shutdown hook* that is invoked when the JVM is shutting down. There are several events that trigger JVM shutdown, such as a call to `System.exit` or an interrupt signal from the operating system, but the shutdown hook is not provided with the reason for the shut down.

`Ice.Application` registers a shutdown hook by default, allowing you to cleanly terminate your application prior to JVM shutdown.

Java

```

package Ice;

public abstract class Application {
    // ...

    synchronized public static void destroyOnInterrupt()
    synchronized public static void shutdownOnInterrupt()
    synchronized public static void setInterruptHook(Thread t)
    synchronized public static void defaultInterrupt()
    synchronized public static boolean interrupted()
}

```

The functions behave as follows:

- `destroyOnInterrupt`
This function installs a shutdown hook that calls `destroy` on the communicator. This is the default behavior.
- `shutdownOnInterrupt`
This function installs a shutdown hook that calls `shutdown` on the communicator.
- `setInterruptHook`
This function installs a custom shutdown hook that takes responsibility for performing whatever action is necessary to terminate the application. Refer to the Java documentation for `Runtime.addShutdownHook` for more information on the semantics of shutdown hooks.
- `defaultInterrupt`
This function removes the shutdown hook.
- `interrupted`
This function returns true if the shutdown hook caused the communicator to shut down, false otherwise. This allows us to distinguish intentional shutdown from a forced shutdown that was caused by the JVM. This is useful, for example, for logging purposes.

By default, `Ice.Application` behaves as if `destroyOnInterrupt` was invoked, therefore our server `main` function requires no change to ensure that the program terminates cleanly on JVM shutdown. (You can disable this default shutdown hook by passing the enumerator `NoSignalHandling` to the constructor. In that case, shutdown is not intercepted and terminates the VM.) However, we add a diagnostic to report the occurrence, so our `main` function now looks like:

Java

```

public class Server extends Ice.Application {
    public int
    run(String[] args)
    {
        // Server code here...

        if (interrupted())
            System.err.println(appName() + ": terminating");

        return 0;
    }

    public static void
    main(String[] args)
    {
        Server app = new Server();
        int status = app.main("Server", args);
        System.exit(status);
    }
}

```

During the course of normal execution, the JVM does not terminate until all non-daemon threads have completed. If an interrupt occurs, the JVM ignores the status of active threads and terminates as soon as it has finished invoking all of the installed shutdown hooks.

In a subclass of `Ice.Application`, the default shutdown hook (as installed by `destroyOnInterrupt`) blocks until the application's main thread completes. As a result, an interrupted application may not terminate successfully if the main thread is blocked. For example, this can occur in an interactive application when the main thread is waiting for console input. To remedy this situation, the application can install an alternate shutdown hook that does not wait for the main thread to finish:

Java

```

public class Server extends Ice.Application {
    class ShutdownHook extends Thread {
        public void
        run()
        {
            try
            {
                communicator().destroy();
            }
            catch(Ice.LocalException ex)
            {
                ex.printStackTrace();
            }
        }
    }

    public int
    run(String[] args)
    {
        setInterruptHook(new ShutdownHook());

        // ...
    }
}

```

After replacing the default shutdown hook using `setInterruptHook`, the JVM will terminate as soon as the communicator is destroyed.

Ice.Application and Properties in Java

Apart from the functionality shown in this section, `Ice.Application` also takes care of initializing the Ice run time with property values. `Properties` allow you to configure the run time in various ways. For example, you can use properties to control things such as the thread pool size or port number for a server. The `main` function of `Ice.Application` is overloaded; the second version allows you to specify the name of a configuration file that will be processed during initialization.

Limitations of Ice.Application in Java

`Ice.Application` is a singleton class that creates a single communicator. If you are using multiple communicators, you cannot use `Ice.Application`. Instead, you must structure your code as we saw in [Hello World Application](#) (taking care to always destroy the communicator). See Also

- [Hello World Application](#)
- [Properties and Configuration](#)
- [Communicator Initialization](#)
- [Logger Facility](#)

Server-Side Java Mapping for Interfaces

The server-side mapping for interfaces provides an up-call API for the Ice run time: by implementing member functions in a servant class, you provide the hook that gets the thread of control from the Ice server-side run time into your application code.

On this page:

- [Skeleton Classes in Java](#)
- [Servant Classes in Java](#)
 - [Normal and idempotent Operations in Java](#)

Skeleton Classes in Java

On the client side, interfaces map to [proxy classes](#). On the server side, interfaces map to *skeleton* classes. A skeleton is a class that has a pure virtual member function for each operation on the corresponding interface. For example, consider our [Slice definition](#) for the `Node` interface:

Slice

```
module Filesystem {
    interface Node {
        idempotent string name();
    };
    // ...
};
```

The Slice compiler generates the following definition for this interface:

Java

```

package Filesystem;

public interface _NodeOperations
{
    String name(Ice.Current current);
}

public interface _NodeOperationsNC
{
    String name();
}

public interface Node extends Ice.Object,
                               _NodeOperations,
                               _NodeOperationsNC
{
    public static final String ice_staticId = "::Filesystem::Node";
    public static final long serialVersionUID = ...;
}

public abstract class _NodeDisp extends Ice.ObjectImpl
                               implements Node
{
    // Mapping-internal code here...
}

```

The important points to note here are:

- As for the client side, Slice modules are mapped to Java packages with the same name, so the skeleton class definitions are part of the `Filesystem` package.
- For each Slice interface `<interface-name>`, the compiler generates Java interfaces `_<interface-name>Operations` and `_<interface-name>OperationsNC` (`_NodeOperations` and `_NodeOperationsNC` in this example). These interfaces contain a method for each operation in the Slice interface. (You can ignore the `Ice.Current` parameter for now.)
- For each Slice interface `<interface-name>`, the compiler generates a Java interface `<interface-name>` (`Node` in this example). That interface extends `Ice.Object` as well as the two operations interfaces, and defines the constant `ice_staticId` with the corresponding Slice type ID.
- For each Slice interface `<interface-name>`, the compiler generates an abstract class `_<interface-name>Disp` (`_NodeDisp` in this example). This abstract class is the actual skeleton class; it is the base class from which you derive your servant class.

Servant Classes in Java

In order to provide an implementation for an Ice object, you must create a servant class that inherits from the corresponding skeleton class. For example, to create a servant for the `Node` interface, you could write:

Java

```

package Filesystem;

public final class NodeI extends _NodeDisp {

    public NodeI(String name)
    {
        _name = name;
    }

    public String name(Ice.Current current)
    {
        return _name;
    }

    private String _name;
}

```

By convention, servant classes have the name of their interface with an `I`-suffix, so the servant class for the `Node` interface is called `NodeI`. (This is a convention only: as far as the Ice run time is concerned, you can choose any name you prefer for your servant classes.) Note that `NodeI` extends `_NodeDisp`, that is, it derives from its skeleton class.

As far as Ice is concerned, the `NodeI` class must implement only a single method: the `name` method that it inherits from its skeleton. This makes the servant class a concrete class that can be instantiated. You can add other member functions and data members as you see fit to support your implementation. For example, in the preceding definition, we added a `_name` member and a constructor. (Obviously, the constructor initializes the `_name` member and the `name` function returns its value.)

Normal and idempotent Operations in Java

Whether an operation is an ordinary operation or an `idempotent` operation has no influence on the way the operation is mapped. To illustrate this, consider the following interface:

Slice

```

interface Example {
    void normalOp();
    idempotent void idempotentOp();
    idempotent string readonlyOp();
};

```

The operations class for this interface looks like this:

Java

```
public interface _ExampleOperations
{
    void normalOp(Ice.Current current);
    void idempotentOp(Ice.Current current);
    String readonlyOp(Ice.Current current);
}
```

Note that the signatures of the member functions are unaffected by the `idempotent` qualifier.

See Also

- [Slice for a Simple File System](#)
- [Java Mapping for Interfaces](#)
- [Parameter Passing in Java](#)
- [Raising Exceptions in Java](#)
- [Tie Classes in Java](#)
- [The Current Object](#)

Parameter Passing in Java

For each parameter of a Slice operation, the Java mapping generates a corresponding parameter for the method in the `_interface-nameOperations` interface. In addition, every operation has a trailing parameter of type `Ice.Current`. For example, the `name` operation of the `Node` interface has no parameters, but the `name` method of the `_NodeOperations` interface has a single parameter of type `Ice.Current`. We will ignore this parameter for now.

Passing Required Parameters in Java

Parameter passing on the server side follows the rules for the [client side](#). To illustrate the rules, consider the following interface that passes string parameters in all possible directions:

```

Slice
module M {
    interface Example {
        string op(string sin, out string sout);
    };
};

```

The generated skeleton class for this interface looks as follows:

```

Java
public interface _ExampleOperations
{
    String op(String sin, Ice.StringHolder sout, Ice.Current current);
}

```

As you can see, there are no surprises here. For example, we could implement `op` as follows:

```

Java
public final class ExampleI extends M._ExampleDisp {

    public String op(String sin, Ice.StringHolder sout,
Ice.Current current)
    {
        System.out.println(sin);    // In params are initialized
        sout.value = "Hello World!"; // Assign out param
        return "Done";
    }
}

```

This code is in no way different from what you would normally write if you were to pass strings to and from a function; the fact that remote procedure calls are involved does not impact on your code in any way. The same is true for parameters of other types, such as proxies, classes, or dictionaries: the parameter passing conventions follow normal Java rules and do not require special-purpose API calls.

Passing Optional Parameters in Java

Suppose we modify the example above to use optional parameters:

```

Slice
module M {
    interface Example {
        optional(1) string op(optional(2) string sin, out optional(3)
string sout);
    };
};

```

The generated skeleton now looks like this:

```

Java
public interface _ExampleOperations
{
    String op(Ice.Optional<String> sin, Ice.StringHolder sout,
Ice.Current current);
}

```

The default mapping treats optional out parameters and return values as if they are required. If your servant needs the ability to return an optional value, you must add the `java:optional` metadata tag:

```

Slice
module M {
    interface Example {
        ["java:optional"]
        optional(1) string op(optional(2) string sin, out optional(3)
string sout);
    };
};

```

This tag can be applied to an interface if you want to use the optional mapping for all of the operations in that interface, or to individual operations as shown here. With this change, the mapping now returns optional values:

```

Java
public interface _ExampleOperations
{
    Ice.Optional<String> op(Ice.Optional<String> sin,
Ice.Optional<String> sout, Ice.Current current);
}

```

The `java:optional` tag affects the return value and all out parameters; it is not possible to modify the mapping only for certain parameters.

Raising Exceptions in Java

Servant Exceptions in Java

To throw an exception from an operation implementation, you simply instantiate the exception, initialize it, and throw it. For example:

```

Java

```

// ...

public void
write(String[] text, Ice.Current current)
 throws GenericError
{
 try
 {
 // Try to write file contents here...
 }
 catch(Exception ex)
 {
 throw new GenericError("Exception during write operation", ex);
 }
}

```

```

Note that, for this example, we have supplied the [optional second parameter](#) to the `GenericError` constructor. This parameter sets the inner exception and preserves the original cause of the error for later diagnosis.

If you throw an arbitrary Java run-time exception (such as a `ClassCastException`), the Ice run time catches the exception and then returns an `UnknownException` to the client. Similarly, if you throw an "impossible" user exception (a user exception that is not listed in the exception specification of the operation), the client receives an `UnknownUserException`.

If you throw an Ice run-time exception, such as `MemoryLimitException`, the client receives an `UnknownLocalException`. For that reason, you should never throw system exceptions from operation implementations. If you do, all the client will see is an `UnknownLocalException`, which does not tell the client anything useful.

Three run-time exceptions are [treated specially](#) and not changed to `UnknownLocalException` when returned to the client: `ObjectNotExistException`, `OperationNotExistException`, and `FacetNotExistException`.

JVM Error Semantics

Servant implementations might inadvertently raise low-level errors during the course of their operation. These exceptions, which are subclasses of `java.lang.Error`, should not normally be trapped by the servant because they often indicate the occurrence of a serious, unrecoverable situation. For example, the JVM throws `StackOverflowError` when a recursive method has used all available stack space.

The Ice run time traps instances of `java.lang.Error` thrown by servants and then attempts to log the exception and send an `UnknownException` to the client. This attempt may or may not succeed, depending on the nature of the error and the condition of the JVM. As an example, the servant implementation might raise `OutOfMemoryError` and Ice's attempt to log the error and send a response could also fail due to lack of memory.

For an occurrence of `OutOfMemoryError` or `AssertionError`, Ice does not re-throw the error after logging a message and sending a response. For all other subclasses of `Error`, Ice re-throws the error so that the JVM's normal error-handling strategy will execute.

When the JVM raises a subclass of `Error`, it usually means that a significant problem has occurred. Ice tries to send an `Unknown`

`Exception` to the client (for twoway requests) in order to prevent the client from waiting indefinitely for a response. However, the JVM may prevent Ice from successfully sending this response, which is another reason your clients should use `invocation timeouts` as a defensive strategy. Finally, in nearly all occurrences of an error, the server is unlikely to continue operating correctly even if Ice is able to complete the client's request. For example, the JVM terminates the thread that raised an uncaught error. In the case of an uncaught error raised by a servant, the thread being terminated is normally from the Ice server-side thread pool. If all of the threads in this pool eventually terminate due to uncaught errors, the server can no longer respond to new client requests.

Tie Classes in Java

The mapping to [skeleton classes](#) requires the servant class to inherit from its skeleton class. Occasionally, this creates a problem: some class libraries require you to inherit from a base class in order to access functionality provided by the library; because Java does not support multiple implementation inheritance, this means that you cannot use such a class library to implement your servants because your servants cannot inherit from both the library class and the skeleton class simultaneously.

To allow you to still use such class libraries, Ice provides a way to write servants that replaces inheritance with delegation. This approach is supported by *tie classes*. The idea is that, instead of inheriting from the skeleton class, you simply create a class (known as an *implementation class* or *delegate class*) that contains methods corresponding to the operations of an interface. You use the `--tie` option with the `slice2java` compiler to create a tie class. For example, the `--tie` option causes the compiler to create exactly the same code for the [Node interface](#) as we saw previously, but to also emit an additional tie class. For an interface `<interface-name>`, the generated tie class has the name `_interface-name>Tie`:

Java

```
package Filesystem;

public class _NodeTie extends _NodeDisp implements Ice.TieBase {

    public _NodeTie() {}

    public
    _NodeTie(_NodeOperations delegate)
    {
        _ice_delegate = delegate;
    }

    public java.lang.Object
    ice_delegate()
    {
        return _ice_delegate;
    }

    public void
    ice_delegate(java.lang.Object delegate)
    {
        _ice_delegate = (_NodeOperations)delegate;
    }

    public boolean
    equals(java.lang.Object rhs)
    {
        if (this == rhs)
        {
            return true;
        }
        if (!(rhs instanceof _NodeTie))
        {
            return false;
        }
    }
}
```

```
        return _ice_delegate.equals(((NodeTie)rhs)._ice_delegate);
    }

    public int
    hashCode()
    {
        return _ice_delegate.hashCode();
    }

    public String
    name(Ice.Current current)
    {
        return _ice_delegate.name(current);
    }
}
```

```

private _NodeOperations _ice_delegate;
}

```

This looks a lot worse than it is: in essence, the generated tie class is simply a servant class (it extends `_NodeDisp`) that delegates to your implementation class each invocation of a method corresponding to a Slice operation:

A skeleton class, tie class, and implementation class.

The generated tie class also implements the `Ice.TieBase` interface, which defines methods for obtaining and changing the delegate object:

```

Java

package Ice;

public interface TieBase {
    java.lang.Object ice_delegate();
    void ice_delegate(java.lang.Object delegate);
}

```

The delegate has type `java.lang.Object` in these methods in order to allow a tie object's delegate to be manipulated without knowing its actual type. However, the `ice_delegate` modifier raises `ClassCastException` if the given delegate object is not of the correct type.

Given this machinery, we can create an implementation class for our `Node` interface as follows:

Java

```
package Filesystem;

public final class NodeI implements _NodeOperations {

    public NodeI(String name)
    {
        _name = name;
    }

    public String name(Ice.Current current)
    {
        return _name;
    }

    private String _name;
}

```

Note that this class is identical to our previous implementation, except that it implements the `_NodeOperations` interface and does not extend `_NodeDisp` (which means that you are now free to extend any other class to support your implementation).

To create a servant, you instantiate your implementation class and the tie class, passing a reference to the implementation instance to the tie constructor:

Java

```
NodeI fred = new NodeI("Fred");           // Create implementation
_NodeTie servant = new _NodeTie(fred);    // Create tie

```

Alternatively, you can also default-construct the tie class and later set its delegate instance by calling `ice_delegate`:

Java

```
_NodeTie servant = new _NodeTie();        // Create tie
// ...
NodeI fred = new NodeI("Fred");          // Create implementation
// ...
servant.ice_delegate(fred);               // Set delegate

```

When using tie classes, it is important to remember that the tie instance is the servant, not your delegate. Furthermore, you must not use a tie instance to `incarnate` an Ice object until the tie has a delegate. Once you have set the delegate, you must not change it for the lifetime of the tie; otherwise, undefined behavior results.

You should use the tie approach only when necessary, that is, if you need to extend some base class in order to implement your servants: using the tie approach is more costly in terms of memory because each Ice object is incarnated by two Java objects (the tie and the delegate) instead of just one. In addition, call dispatch for ties is marginally slower than for ordinary servants because the tie forwards each operation to the delegate, that is, each operation invocation requires two function calls instead of one.

Also note that, unless you arrange for it, there is no way to get from the delegate back to the tie. If you need to navigate back to the tie from the delegate, you can store a reference to the tie in a member of the delegate. (The reference can, for example, be initialized by the constructor of the delegate.)

Object Incarnation in Java

Having created a servant class such as the rudimentary `NodeI` class, you can instantiate the class to create a concrete servant that can receive invocations from a client. However, merely instantiating a servant class is insufficient to incarnate an object. Specifically, to provide an implementation of an Ice object, you must take the following steps:

1. [Instantiate a servant class.](#)
2. [Create an identity](#) for the Ice object incarnated by the servant.
3. [Inform the Ice run time](#) of the existence of the servant.
4. [Pass a proxy for the object](#) to a client so the client can reach it.

On this page:

- [Instantiating a Java Servant](#)
- [Creating an Identity in Java](#)
- [Activating a Java Servant](#)
- [UUIDs as Identities in Java](#)
- [Creating Proxies in Java](#)
 - [Proxies and Servant Activation in Java](#)
 - [Direct Proxy Creation in Java](#)

Instantiating a Java Servant

Instantiating a servant means to allocate an instance:

```

Java

Node servant = new NodeI("Fred");
```

This code creates a new `NodeI` instance and assigns its address to a reference of type `Node`. This works because `NodeI` is derived from `Node`, so a `Node` reference can refer to an instance of type `NodeI`. However, if we want to invoke a member function of the `NodeI` class at this point, we must use a `NodeI` reference:

```

Java

NodeI servant = new NodeI("Fred");
```

Whether you use a `Node` or a `NodeI` reference depends purely on whether you want to invoke a member function of the `NodeI` class: if not, a `Node` reference works just as well as a `NodeI` reference.

Creating an Identity in Java

Each Ice object requires an identity. That identity must be unique for all servants using the same object adapter.

The Ice object model assumes that all objects (regardless of their adapter) have a [globally unique identity](#).

An Ice object identity is a structure with the following Slice definition:

Slice

```
module Ice {
    struct Identity {
        string name;
        string category;
    };
    // ...
};
```

The full identity of an object is the combination of both the `name` and `category` fields of the `Identity` structure. For now, we will leave the `category` field as the empty string and simply use the `name` field. (The `category` field is most often used in conjunction with `servant locators`.)

To create an identity, we simply assign a key that identifies the servant to the `name` field of the `Identity` structure:

Java

```
Ice.Identity id = new Ice.Identity();
id.name = "Fred"; // Not unique, but good enough for now
```

Activating a Java Servant

Merely creating a servant instance does nothing: the Ice run time becomes aware of the existence of a servant only once you explicitly tell the object adapter about the servant. To activate a servant, you invoke the `add` operation on the object adapter. Assuming that we have access to the object adapter in the `_adapter` variable, we can write:

Java

```
_adapter.add(servant, id);
```

Note the two arguments to `add`: the servant and the object identity. Calling `add` on the object adapter adds the servant and the servant's identity to the adapter's servant map and links the proxy for an Ice object to the correct servant instance in the server's memory as follows:

1. The proxy for an Ice object, apart from addressing information, contains the identity of the Ice object. When a client invokes an operation, the object identity is sent with the request to the server.
2. The object adapter receives the request, retrieves the identity, and uses the identity as an index into the servant map.
3. If a servant with that identity is active, the object adapter retrieves the servant from the servant map and dispatches the incoming request into the correct member function on the servant.

Assuming that the object adapter is in the `active state`, client requests are dispatched to the servant as soon as you call `add`.

UUIDs as Identities in Java

The Ice object model assumes that object identities are globally unique. One way of ensuring that uniqueness is to use UUIDs (Universally Unique Identifiers) as identities. Java provides a helper function that we can use to create such identities:

Java

```
public class Example {
    public static void
    main(String[] args)
    {
        System.out.println(java.util.UUID.randomUUID().toString());
    }
}
```

When executed, this program prints a unique string such as 5029a22c-e333-4f87-86b1-cd5e0fcce509. Each call to `randomUUID` creates a string that differs from all previous ones.

You can use a UUID such as this to create object identities. For convenience, the object adapter has an operation `addWithUUID` that generates a UUID and adds a servant to the servant map in a single step. Using this operation, we can create an identity and register a servant with that identity in a single step as follows:

Java

```
_adapter.addWithUUID(new NodeI("Fred"));
```

Creating Proxies in Java

Once we have activated a servant for an Ice object, the server can process incoming client requests for that object. However, clients can only access the object once they hold a proxy for the object. If a client knows the server's address details and the object identity, it can create a proxy from a string, as we saw in our first example in [Hello World Application](#). However, creation of proxies by the client in this manner is usually only done to allow the client access to initial objects for bootstrapping. Once the client has an initial proxy, it typically obtains further proxies by invoking operations.

The object adapter contains all the details that make up the information in a proxy: the addressing and protocol information, and the object identity. The Ice run time offers a number of ways to create proxies. Once created, you can pass a proxy to the client as the return value or as an out-parameter of an operation invocation.

Proxies and Servant Activation in Java

The `add` and `addWithUUID` servant activation operations on the object adapter return a proxy for the corresponding Ice object. This means we can write:

Java

```
NodePrx proxy = NodePrxHelper.uncheckedCast(_adapter.addWithUUID(new No
deI("Fred")));
```

Here, `addWithUUID` both activates the servant and returns a proxy for the Ice object incarnated by that servant in a single step.

Note that we need to use an `uncheckedCast` here because `addWithUUID` returns a proxy of type `Ice.ObjectPrx`.

Direct Proxy Creation in Java

The object adapter offers an operation to create a proxy for a given identity:

Slice

```

module Ice {
    local interface ObjectAdapter {
        Object* createProxy(Identity id);
        // ...
    };
};

```

Note that `createProxy` creates a proxy for a given identity whether a servant is activated with that identity or not. In other words, proxies have a life cycle that is quite independent from the life cycle of servants:

Java

```

Ice.Identity id = new Ice.Identity();
id.name = java.util.UUID.randomUUID().toString();
Ice.ObjectPrx o = _adapter.createProxy(id);

```

This creates a proxy for an Ice object with the identity returned by `randomUUID`. Obviously, no servant yet exists for that object so, if we return the proxy to a client and the client invokes an operation on the proxy, the client will receive an `ObjectNotExistException`. (We examine these life cycle issues in more detail in [Object Life Cycle](#).)

Asynchronous Method Dispatch (AMD) in Java

The number of simultaneous synchronous requests a server is capable of supporting is determined by the number of threads in the server's [thread pool](#). If all of the threads are busy dispatching long-running operations, then no threads are available to process new requests and therefore clients may experience an unacceptable lack of responsiveness.

Asynchronous Method Dispatch (AMD), the server-side equivalent of [AMI](#), addresses this scalability issue. Using AMD, a server can receive a request but then suspend its processing in order to release the dispatch thread as soon as possible. When processing resumes and the results are available, the server sends a response explicitly using a callback object provided by the Ice run time.

AMD is transparent to the client, that is, there is no way for a client to distinguish a request that, in the server, is processed synchronously from a request that is processed asynchronously.

In practical terms, an AMD operation typically queues the request data (i.e., the callback object and operation arguments) for later processing by an application thread (or thread pool). In this way, the server minimizes the use of dispatch threads and becomes capable of efficiently supporting thousands of simultaneous clients.

An alternate use case for AMD is an operation that requires further processing after completing the client's request. In order to minimize the client's delay, the operation returns the results while still in the dispatch thread, and then continues using the dispatch thread for additional work.

On this page:

- [Enabling AMD with Metadata in Java](#)
- [AMD Mapping in Java](#)
 - [Callback interface for AMD](#)
 - [Dispatch method for AMD](#)
- [AMD Exceptions in Java](#)
- [AMD Example in Java](#)

Enabling AMD with Metadata in Java

To enable asynchronous dispatch, you must add an ["amd"] metadata directive to your Slice definitions. The directive applies at the interface and the operation level. If you specify ["amd"] at the interface level, all operations in that interface use asynchronous dispatch; if you specify ["amd"] for an individual operation, only that operation uses asynchronous dispatch. In either case, the metadata directive *replaces* synchronous dispatch, that is, a particular operation implementation must use synchronous or asynchronous dispatch and cannot use both.

Consider the following Slice definitions:

Slice

```

["amd"] interface I {
    bool isValid();
    float computeRate();
};

interface J {
    ["amd"] void startProcess();
    int endProcess();
};

```

In this example, both operations of interface `I` use asynchronous dispatch, whereas, for interface `J`, `startProcess` uses asynchronous dispatch and `endProcess` uses synchronous dispatch.

Specifying metadata at the operation level (rather than at the interface or class level) minimizes the amount of generated code and, more importantly, minimizes complexity: although the asynchronous model is more flexible, it is also more complicated to use. It is therefore in your best interest to limit the use of the asynchronous model to those operations that need it, while using the simpler synchronous model for the rest.

AMD Mapping in Java

The Java mapping emits the following code for each AMD operation:

1. [Callback interface](#)
2. [Dispatch method](#)

Callback interface for AMD

A callback interface is used by the implementation to notify the Ice run time about the completion of an operation. The name of this interface is formed using the pattern `AMD_class_op`. For example, an operation named `foo` defined in interface `I` results in an interface named `AMD_I_foo`. The interface is generated in the same scope as the interface or class containing the operation. Two methods are provided:

```

Java

public void ice_response(<params>);
```

The `ice_response` method allows the server to report the successful completion of the operation. If the operation has a non-void return type, the first parameter to `ice_response` is the return value. Parameters corresponding to the operation's out parameters follow the return value, in the order of declaration.

```

Java

public void ice_exception(java.lang.Exception ex);
```

The `ice_exception` method allows the server to raise an exception. With respect to exceptions, there is less compile-time type safety in an AMD implementation because there is no `throws` clause on the dispatch method and any exception type could conceivably be passed to `ice_exception`. However, the Ice run time [validates](#) the exception value using the same semantics as for synchronous dispatch.

Neither `ice_response` nor `ice_exception` throw any exceptions to the caller.

Dispatch method for AMD

The dispatch method, whose name has the suffix `_async`, has a `void` return type. The first parameter is a reference to an instance of the callback interface described above. The remaining parameters comprise the `in` parameters of the operation, in the order of declaration.

For example, suppose we have defined the following operation:

```

Slice

interface I {
    ["amd"] int foo(short s, out long l);
};
```

The callback interface generated for operation `foo` is shown below:

Java

```
public interface AMD_I_foo {
    void ice_response(int __ret, long l);
    void ice_exception(java.lang.Exception ex);
}
```

The dispatch method for asynchronous invocation of operation `foo` is generated as follows:

Java

```
void foo_async(AMD_I_foo __cb, short s);
```

AMD Exceptions in Java

There are two processing contexts in which the logical implementation of an AMD operation may need to report an exception: the dispatch thread (the thread that receives the invocation), and the response thread (the thread that sends the response).

These are not necessarily two different threads: it is legal to send the response from the dispatch thread.

Although we recommend that the callback object be used to report all exceptions to the client, it is legal for the implementation to raise an exception instead, but only from the dispatch thread.

As you would expect, an exception raised from a response thread cannot be caught by the Ice run time; the application's run time environment determines how such an exception is handled. Therefore, a response thread must ensure that it traps all exceptions and sends the appropriate response using the callback object. Otherwise, if a response thread is terminated by an uncaught exception, the request may never be completed and the client might wait indefinitely for a response.

Whether raised in a dispatch thread or reported via the callback object, user exceptions are [validated](#) and local exceptions may undergo [translation](#).

AMD Example in Java

To demonstrate the use of AMD in Ice, let us define the Slice interface for a simple computational engine:

Slice

```

module Demo {
    sequence<float> Row;
    sequence<Row> Grid;

    exception RangeError {};

    interface Model {
        ["amd"] Grid interpolate(Grid data, float factor)
            throws RangeError;
    };
};

```

Given a two-dimensional grid of floating point values and a factor, the `interpolate` operation returns a new grid of the same size with the values interpolated in some interesting (but unspecified) way.

Our servant class derives from `Demo._ModelDisp` and supplies a definition for the `interpolate_async` method that creates a `Job` to hold the callback object and arguments, and adds the `Job` to a queue. The method is synchronized to guard access to the queue:

Java

```

public final class ModelI extends Demo._ModelDisp {
    synchronized public void interpolate_async(
        Demo.AMD_Model_interpolate cb,
        float[][] data,
        float factor,
        Ice.Current current)
        throws RangeError
    {
        _jobs.add(new Job(cb, data, factor));
    }

    java.util.LinkedList<Job> _jobs = new java.util.LinkedList<Job>();
}

```

After queuing the information, the operation returns control to the Ice run time, making the dispatch thread available to process another request. An application thread removes the next `Job` from the queue and invokes `execute`, which uses `interpolateGrid` (not shown) to perform the computational work:

Java

```

class Job {
    Job(Demo.AMD_Model_interpolate cb,
        float[][] grid,
        float factor)
    {
        _cb = cb;
        _grid = grid;
        _factor = factor;
    }

    void execute()
    {
        if (!interpolateGrid()) {
            _cb.ice_exception(new Demo.RangeError());
            return;
        }
        _cb.ice_response(_grid);
    }

    private boolean interpolateGrid() {
        // ...
    }

    private Demo.AMD_Model_interpolate _cb;
    private float[][] _grid;
    private float _factor;
}

```

If `interpolateGrid` returns false, then `ice_exception` is invoked to indicate that a range error has occurred. The `return` statement following the call to `ice_exception` is necessary because `ice_exception` does not throw an exception; it only marshals the exception argument and sends it to the client.

If interpolation was successful, `ice_response` is called to send the modified grid back to the client.

Example of a File System Server in Java

This page presents the source code for a Java server that implements our [file system](#) and communicates with the [client](#) we wrote earlier. The code is fully functional, apart from the required interlocking for threads.

Note that the server is remarkably free of code that relates to distribution: most of the server code is simply application logic that would be present just the same for a non-distributed version. Again, this is one of the major advantages of Ice: distribution concerns are kept away from application code so that you can concentrate on developing application logic instead of networking infrastructure.

The server code shown here is not quite correct as it stands: if two clients access the same file in parallel, each via a different thread, one thread may read the `_lines` data member while another thread updates it. Obviously, if that happens, we may write or return garbage or, worse, crash the server. However, it is trivial to make the `read` and `write` operations thread-safe. We discuss thread safety in [The Ice Threading Model](#).

On this page:

- [Implementing a File System Server in Java](#)
- [Server Main Program in Java](#)
- [FileI Servant Class in Java](#)
- [DirectoryI Servant Class in Java](#)
 - [DirectoryI Data Members](#)
 - [DirectoryI Constructor](#)
 - [DirectoryI Methods](#)

Implementing a File System Server in Java

We have now seen enough of the server-side Java mapping to implement a server for our [file system](#). (You may find it useful to review these [Slice definitions](#) before studying the source code.)

Our server is composed of three source files:

- `Server.java`
This file contains the server main program.
- `Filesystem/DirectoryI.java`
This file contains the implementation for the `Directory` servants.
- `Filesystem/FileI.java`
This file contains the implementation for the `File` servants.

Server Main Program in Java

Our server main program, in the file `Server.java`, uses the `Ice.Application` class. The `run` method installs a shutdown hook, creates an object adapter, instantiates a few servants for the directories and files in the file system, and then activates the adapter. This leads to a main program as follows:

Java

```
import Filesystem.*;

public class Server extends Ice.Application {
    public int
    run(String[] args)
    {
        //
        // Terminate cleanly on receipt of a signal
        //
        shutdownOnInterrupt();
    }
}
```

```

// Create an object adapter (stored in the _adapter
// static members)
//
Ice.ObjectAdapter adapter
= communicator().createObjectAdapterWithEndpoints(
    "SimpleFilesystem", "default -p 10000");
DirectoryI._adapter = adapter;
FileI._adapter = adapter;

// Create the root directory (with name "/" and no parent)
//
DirectoryI root = new DirectoryI("/", null);

// Create a file "README" in the root directory
//
File file = new FileI("README", root);
String[] text;
text = new String[] {
    "This file system contains a collection of poetry."
};
try {
    file.write(text, null);
} catch (GenericError e) {
    System.err.println(e.reason);
}

// Create a directory "Coleridge" in the root directory
//
DirectoryI coleridge = new DirectoryI("Coleridge", root);

// Create a file "Kubla_Khan" in the Coleridge directory
//
file = new FileI("Kubla_Khan", coleridge);
text = new String[] { "In Xanadu did Kubla Khan",
    "A stately pleasure-dome decree:",
    "Where Alph, the sacred river, ran",
    "Through caverns measureless to man",
    "Down to a sunless sea." };
try {
    file.write(text, null);
} catch (GenericError e) {
    System.err.println(e.reason);
}

// All objects are created, allow client requests now
//
adapter.activate();

// Wait until we are done

```

```
        //
        communicator().waitForShutdown();

        return 0;
    }

    public static void
    main(String[] args)
    {
        Server app = new Server();
        System.exit(app.main("Server", args));
    }
}
```

```

    }
}

```

The code imports the contents of the `Filesystem` package. This avoids having to continuously use fully-qualified identifiers with a `Filesystem.` prefix.

The next part of the source code is the definition of the `Server` class, which derives from `Ice.Application` and contains the main application logic in its `run` method. Much of this code is boiler plate that we saw previously: we create an object adapter, and, towards the end, activate the object adapter and call `waitForShutdown`.

The interesting part of the code follows the adapter creation: here, the server instantiates a few nodes for our file system to create the structure shown below:

A small file system.

As we will see shortly, the servants for our directories and files are of type `DirectoryI` and `FileI`, respectively. The constructor for either type of servant accepts two parameters, the name of the directory or file to be created and a reference to the servant for the parent directory. (For the root directory, which has no parent, we pass a null parent.) Thus, the statement

Java

```
DirectoryI root = new DirectoryI("/", null);
```

creates the root directory, with the name `" / "` and no parent directory.

Here is the code that establishes the structure in the above illustration:

Java

```

// Create the root directory (with name "/" and no parent)
//
DirectoryI root = new DirectoryI("/", null);

// Create a file "README" in the root directory
//
File file = new FileI("README", root);
String[] text;
text = new String[] {
    "This file system contains a collection of poetry."
};
try {
    file.write(text, null);
} catch (GenericError e) {
    System.err.println(e.reason);
}

// Create a directory "Coleridge" in the root directory
//
DirectoryI coleridge = new DirectoryI("Coleridge", root);

// Create a file "Kubla_Khan" in the Coleridge directory
//
file = new FileI("Kubla_Khan", coleridge);
text = new String[] { "In Xanadu did Kubla Khan",
    "A stately pleasure-dome decree:",
    "Where Alph, the sacred river, ran",
    "Through caverns measureless to man",
    "Down to a sunless sea." };
try {
    file.write(text, null);
} catch (GenericError e) {
    System.err.println(e.reason);
}

```

We first create the root directory and a file `README` within the root directory. (Note that we pass a reference to the root directory as the parent when we create the new node of type `FileI`.)

The next step is to fill the file with text:

Java

```
String[] text;
text = new String[] {
    "This file system contains a collection of poetry."
};
try {
    file.write(text, null);
} catch (GenericError e) {
    System.err.println(e.reason);
}
```

Recall that [Slice sequences](#) by default map to Java arrays. The Slice type `Lines` is simply an array of strings; we add a line of text to our `README` file by initializing the `text` array to contain one element.

Finally, we call the Slice `write` operation on our `FileI` servant by writing:

Java

```
file.write(text, null);
```

This statement is interesting: the server code invokes an operation on one of its own servants. Because the call happens via a reference to the servant (of type `FileI`) and *not* via a proxy (of type `FilePrx`), the Ice run time does not know that this call is even taking place — such a direct call into a servant is not mediated by the Ice run time in any way and is dispatched as an ordinary Java function call.

In similar fashion, the remainder of the code creates a subdirectory called `Coleridge` and, within that directory, a file called `Kubla_Khan` to complete the structure in the illustration listed above.

FileI Servant Class in Java

Our `FileI` servant class has the following basic structure:

Java

```
public class FileI extends _FileDisp
{
    // Constructor and operations here...

    public static Ice.ObjectAdapter _adapter;
    private String _name;
    private DirectoryI _parent;
    private String[] _lines;
}
```

The class has a number of data members:

- `_adapter`
This static member stores a reference to the single object adapter we use in our server.

- `_name`
This member stores the name of the file incarnated by the servant.
- `_parent`
This member stores the reference to the servant for the file's parent directory.
- `_lines`
This member holds the contents of the file.

The `_name` and `_parent` data members are initialized by the constructor:

```

Java

public
FileI(String name, DirectoryI parent)
{
    _name = name;
    _parent = parent;

    assert(_parent != null);

    // Create an identity
    //
    Ice.Identity myID = new Ice.Identity();
    myID.name = java.util.UUID.randomUUID().toString();

    // Add the identity to the object adapter
    //
    _adapter.add(this, myID);

    // Create a proxy for the new node and
    // add it as a child to the parent
    //
    NodePrx thisNode
= NodePrxHelper.uncheckedCast(_adapter.createProxy(myID));
    _parent.addChild(thisNode);
}

```

After initializing the `_name` and `_parent` members, the code verifies that the reference to the parent is not null because every file must have a parent directory. The constructor then generates an identity for the file by calling `java.util.UUID.randomUUID` and adds itself to the servant map by calling `ObjectAdapter.add`. Finally, the constructor creates a proxy for this file and calls the `addChild` method on its parent directory. `addChild` is a helper function that a child directory or file calls to add itself to the list of descendant nodes of its parent directory. We will see the implementation of this function in [DirectoryI Methods](#).

The remaining methods of the `FileI` class implement the Slice operations we defined in the `Node` and `File` Slice interfaces:

Java

```

// Slice Node::name() operation

public String
name(Ice.Current current)
{
    return _name;
}

// Slice File::read() operation

public String[]
read(Ice.Current current)
{
    return _lines;
}

// Slice File::write() operation

public void
write(String[] text, Ice.Current current)
    throws GenericError
{
    _lines = text;
}

```

The `name` method is inherited from the generated `Node` interface (which is a base interface of the `_FileDisp` class from which `FileI` is derived). It returns the value of the `_name` member.

The `read` and `write` methods are inherited from the generated `File` interface (which is a base interface of the `_FileDisp` class from which `FileI` is derived) and return and set the `_lines` member.

DirectoryI Servant Class in Java

The `DirectoryI` class has the following basic structure:

Java

```
package Filesystem;

public final class DirectoryI extends _DirectoryDisp
{
    // Constructor and operations here...

    public static Ice.ObjectAdapter _adapter;
    private String _name;
    private DirectoryI _parent;
    private java.util.ArrayList<NodePrx> _contents
= new java.util.ArrayList<NodePrx>();
}
```

DirectoryI Data Members

As for the `FileI` class, we have data members to store the object adapter, the name, and the parent directory. (For the root directory, the `_parent` member holds a null reference.) In addition, we have a `_contents` data member that stores the list of child directories. These data members are initialized by the constructor:

Java

```

public
DirectoryI(String name, DirectoryI parent)
{
    _name = name;
    _parent = parent;

    // Create an identity. The parent has the
    // fixed identity "RootDir"
    //
    Ice.Identity myID = new Ice.Identity();
    myID.name = _parent != null ? java.util.UUID.randomUUID().toString(
) : "RootDir";

    // Add the identity to the object adapter
    //
    _adapter.add(this, myID);

    // Create a proxy for the new node and add it as a
    // child to the parent
    //
    NodePrx thisNode
= NodePrxHelper.uncheckedCast(_adapter.createProxy(myID));
    if (_parent != null)
        _parent.addChild(thisNode);
}

```

DirectoryI Constructor

The constructor creates an identity for the new directory by calling `java.util.UUID.randomUUID()`. (For the root directory, we use the fixed identity "RootDir".) The servant adds itself to the servant map by calling `ObjectAdapter.add` and then creates a reference to itself and passes it to the `addChild` helper function.

DirectoryI Methods

`addChild` adds the passed reference to the `_contents` list:

Java

```

void
addChild(NodePrx child)
{
    _contents.add(child);
}

```

The remainder of the operations, `name` and `list`, are equally trivial:

Java

```
public String
name(Ice.Current current)
{
    return _name;
}

// Slice Directory::list() operation

public NodePrx[]
list(Ice.Current current)
{
    NodePrx[] result = new NodePrx[_contents.size()];
    _contents.toArray(result);
    return result;
}
```

Note that the `_contents` member is of type `java.util.ArrayList<NodePrx>`, which is convenient for the implementation of the `addChild` method. However, this requires us to convert the list into a Java array in order to return it from the `list` operation.

The Java Utility Library

Ice for Java includes a number of utility APIs in the `IceUtil` package and the `Ice.Util` class. This section summarizes the contents of these APIs for your reference.

The IceUtil Package in Java

Cache and Store Classes

The `Cache` class allows you to efficiently maintain a cache that is backed by secondary storage, such as a Berkeley DB database, without holding a lock on the entire cache while values are being loaded from the database. If you want to create [evictors for servants](#) that store their state in a database, the `Cache` class can simplify your evictor implementation considerably.

You may also want to examine the implementation of the Freeze background save evictor in the source distribution; it uses `IceUtil.Cache` for its implementation.

The `Cache` class has the following interface:

```

Java

package IceUtil;

public class Cache {
    public Cache(Store store);

    public Object pin(Object key);
    public Object pin(Object key, Object o);
    public Object unpin(Object key);

    public Object putIfAbsent(Object key, Object newObj);
    public Object getIfPinned(Object key);

    public void clear();
    public int size();
}

```

Internally, a `Cache` maintains a map of name-value pairs. The implementation of `Cache` takes care of maintaining the map; in particular, it ensures that concurrent lookups by callers are possible without blocking even if some of the callers are currently loading values from the backing store. In turn, this is useful for evictor implementations, such as the Freeze [background save evictor](#). The `Cache` class does not limit the number of entries in the cache — it is the job of the evictor implementation to limit the map size by calling `unpin` on elements of the map that it wants to evict.

The `Cache` class works in conjunction with a `Store` interface for which you must provide an implementation. The `Store` interface is trivial:

```

Java

package IceUtil;

public interface Store {
    Object load(Object key);
}

```

You must implement the `load` method in a class that you derive from `Store`. The `Cache` implementation calls `load` when it needs to retrieve the value for the passed key from the backing store. If `load` cannot locate a record for the given key because no such record exists, it must return `null`. If `load` fails for some other reason, it can throw an exception derived from `java.lang.RuntimeException`, which is propagated back to the application code.

The public member functions of `Cache` behave as follows:

```
Cache(Store s)
```

The constructor initializes the cache with your implementation of the `Store` interface.

```
Object pin(Object key, Object val)
```

To add a key-value pair to the cache, your evictor can call `pin`. The return value is `null` if the key and value were added; otherwise, if the map already contains an entry with the given key, the entry is unchanged and `pin` returns the original value for that key.

This version of `pin` does *not* call `load` to retrieve the entry from backing store if it is not yet in the cache. This is useful when you add a newly-created object to the cache.

```
Object pin(Object key)
```

This version of `pin` returns the value stored in the cache for the given key if the cache already contains an entry for that key. If no entry with the given key is in the cache, `pin` calls `load` to retrieve the corresponding value (if any) from the backing store. `pin` returns the value returned by `load`, that is, the value if `load` could retrieve it, `null` if `load` could not retrieve it, or any exception thrown by `load`.

```
Object unpin(Object key)
```

`unpin` removes the entry for the given key from the cache. If the cache contained an entry for the key, the return value is the value for that key; otherwise, the return value is `null`.

```
Object putIfAbsent(Object key, Object val)
```

This function adds a key-value pair to the cache. If the cache already contains an entry for the given key, `putIfAbsent` returns the original value for that key. If no entry with the given key is in the cache, `putIfAbsent` calls `load` to retrieve the corresponding entry (if any) from the backing store and returns the value returned by `load`.

If the cache does not contain an entry for the given key and `load` does not retrieve a value for the key, the method adds the new entry and returns `null`.

```
Object getIfPinned(Object key)
```

This function returns the value stored for the given key. If an entry for the given key is in the map, the function returns the corresponding value; otherwise, the function returns `null`. `getIfPinned` does not call `load`.

```
void clear()
```

This function removes all entries in the map.

```
int size()
```

This function returns the number of entries in the map.

The `Ice.Util` Class in Java

Communicator Initialization Methods

`Ice.Util` provides a number of overloaded `initialize` methods that create a communicator.

Identity Conversion

`Ice.Util` contains two methods for [converting object identities](#) of type `Ice.Identity` to and from strings.

Per-Process Logger Methods

`Ice.Util` provides methods for [getting and setting the per-process logger](#).

Property Creation Methods

`Ice.Util` provides a number of overloaded `createProperties` methods that [create property sets](#).

Proxy Comparison Methods

Two methods, `proxyIdentityCompare` and `proxyIdentityAndFacetCompare`, allow you to [compare object identities](#) that are stored in proxies (either ignoring the facet or taking the facet into account).

Stream Creation

The methods `createInputStream`, `wrapInputStream` and `createOutputStream` create [streams](#) for use with dynamic invocation.

Version Information

The `stringVersion` and `intVersion` methods return the version of the Ice run time:

Java
<pre>public static String stringVersion(); public static int intVersion();</pre>

The `stringVersion` method returns the Ice version in the form `<major>.<minor>.<patch>`, for example, `3.4.2`. For beta releases, the version is `<major>.<minor>b`, for example, `3.4b`.

The `intVersion` method returns the Ice version in the form `AABBCC`, where `AA` is the major version number, `BB` is the minor version number, and `CC` is patch level, for example, `30402` for version `3.4.2`. For beta releases, the patch level is set to `51` so, for example, for version `3.4b`, the value is `30451`.

Custom Class Loaders

Certain features of the Ice for Java run-time necessitate dynamic class loading. Applications with special requirements can supply a custom class loader for Ice to use in the following situations:

- Unmarshaling [user exceptions](#) and instances of concrete Slice classes
- Loading Ice [plug-ins](#)
- Loading [IceSSL](#) certificate verifiers and password callbacks

If an application does not supply a class loader (or if the application-supplied class loader fails to locate a class), the Ice run time attempts to load the class using class loaders in the following order:

- current thread's class loader
- default class loader (that is, by calling `Class.forName()`)
- system class loader

Note that an application must install [object factories](#) for any abstract Slice classes it might receive, regardless of whether the application also installs a custom class loader.

To install a custom class loader, set the `classLoader` member of `Ice.InitializationData` prior to creating a communicator:

Java

```
Ice.InitializationData initData = new Ice.InitializationData();
initData.classLoader = new MyClassLoader();
Ice.Communicator communicator = Ice.Util.initialize(args, initData);
```

Java Interrupts

As of Ice 3.6, Java applications can safely interrupt a thread that calls a [blocking Ice API](#).

You must enable the `Ice.ThreadInterruptSafe` property to use interrupts. Enabling interrupts causes Ice to disable message buffer caching, which may incur a slight performance penalty.

With interrupt support enabled, Ice guarantees that every call into the run time that could potentially block indefinitely is an *interruption point*. On entry, an interruption point raises the unchecked exception `Ice.OperationInterruptedException` immediately if the current thread's interrupted flag is true. If the application interrupts the run time after the interruption point has begun its processing, the interruption point will either raise `Ice.OperationInterruptedException` or return control to the application with the thread's interrupted flag set. Under no circumstances will Ice silently discard an interrupt.

For example, the following code shows how to interrupt a thread that's blocked while making a synchronous proxy invocation:

```

Java

Thread proxyThread = Thread.currentThread();
AccountPrx account = // get proxy...

try {
    String name = account.getName(); // Blocks calling thread
    ...
} catch (Ice.OperationInterruptedException ex) {
    // The invocation was interrupted.
}

// At this point either the invocation was interrupted with an
// OperationInterruptedException or proxyThread.isInterrupted() is true.

// In another thread either just prior to or during the getName()
// invocation.
proxyThread.interrupt();
```

Here is a similar example that uses the asynchronous proxy API instead:

Java

```

Thread proxyThread = Thread.currentThread();
AccountPrx account = // get proxy...

Ice.AsyncResult r = account.begin_getName(); // Never blocks

try {
    // do more work
    String name = account.end_getName(r); // May block calling thread
    ...
} catch (Ice.OperationInterruptedException ex) {
    // The invocation was interrupted.
}

// At this point either the invocation was interrupted with an
// OperationInterruptedException or proxyThread.isInterrupted() is true.

// In another thread either just prior to or during the getName()
// invocation.
proxyThread.interrupt();

```

Synchronous proxy invocations are interruption points. For an asynchronous proxy invocation, the `begin_` method never blocks and therefore it is not an interruption point, however the `end_` method is an interruption point.

Additionally, all of the methods listed in [Blocking API Calls](#) are also interruption points. In the specific case of `Communicator.destroy()`, we recommend calling `destroy` in a loop as shown below:

Java

```

while(true) {
    try {
        communicator.destroy();
        break;
    } catch (Ice.OperationInterruptedException ex) {
        continue;
    }
}

```

Interrupting a call to `destroy` could leave the Ice run time in a partially-destroyed state; calling `destroy` again as we've done here ensures Ice can finish reclaiming the communicator's resources.

JavaScript Mapping

Supported Features of the JavaScript Mapping

Ice for JavaScript does not support the entire set of Ice features that are found in the C++, Java, and C# language mappings, primarily due to platform and API limitations. Furthermore, there are some differences between using Ice for JavaScript in a browser and in Node.js.

The table below provides more details on the Ice for JavaScript feature set:

Feature	Browser	Node.js	Notes
Synchronous invocations			Blocking RPCs are not compatible with JavaScript's execution model.
Asynchronous invocations	✓	✓	Also see Asynchronous APIs in JavaScript
Synchronous dispatch	✓	✓	
Asynchronous dispatch	✓	✓	
Outgoing TCP connections		✓	
Incoming TCP connections			Applications must use bidirectional connections to receive callbacks.
Outgoing WS connections	✓		WebSocket connections require the server to use the IceWS transport.
Outgoing WSS connections	✓		Secure WebSocket (WSS) connections require the server to use the IceWS transport.
Outgoing SSL connections			Browser applications can use WSS.
Datagrams			
DNS queries	⚠	⚠	The lack of support for DNS queries affects fault tolerance .
File logging			
Property files			
Flow control API			"Sent" callbacks are not supported.
Thread pools			Threads are not supported in JavaScript.
PerThread implicit context			Threads are not supported in JavaScript.
Protocol compression			Ice uses the bzip2 algorithm, which is not natively supported in JavaScript.
Communicator plug-ins			
Dispatcher API			
DispatchInterceptor API			
Collocated invocations			
Streaming API			
Admin facility			

DNS limitations

In most language mappings, the Ice run time performs a DNS query to resolve an endpoint's host name into one or more IP addresses. Specifying a multi-homed host name in an endpoint provides the client with a simple form of fault tolerance because Ice has multiple addresses to use during [connection establishment](#).

This form of fault tolerance is not available when using Ice for JavaScript because the DNS API is not supported.

Topics

- [Asynchronous APIs in JavaScript](#)

- [Client-Side Slice-to-JavaScript Mapping](#)
- [Server-Side Slice-to-JavaScript Mapping](#)

Asynchronous APIs in JavaScript

Given JavaScript's lack of support for threads, Ice for JavaScript uses asynchronous semantics in every situation that has the potential to block, including both local and non-local invocations. Synchronous proxy invocations are not supported.

Here is an example of a simple proxy invocation:

```

JavaScript

```

var proxy = HelloPrx.uncheckedCast(...);
var asyncResult = proxy.sayHello();
asyncResult.then(
 function(ar) {
 // handle success...
 },
 function(ex, ar) {
 // handle failure...
 }
);

```

```

The API design is similar to that of other asynchronous Ice language mappings in that the return value of a proxy invocation is an instance of `Ice.AsyncResult`, through which the program configures callbacks to handle the eventual success or failure of the invocation. The JavaScript implementation of `Ice.AsyncResult` also provides [promise](#) functionality.

Certain operations of local Ice run-time objects can also block, either because their implementations make remote invocations, or because their purpose is to block until some condition is satisfied:

- `Communicator::destroy`
- `Communicator::waitForShutdown`
- `Communicator::createObjectAdapterWithRouter`
- `Communicator::flushBatchRequests`
- `Connection::close`
- `Connection::flushBatchRequests`
- `ObjectPrx::ice_getConnection`

These operations use the same asynchronous API as for proxy invocations. The example below shows how to call `ice_getConnection` on a proxy:

```

JavaScript

```

var communicator = ...;
var proxy = communicator.stringToProxy("...");
proxy.ice_getConnection().then(
 function(connection, asyncResult) {
 // got connection...
 },
 function(ex, asyncResult) {
 // connection failed...
 }
);

```

```

Client-Side Slice-to-JavaScript Mapping

In this section, we present the client-side Slice-to-JavaScript mapping. The client-side Slice-to-JavaScript mapping defines how Slice data types are translated to JavaScript types, and how clients invoke operations, pass parameters, and handle errors. Much of the JavaScript mapping is intuitive. For example, Slice sequences map to JavaScript arrays, so there is essentially nothing new you have to learn in order to use Slice sequences in JavaScript.

Much of what appears in this chapter is reference material. We suggest that you skim the material on the initial reading and refer back to specific sections as needed. However, we recommend that you read at least the mappings for [exceptions](#), [interfaces](#), and [operations](#) in detail because these sections cover how to call operations from a client, pass parameters, and handle exceptions.

In order to use the JavaScript mapping, you should need no more than the Slice definition of your application and knowledge of the JavaScript mapping rules. In particular, looking through the generated code in order to discern how to use the JavaScript mapping is likely to be inefficient, due to the amount of detail. Of course, occasionally, you may want to refer to the generated code to confirm a detail of the mapping, but we recommend that you otherwise use the material presented here to see how to write your client-side code.

The Ice Scope

All of the APIs for the Ice run time are nested in the `Ice` scope, to avoid clashes with definitions for other libraries or applications. Some of the contents of the `Ice` scope are generated from Slice definitions; other parts of the `Ice` scope provide special-purpose definitions that do not have a corresponding Slice definition. We will incrementally cover the contents of the `Ice` scope throughout the remainder of the manual.

JavaScript Mapping for Identifiers

A Slice [identifier](#) maps to an identical JavaScript identifier. For example, the Slice identifier `clock` becomes the JavaScript identifier `clock`. There is one exception to this rule: if a Slice identifier is the same as a JavaScript keyword or is an identifier reserved by the Ice run time (such as `checkedCast`), the corresponding JavaScript identifier is prefixed with an underscore. For example, the Slice identifier `while` is mapped as `_while`.

You should try to [avoid such identifiers](#) as much as possible.

A single Slice identifier often results in several JavaScript identifiers. For example, for a Slice interface named `Foo`, the generated JavaScript code uses the identifiers `Foo` and `FooPrx` (among others). If the interface has the name `while`, the generated identifiers are `_while` and `whilePrx` (*not* `_whilePrx`), that is, the underscore prefix is applied only to those generated identifiers that actually require it.

- [JavaScript Mapping for Exceptions](#)

JavaScript Mapping for Modules

A Slice `module` maps to a JavaScript scope with the same name as the Slice module. The mapping preserves the nesting of the Slice definitions. For example:

Slice
<pre>// Definitions at global scope here... module M1 { // Definitions for M1 here... module M2 { // Definitions for M2 here... }; }; // ... module M1 { // Reopen M1 // More definitions for M1 here... };</pre>

This definition maps to the corresponding JavaScript definitions:

JavaScript
<pre>(function(module, require, exports) { var Ice = ... var __M = Ice.__M; var M1 = __M.module("M1"); // Definitions for M1 here... M1.M2 = __M.module("M1.M2"); // Definitions for M2 here... // More definitions for M1 here... exports.M1 = M1; } (typeof (global) !== ...);</pre>

The definitions exported by the generated Slice code for top-level modules add symbols to the global window object in browsers, or to the native exports object in NodeJS.

When developing for NodeJS, you include the various Ice components with `require` statements as shown below:

JavaScript

```
var Ice = require("ice").Ice;
var IceGrid = require("ice").IceGrid;
var IceStorm = require("ice").IceStorm;
...
```

Importing the generated code for your own Slice definitions works the same way:

JavaScript

```
var M1 = require("M1Defs").M1;
```

This example assumes the generated Slice definitions are in the file `M1Defs.js`.

In a browser application, the necessary JavaScript files are usually loaded via HTML:

```
<script type="text/javascript" src="Ice.js"></script>
<script type="text/javascript" src="M1Defs.js"></script>
<script type="text/javascript">
  // You can now access Ice and M1 as global objects
</script>
```

The file `Ice.js` shown above only provides definitions for the Ice run time; you would need to explicitly include the corresponding files for any other Ice components that your application needs, such as `IceGrid.js`.

JavaScript Mapping for Built-In Types

On this page:

- [Mapping of Slice Built-In Types to JavaScript Types](#)
- [JavaScript Mapping for Long Integers](#)

Mapping of Slice Built-In Types to JavaScript Types

The Slice built-in types are mapped to JavaScript types as follows:

Slice	JavaScript
bool	Boolean
byte	Number
short	Number
int	Number
long	Ice.Long
float	Number
double	Number
string	String

Mapping of Slice built-in types to JavaScript.

JavaScript Mapping for Long Integers

JavaScript does not provide a type that is capable of fully representing a Slice `long` value (a 64-bit integer), therefore Ice provides the `Ice.Long` type. An instance of `Ice.Long` encapsulates the high and low order 32-bit words (in little endian format) representing the 64-bit `long` value and provides access to these values via the `high` and `low` properties. Instances also provide the `toNumber` method, which returns a `Number` if the long value can be correctly represented by the `Number` type's integer range, otherwise it returns `Number.POSITIVE_INFINITY` or `Number.NEGATIVE_INFINITY` for positive and negative values, respectively.

`Ice.Long` objects have limited functionality because their primary purpose is to allow a `long` value to be re-transmitted, but instances do support the methods `hashCode`, `equals`, and `toString`.

JavaScript Mapping for Enumerations

JavaScript does not have an enumerated type, so a Slice enumeration is emulated using JavaScript objects where each enumerator is an instance of the same type. For example:

Slice
<pre>enum Fruit { Apple, Pear, Orange };</pre>

The generated JavaScript code is equivalent to the following:

JavaScript
<pre>var Fruit = function(name, value) { ... }; Fruit.Apple = new Fruit("Apple", 0); Fruit.Pear = new Fruit("Pear", 1); Fruit.Orange = new Fruit("Orange", 2);</pre>

Each enumerator defines `name` and `value` properties that supply the enumerator's name and ordinal value, respectively. Enumerators also define `hashCode`, `equals` and `toString` methods, and the enumerated type itself defines a `valueOf` method that converts ordinal values into their corresponding enumerators.

Suppose we modify the Slice definition to include a custom enumerator value:

Slice
<pre>enum Fruit { Apple, Pear = 3, Orange };</pre>

The generated code changes accordingly:

JavaScript
<pre>var Fruit = function(name, value) { ... }; Fruit.Apple = new Fruit("Apple", 0); Fruit.Pear = new Fruit("Pear", 3); Fruit.Orange = new Fruit("Orange", 4);</pre>

Given the above definitions, we can use enumerated values as follows:

JavaScript

```

var f1 = Fruit.Apple;
var f2 = Fruit.Orange;

if (f1 === Fruit.Apple) // Compare with constant
    // ...

if (f1 === f2)          // Compare two enums
    // ...

switch (f2) {           // Switch on enum
case Fruit.Apple:
    // ...
    break;
case Fruit.Pear:
    // ...
    break;
case Fruit.Orange:
    // ...
    break;
}

var f = Fruit.valueOf(3); // Convert an ordinal value to its enumerator,
or undefined if no match
console.log(f.name + " = " + f.value); // Outputs "Pear = 3"

```

Note that the generated type may contain other members, which we have not shown. These members are internal to the Ice run time and you must not use them in your application code (because they may change from release to release).

JavaScript Mapping for Structures

On this page:

- [Basic JavaScript Mapping for Structures](#)
- [JavaScript Constructors for Structures](#)

Basic JavaScript Mapping for Structures

A Slice [structure](#) maps to a JavaScript type with the same name. For each Slice data member, the JavaScript instance contains a corresponding property. As an example, here is our [Employee](#) structure once more:

Slice
<pre>struct Employee { long number; string firstName; string lastName; };</pre>

The JavaScript mapping for this structure is equivalent to the following code:

JavaScript
<pre>var Employee = function(number, firstName, lastName) { this.number = ... this.firstName = ... this.lastName = ... };</pre>

For each data member in the Slice definition, the JavaScript constructor assigns a value to its corresponding property. Instances define an `equals` method for comparison purposes and a `clone` method to create a shallow copy.

If the structure qualifies for use as a [dictionary key](#), instances also define a `hashCode` function as required by the `Ice.HashMap` type.

JavaScript Constructors for Structures

The generated constructor has one parameter for each data member. This allows you to construct and initialize an instance in a single statement (instead of first having to construct the instance and then assign to its members). The constructor assigns a default value to each property appropriate for the type of its corresponding member:

Data Member Type	Default Value
string	Empty string
enum	First enumerator in enumeration
struct	Default-constructed value
Numeric	Zero

<code>bool</code>	False
<code>sequence</code>	Null
<code>dictionary</code>	Null
<code>class/interface</code>	Null

If you wish to ensure that data members of primitive and enumerated types are initialized to specific values, you can declare default values in your [Slice definition](#). The constructor initializes each of these data members to its declared value instead.

JavaScript Mapping for Sequences

On this page:

- [Basic JavaScript Mapping for Sequences](#)
- [JavaScript Mapping for Byte Sequences](#)

Basic JavaScript Mapping for Sequences

A Slice `sequence` maps to a native JavaScript array. This means that the Slice-to-JavaScript compiler does not generate a separate named type for a Slice sequence. It also means that you can take advantage of all the inherent functionality offered by JavaScript's array type. For example:

Slice
<pre>sequence<Fruit> FruitPlatter;</pre>

We can use the `FruitPlatter` sequence as shown below:

JavaScript
<pre>var platter = [Fruit.Apple]; platter.push(Fruit.Pear);</pre>

JavaScript Mapping for Byte Sequences

As an optimization, occurrences of `sequence<byte>` map to a native buffer type, which is more efficient than native arrays for working with binary data. For browser applications, `sequence<byte>` maps to `Uint8Array`, and for Node.js applications it maps to the native `Buffer` type.

See Also

- [Sequences](#)
- [JavaScript Mapping for Enumerations](#)
- [JavaScript Mapping for Structures](#)
- [JavaScript Mapping for Dictionaries](#)

JavaScript Mapping for Dictionaries

Here is the definition of our `EmployeeMap` once more:

```
Slice
```

```
dictionary<long, Employee> EmployeeMap;
```

In the JavaScript mapping, all dictionaries are instances of the `Ice.HashMap` type. The mapping also generates a type-specific constructor with the same name as the dictionary. For example:

```
JavaScript
```

```
var em = new EmployeeMap();

var e = new Employee();
e.number = new Ice.Long(31);
e.firstName = "James";
e.lastName = "Gosling";

em.set(e.number, e);
```

`HashMap` objects support the following properties and functions:

- `HashMap(keyComparator, valueComparator)`
This version of the constructor accepts optional comparator functions that the map uses to compare keys and values for equality. If you instantiate a map directly using `new Ice.HashMap()` without specifying comparator functions, the default comparators use the `===` operator to compare keys and values. As an example, the following map compares its keys and values using `equals` methods:

```
JavaScript
```

```
function compareEquals(a, b) { return a.equals(b); }
var m = new Ice.HashMap(compareEquals, compareEquals);
```

The `valueComparator` function is only used when comparing two maps for equality.

```
The type-specific constructor generated for a Slice dictionary supplies comparator functions appropriate for its key and value types.
```

- `HashMap(h)`
This version of the constructor accepts an optional `HashMap` object from which all entries are (shallow) copied. The new map inherits the comparator functions of the original.
- `size`
The `size` property indicates how many entries are currently in the map.
- `entries`
The `entries` property holds the head of a linked list that can be used to traverse all map entries.

- `get(key)`
Returns the value associated with the given key, or `undefined` if no entry has a matching key.
- `set(key, value)`
Adds a new entry to the map having the given key and value. Always returns `undefined`.
- `has(key)`
Returns true if the map contains an entry with a matching key, or false otherwise.
- `delete(key)`
Removes the entry associated with the given key. Returns the entry's current value if a match was found, or `undefined` otherwise.
- `clear()`
Removes all entries in the current map.
- `keys()`
Returns an array containing all keys in an unspecified order.
- `values()`
Returns an array containing all values in an unspecified order.
- `forEach(fn, thisArg)`
Iterates over the entries in the map in an unspecified order, calling the given function once for each entry. The optional `thisArg` parameter is used as `this` when executing the function. The arguments to the function are `key` and `value`, representing the key and value of each element.
- `equals(other, valueComparator)`
Returns true if this map compares equal to the given map, false otherwise. You can optionally supply a function for `valueComparator` that the map uses when comparing values; this function takes precedence over the comparator supplied to the map's constructor.
- `clone()`
Returns a shallow copy of the map.

Legal key types for `HashMap` include JavaScript's primitive types along with `null`, `NaN`, and any object that defines a `hashCode` method. The generated code for a Slice structure that qualifies as a [legal dictionary key](#) type includes a `hashCode` method. Suppose we define another dictionary type:

Slice

```
dictionary<Employee, string> EmployeeDeptMap;
```

The Slice compiler generates a constructor function equivalent to the following code:

JavaScript

```
var EmployeeDeptMap = function(h)
{
  var keyComparator = ...;
  var valueComparator = ...;
  return new Ice.HashMap(h || keyComparator, valueComparator);
};
```

Since the key is a user-defined structure type, the map requires a comparator that properly compares keys. Instantiating a map using `new EmployeeDeptMap` automatically sets the comparators, whereas calling `new Ice.HashMap` in this case would require you to supply your own comparators.

Ice applications should always instantiate a Slice dictionary using the generated constructor.

It is not possible to use JavaScript's native `for...in` syntax to iterate over the map's entries. In addition to the `forEach` method described above, the map also maintains an unordered linked list of its entries that you can iterate through as shown below:

JavaScript

```
var em = new EmployeeMap();
// ...
for(var e = em.entries; e !== null; e = e.next)
{
    var employeeNum = e.key;
    var employee = e.value;
    ...
}
```

Each entry object supports the read-only properties `key`, `value` and `next`.

Notes

- Attempting to use the `map[key] = value` syntax to add an element to the map will not have the desired effect; you must use the `set` function instead.
- The Ice run time validates the elements of a dictionary to ensure that they are compatible with the declared type; an `Error` exception is raised if an incompatible type is encountered.
- The `HashMap` API is largely compatible with the draft EcmaScript 6 `Map` type, but there are also some differences between the two. Ice for JavaScript may replace `HashMap` with the standard `Map` when it is widely supported.

JavaScript Mapping for Constants

Here are the sample constant definitions once more:

Slice
<pre> module Example { const bool AppendByDefault = true; const byte LowerNibble = 0x0f; const string Advice = "Don't Panic!"; const short TheAnswer = 42; const double PI = 3.1416; enum Fruit { Apple, Pear, Orange }; const Fruit FavoriteFruit = Pear; }; </pre>

For each constant, the JavaScript mapping generates a read-only property of the same name in the enclosing scope as shown below:

JavaScript
<pre> Object.defineProperty(Example, 'AppendByDefault', {value: true}); Object.defineProperty(Example, 'LowerNibble', {value: 15}); Object.defineProperty(Example, 'Advice', {value: "Don't Panic!"}); Object.defineProperty(Example, 'TheAnswer', {value: 42}); Object.defineProperty(Example, 'PI', {value: 3.1416}); Object.defineProperty(Example, 'FavoriteFruit', {value: Fruit.Pear}); </pre>

Slice string literals that contain non-ASCII characters or universal character names are mapped to JavaScript string literals with universal character names. For example:

Slice
<pre> const string Egg = "æuf"; const string Heart = "c\u0153ur"; const string Banana = "\U0001F34C"; </pre>

is mapped to:

JavaScript
<pre> Object.defineProperty(Example, 'Egg', {value: "\u0153uf"}); Object.defineProperty(Example, 'Heart', {value: "c\u0153ur"}); Object.defineProperty(Example, 'Banana', {value: "\ud83c\udf4c"}); </pre>

JavaScript Mapping for Exceptions

On this page:

- [JavaScript Mapping for User Exceptions](#)
- [JavaScript Constructors for User Exceptions](#)
- [JavaScript Mapping for Run-Time Exceptions](#)

JavaScript Mapping for User Exceptions

Here is a fragment of the `Slice` definition for our world time server once more:

```

Slice

exception GenericError {
    string reason;
};
exception BadTimeVal extends GenericError {};
exception BadZoneName extends GenericError {};
```

These exception definitions map as follows:

```

JavaScript

GenericError = function(reason, cause) { ... }
GenericError.prototype = new Ice.UserException();
GenericError.prototype.constructor = GenericError;
GenericError.prototype.ice_name = function() { return "M::GenericError"; }

BadTimeVal = function(reason, cause) { ... }
BadTimeVal.prototype = new GenericError();
BadTimeVal.prototype.constructor = BadTimeVal;
BadTimeVal.prototype.ice_name = function() { return "M::BadTimeVal"; }

BadZoneName = function(reason, cause) { ... }
BadZoneName.prototype = new GenericError();
BadZoneName.prototype.constructor = BadZoneName;
BadZoneName.prototype.ice_name = function() { return "M::BadZoneName"; }
```

Each `Slice` exception maps to a JavaScript type with the same name. Each data member of an exception corresponds to a property in the JavaScript type.

The inheritance structure of the `Slice` exceptions is preserved for the generated types, so the prototypes for `BadTimeVal` and `BadZoneName` inherit from `GenericError`.

Each exception also defines the `ice_name` member function, which returns the name of the exception.

All user exceptions ultimately derive from the base type `Ice.UserException`. This allows you to handle any user exception generically as an `Ice.UserException`. Similarly, you can handle any Ice run-time exceptions as an `Ice.LocalException`, and you can handle any Ice exception as an `Ice.Exception`.

Note that the generated exception types may contain other properties and functions that are not shown. However, these elements are internal to the JavaScript mapping and are not meant to be used by application code.

JavaScript Constructors for User Exceptions

The generated constructor has one parameter for each data member. This allows you to construct and initialize an instance in a single statement (instead of first having to construct the instance and then assign to its members). For derived exceptions, the constructor accepts one argument for each base exception member, plus one argument for each derived exception member, in base-to-derived order.

The constructor assigns a default value to each property appropriate for the type of its corresponding member:

Data Member Type	Default Value
string	Empty string
enum	First enumerator in enumeration
struct	Default-constructed value
Numeric	Zero
bool	False
sequence	Null
dictionary	Null
class/interface	Null

If you wish to ensure that data members of primitive and enumerated types are initialized to specific values, you can declare default values in your [Slice definition](#). The constructor initializes each of these data members to its declared value instead.

The generated constructor accepts an optional trailing argument representing the entity that caused the exception. This value is typically an instance of `Error`, but that is not a requirement. The value is used to initialize the `ice_cause` property inherited from `Ice.Exception`.

JavaScript Mapping for Run-Time Exceptions

The Ice run time throws run-time exceptions for a number of pre-defined error conditions. All run-time exceptions directly or indirectly derive from `Ice.LocalException` (which, in turn, derives from `Ice.Exception`).

Recall the [inheritance diagram](#) for user and run-time exceptions. By catching exceptions at the appropriate point in the hierarchy, you can handle exceptions according to the category of error they indicate:

- `Ice.Exception`
This is the root of the inheritance tree for both run-time and user exceptions.
- `Ice.LocalException`
This is the root of the inheritance tree for run-time exceptions.
- `Ice.UserException`
This is the root of the inheritance tree for user exceptions.
- `Ice.TimeoutException`
This is the base exception for both operation-invocation and connection-establishment timeouts.
- `Ice.ConnectTimeoutException`
This exception is raised when the initial attempt to establish a connection to a server times out.

For example, a `ConnectTimeoutException` can be handled as `ConnectTimeoutException`, `TimeoutException`, `LocalException`, or `Exception`.

You will probably have little need to catch run-time exceptions as their most-derived type and instead catch them as `LocalException`; the fine-grained error handling offered by the remainder of the hierarchy is of interest mainly in the implementation of the Ice run time. Exceptions to this rule are the exceptions related to [facet](#) and [object](#) life cycles, which you may want to catch explicitly. These exceptions are `FacetNotExistException` and `ObjectNotExistException`, respectively.

JavaScript Mapping for Interfaces

The mapping of Slice interfaces revolves around the idea that, to invoke a remote operation, you call a member function on a local class instance that is a [proxy](#) for the remote object. This makes the mapping easy and intuitive to use because making a remote procedure call is no different from making a local procedure call (apart from error semantics).

On this page:

- [Proxy Interfaces in JavaScript](#)
- [The Ice.ObjectPrx Interface in JavaScript](#)
- [Down-casting Proxies in JavaScript](#)
- [Type IDs in JavaScript](#)
- [Using Proxy Methods in JavaScript](#)
- [Object Identity and Proxy Comparison in JavaScript](#)

Proxy Interfaces in JavaScript

On the client side, a Slice interface maps to a JavaScript type with methods that correspond to the operations on that interface. Consider the following simple interface:

Slice

```
interface Simple {
    void op();
};
```

The Slice compiler generates code for use by the client similar to the following:

JavaScript

```
var SimplePrx = function() { ... }
SimplePrx.prototype.op = function(__ctx) { ... }
```

As you can see, the compiler generates a *proxy type* `SimplePrx`. In general, the generated name is `<interface-name>Prx`. If an interface is nested in a module `M`, the fully-qualified name is `M.<interface-name>Prx`.

In the client's address space, an instance of `SimplePrx` is the local ambassador for a remote instance of the `Simple` interface in a server and is known as a proxy instance. All the details about the server-side object, such as its address, what protocol to use, and its object identity are encapsulated in that instance.

Note that the prototype for `SimplePrx` inherits from `Ice.ObjectPrx`. This reflects the fact that all Ice interfaces implicitly inherit from `Ice::Object`.

For each operation in the interface, the proxy type defines a function with the same name. For the preceding example, we find that the operation `op` has been mapped to the function `op`. The function has an optional parameter `__ctx` that is used by the Ice run time to store information about how to deliver a request. You normally do not need to use it. Legal values for this parameter are `null` or an instance of `Ice.Context` (which is an `Ice.HashMap`). (We examine the `__ctx` parameter in detail in [Request Contexts](#). The parameter is also used by `IceStorm`.)

Asynchronous Operations

Unlike most other Ice language mappings, where a Slice operation generates both synchronous and asynchronous proxy methods, the JavaScript language mapping generates only an asynchronous method. Given the event-driven nature of JavaScript and its networking API, it is not feasible to provide the traditional blocking RPC model.

Client code must not create an instance of a `<interface-name>Prx` type directly. Instead, proxy instances are always created on behalf of the client by the Ice run time, so client code never has any need to instantiate a proxy directly.

A value of `null` denotes the null proxy. The null proxy is a dedicated value that indicates that a proxy points "nowhere" (denotes no object).

The `Ice.ObjectPrx` Interface in JavaScript

All Ice objects have `Object` as the ultimate ancestor type, so all proxies inherit from `Ice.ObjectPrx`. `ObjectPrx` provides a number of functions:

JavaScript

```
ObjectPrx.prototype.equals = function(r) { ... }
ObjectPrx.prototype.ice_getIdentity = function() { ... }
ObjectPrx.prototype.ice_isA = function(id, __ctx) { ... }
ObjectPrx.prototype.ice_ids = function(__ctx) { ... }
ObjectPrx.prototype.ice_id = function(__ctx) { ... }
ObjectPrx.prototype.ice_ping = function(__ctx) { ... }
```

The functions behave as follows:

- **equals**

This function compares two proxies for equality. Note that all aspects of proxies are compared by this function, such as the communication endpoints for the proxy. This means that, in general, if two proxies compare unequal, that does *not* imply that they denote different objects. For example, if two proxies denote the same Ice object via different transport endpoints, `equals` returns `false` even though the proxies denote the same object.

- **ice_getIdentity**

This function returns the identity of the object denoted by the proxy. The identity of an Ice object has the following Slice type:

Slice

```
module Ice {
  struct Identity {
    string name;
    string category;
  };
};
```

To see whether two proxies denote the same object, first obtain the identity for each object and then compare the identities:

JavaScript

```

var prx1 = ...;
var prx2 = ...;
var ident1 = prx1.ice_getIdentity();
var ident2 = prx2.ice_getIdentity();

if (i1.equals(i2))
    // o1 and o2 denote the same object
else
    // o1 and o2 denote different objects

```

- **ice_isA**

The `ice_isA` function determines whether the object supports a specific interface. The argument to `ice_isA` is a [type ID](#). For example, to see whether a proxy of type `ObjectPrx` denotes a `Printer` object, we can write:

JavaScript

```

var prx = ...;
if (prx !== null) {
    prx.ice_isA("::Printer").then(
        function(b)
        {
            if(b)
                // Target object supports the Printer interface!
            else
                // Oops, target object is a different type
        },
        function(ex)
        {
            // Handle failure
        });
}

```

Note that we are testing whether the proxy is null before attempting to invoke the `ice_isA` method. This avoids getting a run-time error if the proxy is null.

- **ice_ids**

The `ice_ids` function obtains an array of strings representing all of the type IDs that the object supports.

- **ice_id**

The `ice_id` function obtains the type ID of the object. Note that the type returned is the type of the actual object, which may be more derived than the static type of the proxy. For example, if we have a proxy of type `BasePrx`, with a static type ID of `::Base`, the actual type ID might be `::Base`, or it might something more derived, such as `::Derived`.

- **ice_ping**

The `ice_ping` function provides a basic reachability test for the object. If the object can physically be contacted (that is, the object exists and its server is running and reachable), the call completes normally; otherwise, it throws an exception that indicates why the object could not be reached, such as `ObjectNotExistException` or `ConnectTimeoutException`.

As remote operations, the `ice_isA`, `ice_ids`, `ice_id`, and `ice_ping` functions support an optional trailing argument representing a `request context`. Also note that there are [other methods](#) in `ObjectPrx`, not shown here. These methods provide different ways to dispatch a call and also provide access to an object's `facets`.

Down-casting Proxies in JavaScript

In addition to the methods corresponding to Slice operations, the Slice-to-JavaScript compiler also generates two helper methods that support down-casting:

JavaScript

```
SimplePrx.checkedCast = function(prx, facet, __ctx) { ... }
SimplePrx.uncheckedCast = function(prx, facet) { ... }
```

For `checkedCast`, if the passed proxy is for an object of type `Simple`, or a proxy for an object with a type derived from `Simple`, the result of the cast is a non-null reference to a proxy of type `SimplePrx`; otherwise, if the passed proxy denotes an object of a different type (or if the passed proxy is null), the result of the cast is a null reference.

Note that a checked cast contacts the server. This is necessary because only the implementation of an object in the server has definite knowledge of the type of an object. Consequently, a checked cast is implemented as the asynchronous method `checkedCast`, which may result in a `ConnectTimeoutException` or an `ObjectNotExistException`.

Given a proxy of any type, you can use a checked cast to determine whether the corresponding object supports a given type, for example:

JavaScript

```
var prx = ...; // Get a proxy from somewhere...
SimplePrx.checkedCast(prx).then(
  function(proxy)
  {
    if(proxy !== null)
      // Object supports the Simple interface...
    else
      // Object is not of type Simple...
  },
  function(ex)
  {
    // Handle failure
  });
```

In contrast, an unchecked cast does not contact the server and unconditionally returns a proxy of the requested type. However, if you do use `uncheckedCast`, you must be certain that the proxy really does support the type you are casting to; otherwise, if you get it wrong, you will most likely get a run-time exception when you invoke an operation on the proxy. The most likely error for such a type mismatch is `OperationNotExistException`. However, other exceptions, such as a marshaling exception are possible as well. And, if the object happens to have an operation with the correct name, but different parameter types, no exception may be reported at all and you simply end up sending the invocation to an object of the wrong type; that object may do rather nonsensical things. To illustrate this, consider the following two interfaces:

Slice

```
interface Process {
    void launch(int stackSize, int dataSize);
};

// ...

interface Rocket {
    void launch(float xCoord, float yCoord);
};
```

Suppose you expect to receive a proxy for a `Process` object and use an `uncheckedCast` to down-cast the proxy:

JavaScript

```
var obj = ...; // Get proxy...
var process = ProcessPrx.uncheckedCast(obj); // No worries...
process.launch(40, 60); // Oops...
```

If the proxy you received actually denotes a `Rocket` object, the error will go undetected by the Ice run time: because `int` and `float` have the same size and because the Ice protocol does not tag data with its type on the wire, the implementation of `Rocket::launch` will simply misinterpret the passed integers as floating-point numbers.

In fairness, this example is somewhat contrived. For such a mistake to go unnoticed at run time, both objects must have an operation with the same name and, in addition, the run-time arguments passed to the operation must have a total marshaled size that matches the number of bytes that are expected by the unmarshaling code on the server side. In practice, this is extremely rare and an incorrect `uncheckedCast` typically results in a run-time exception.

Type IDs in JavaScript

You can discover the `type ID` string corresponding to an interface by calling the `ice_staticId` function on the proxy type:

JavaScript

```
var id = SimplePrx.ice_staticId();
```

As an example, for an interface `Simple` in module `M`, the `ice_staticId` function returns the string `":M::Simple"`.

Using Proxy Methods in JavaScript

The base proxy class `ObjectPrx` supports a variety of [methods for customizing a proxy](#). Since proxies are immutable, each of these "factory methods" returns a copy of the original proxy that contains the desired modification. For example, you can obtain a proxy configured with a ten second timeout as shown below:

JavaScript

```
var proxy = communicator.stringToProxy(...);
proxy = proxy.ice_timeout(10000);
```

A factory method returns a new proxy object if the requested modification differs from the current proxy, otherwise it returns the current proxy. With few exceptions, factory methods return a proxy of the same type as the current proxy, therefore it is generally not necessary to repeat a checked or unchecked cast after using a factory method. The only exceptions are the factory methods `ice_facet` and `ice_identity`. Calls to either of these methods may produce a proxy for an object of an unrelated type, therefore they return a base proxy that you must subsequently down-cast to an appropriate type.

Object Identity and Proxy Comparison in JavaScript

Proxies provide an `equals` function that compares proxies:

JavaScript

```
ObjectPrx.prototype.equals = function(other) { ... }
```

Note that proxy comparison with `equals` uses *all* of the information in a proxy for the comparison. This means that not only the object identity must match for a comparison to succeed, but other details inside the proxy, such as the protocol and endpoint information, must be the same. In other words, comparison with `equals` tests for *proxy* identity, *not* object identity. A common mistake is to write code along the following lines:

JavaScript

```
var p1 = ...;           // Get a proxy...
var p2 = ...;           // Get another proxy...

if(!p1.equals(p2)) {
    // p1 and p2 denote different objects           // WRONG!
} else {
    // p1 and p2 denote the same object             // Correct
}
```

Even though `p1` and `p2` differ, they may denote the same Ice object. This can happen because, for example, both `p1` and `p2` embed the same object identity, but each use a different protocol to contact the target object. Similarly, the protocols may be the same, but denote different endpoints (because a single Ice object can be contacted via several different transport endpoints). In other words, if two proxies compare equal with `equals`, we know that the two proxies denote the same object (because they are identical in all respects); however, if two proxies compare unequal with `equals`, we know absolutely nothing: the proxies may or may not denote the same object.

To compare the object identities of two proxies, you can use a helper function:

JavaScript

```
Ice.proxyIdentityCompare = function(lhs, rhs) { ... }
Ice.proxyIdentityAndFacetCompare = function(lhs, rhs) { ... }
```

`proxyIdentityCompare` allows you to correctly compare proxies for identity:

JavaScript

```
var p1 = ...;           // Get a proxy...
var p2 = ...;           // Get another proxy...

if (Ice.proxyIdentityCompare(p1, p2) !== 0) {
    // p1 and p2 denote different objects      // Correct
} else {
    // p1 and p2 denote the same object        // Correct
}
```

The function returns 0 if the identities are equal, -1 if `p1` is less than `p2`, and 1 if `p1` is greater than `p2`. (The comparison uses `name` as the major and `category` as the minor sort key.)

The `proxyIdentityAndFacetCompare` function behaves similarly, but compares both the identity and the [facet name](#).

JavaScript Mapping for Operations

JavaScript's event-driven APIs makes a synchronous invocation model impractical, therefore the JavaScript language mapping provides only an asynchronous model.

Asynchronous Method Invocation (AMI) is the term used to describe the client-side support for the asynchronous programming model. AMI supports both oneway and twoway requests and invocations never block. When a client issues an AMI request, the Ice run time hands the message off to the local transport buffer or, if the buffer is currently full, queues the request for later delivery. The application can then continue its activities and receive a callback when the invocation completes.

AMI is transparent to the server: there is no way for the server to tell whether a client sent a request synchronously or asynchronously.

Basic Asynchronous API in JavaScript

Consider the following simple Slice definition:

Slice

```

module Demo {
    interface Employees {
        string getName(int number);
        string getAddress(int number);
    };
};

```

Asynchronous Proxy Methods in JavaScript

`slice2js` generates the following asynchronous proxy methods:

JavaScript

```

EmployeesPrx.prototype.getName = function(number, __ctx) { ... }
EmployeesPrx.prototype.getAddress = function(number, __ctx) { ... }

```

As you can see, a Slice operation maps to a method of the same name. (Each function accepts an optional trailing [per-invocation context](#).)

The `getName` function, for example, sends an invocation of `getName`. Because proxy invocations do not block, the application can do other things while the operation is in progress. The application receives notification about the completion of the request by [registering callbacks](#) for success and failure.

The `getName` function, as with all functions corresponding to Slice operations, returns a value of type `Ice.AsyncResult`. This value contains the state that the Ice run time requires to keep track of the asynchronous invocation.

A proxy function has one parameter for each in-parameter of the corresponding Slice operation. For example, consider the following operation:

```
Slice
```

```
double op(int inp1, string inp2, out bool outp1, out long outp2);
```

The `op` member function has the following signature:

```
JavaScript
```

```
function op(inp1, inp2, __ctx); // Returns Ice.AsyncResult
```

The operation's return value, as well as the values of its two out-parameters, are delivered to the [success callback](#) upon completion of the request.

Passing Parameters in JavaScript

The parameter passing rules for the JavaScript mapping are very simple: parameters are passed either by value (for simple types) or by reference (for complex types). Semantically, the two ways of passing parameters are identical: it is guaranteed that the value of a parameter will not be changed by the invocation.

Here is an interface with operations that pass parameters of various types from client to server:

```
Slice
```

```
struct NumberAndString {
    int x;
    string str;
};

sequence<string> StringSeq;

dictionary<long, StringSeq> StringTable;

interface ClientToServer {
    void op1(int i, float f, bool b, string s);
    void op2(NumberAndString ns, StringSeq ss, StringTable st);
    void op3(ClientToServer* proxy);
};
```

The Slice compiler generates the following proxy methods for these definitions:

JavaScript

```
ClientToServerPrx.prototype.op1 = function(i, f, b, s, __ctx) { ... }
ClientToServerPrx.prototype.op2 = function(ns, ss, st, __ctx) { ... }
ClientToServerPrx.prototype.op3 = function(proxy, __ctx) { ... }
```

Given a proxy to a `ClientToServer` interface, the client code can pass parameters as in the following example:

JavaScript

```
var p = ...;           // Get ClientToServerPrx proxy...

p.op1(42, 3.14, true, "Hello world!"); // Pass simple literals

var i = 42;
var f = 3.14;
var b = true;
var s = "Hello world!";
p.op1(i, f, b, s);           // Pass simple variables

var ns = new NumberAndString();
ns.x = 42;
ns.str = "The Answer";
var ss = [];
ss.push("Hello world!");
var st = new StringTable();
st.set(0, ss);
p.op2(ns, ss, st);           // Pass complex variables

p.op3(p);                   // Pass proxy
```

Null Parameters in JavaScript

Some Slice types naturally have "empty" or "not there" semantics. Specifically, sequences, dictionaries, and strings all can be `null`, but the corresponding Slice types do not have the concept of a null value. To make life with these types easier, whenever you pass `null` as a parameter or return value of type sequence, dictionary, or string, the Ice run time automatically sends an empty sequence, dictionary, or string to the receiver.

This behavior is useful as a convenience feature: especially for deeply-nested data types, members that are sequences, dictionaries, or strings automatically arrive as an empty value at the receiving end. This saves you having to explicitly initialize, for example, every string element in a large sequence before sending the sequence in order to avoid a run-time error. Note that using null parameters in this way does *not* create null semantics for Slice sequences, dictionaries, or strings. As far as the object model is concerned, these do not exist (only *empty* sequences, dictionaries, and strings do). For example, whether you send a string as `null` or as an empty string makes no difference to the receiver: either way, the receiver sees an empty string.

Optional Parameters in JavaScript

[Optional parameters](#) use the same mapping as required parameters. The only difference is that `undefined` can be passed as the value of an optional parameter or return value to indicate an "unset" condition. Consider the following operation:

Slice

```
optional(1) int execute(optional(2) string params, out optional(3) float
value);
```

A client can invoke this operation as shown below:

JavaScript

```
proxy.execute("--file log.txt").then(
  function(retval, value)
  {
    if(value !== undefined)
      console.log("value =", value);
  });
```

A well-behaved program must always compare an optional parameter to `undefined` prior to using its value.

For Slice types that support null semantics, such as proxies and objects by value, passing `null` for an optional parameter has a different meaning than passing `undefined`:

- `null` means a value was supplied for the parameter, and that value happens to be `null`
- `undefined` means no value was supplied for the parameter

`undefined` is not a legal value for required parameters.

Asynchronous Exception Semantics in JavaScript

If an invocation raises an exception, the exception is delivered to the [failure callback](#), even if the actual error condition for the exception was encountered during the proxy function ("on the way out"). The advantage of this behavior is that all exception handling is located in the failure callback (instead of being present twice, once where the proxy function is called, and again in the failure callback).

There is one exception to the above rule: if you destroy the communicator and then make an asynchronous invocation, the proxy function throws `CommunicatorDestroyedException`. This is necessary because, once the run time is finalized, it can no longer deliver an exception to the failure callback.

The only other exception that is thrown by the proxy function is `Error`. This exception indicates that you have used the API incorrectly. For example, the proxy function throws this exception if you pass an invalid argument for one of the operation's parameters.

AsyncResult Type in JavaScript

The `AsyncResult` object returned by an Ice API call encapsulates the state of the asynchronous invocation.

In other Ice language mappings, the `AsyncResult` type is only used for asynchronous remote invocations. In JavaScript, an `AsyncResult` object can also be returned by methods of local Ice run time objects such as `Communicator` and `ObjectAdapter` when those methods have the potential to block or internally make remote invocations.

An instance of `AsyncResult` defines the following properties:

- `communicator`
The communicator that sent the invocation.
- `connection`

This method returns the connection that was used for the invocation. Note that, for typical proxy invocations, this method returns a nil value because the possibility of automatic retries means the connection that is currently in use could change unexpectedly. The `connection` property only returns a non-nil value when the `AsyncResult` object is obtained by calling `flushBatchRequests` on a `Connection` object.

- `proxy`
The proxy that was used for the invocation, or nil if the `AsyncResult` object was not obtained via a proxy invocation.
- `adapter`
The object adapter that was used for the invocation, or nil if the `AsyncResult` object was not obtained via an object adapter invocation.
- `operation`
The name of the operation being invoked.

`AsyncResult` objects also support the following methods:

- `cancel()`
This method prevents a queued invocation from being sent or, if the invocation has already been sent, ignores a reply if the server sends one. `cancel` is a local operation and has no effect on the server. A canceled invocation is considered to be completed, meaning `isCompleted` returns true, and the result of the invocation is an `Ice.InvocationCanceledException`.
- `isCompleted()`
This method returns true if, at the time it is called, the result of an invocation is available, indicating that a call to the `end_` method will not block the caller. Otherwise, if the result is not yet available, the method returns false.
- `isSent()`
When you make a proxy invocation, the Ice run time attempts to write the corresponding request to the client-side transport. If the transport cannot accept the request, the Ice run time queues the request for later transmission. `isSent` returns true if, at the time it is called, the request has been written to the local transport (whether it was initially queued or not). Otherwise, if the request is still queued or an exception occurred before the request could be sent, `isSent` returns false.
- `throwLocalException()`
This method throws the local exception that caused the invocation to fail. If no exception has occurred yet, `throwLocalException` does nothing.
- `sentSynchronously()`
This method returns true if a request was written to the client-side transport without first being queued. If the request was initially queued, `sentSynchronously` returns false (independent of whether the request is still in the queue or has since been written to the client-side transport).

As described in the next section, an `AsyncResult` object provides additional functionality, including support for success and failure callbacks, that it inherits from a base type.

Promise Type in JavaScript

The `Ice.AsyncResult` type actually derives from `Ice.Promise`. This type is an implementation of the *promise* concept commonly used in JavaScript applications for simplifying the handling of asynchronous invocations. As you'll see below, one especially useful feature of a promise is its support for chaining, which allows you to make a series of asynchronous calls while still maintaining code readability.

Basic Promise Concepts

A promise is a relatively simple object whose purpose is to invoke callback functions upon the success or failure of a condition. The object always starts out in a pending state, and then transitions to a success or failure state via calls to its `succeed` and `fail` methods, respectively. This state transition, known as *resolving* a promise, occurs only once, with any subsequent calls to `succeed` or `fail` ignored. The initial caller of `succeed` or `fail` can supply arguments that the promise object will pass along to its success or failure callbacks. Any number of callbacks can be registered on a single promise, and they can be registered before or after the promise has been resolved.

The promise implementation always invokes its callbacks asynchronously via `setTimeout`, which avoids the complexities that could occur if the callbacks were invoked immediately as nested calls. For the purposes of this discussion, when we say that a promise "invokes" its callbacks, we actually mean that it queues the callbacks for invocation.

A promise invokes any registered callbacks at the time the promise is resolved. Callbacks registered after a promise has already been resolved are invoked immediately. The promise keeps references to the arguments passed to `succeed` or `fail` so that it can pass them to callbacks registered later.

Getting Started with Promises

The `Promise` method you'll use most often is `then`, which accepts two arguments:

JavaScript

```
function then(successFn, failureFn) { ... }
```

Both arguments are optional. Here is a simple example:

JavaScript

```
var p = new Ice.Promise();
p.then(
  function(str, i) {
    console.log("received " + str + " and " + i);
  },
  function(ex) {
    console.log("failed: " + ex);
  });

try {
  // do something...
  p.succeed("string arg", 5);
}
catch(ex) {
  p.fail(ex);
}
```

The call to `succeed` resolves the promise and supplies two arguments that the promise passes to the success callback. Similarly, the call to `fail` passes along the exception caught by the caller.

As you can see, the success and fail callbacks typically must know what arguments to expect when the promise is resolved.

Chaining Promises

The convenience and power offered by the promise concept becomes clear when you need to execute a sequence of asynchronous actions. Consider this example:

JavaScript

```

var p = new Ice.Promise();
p.then(    // A
  function() {
    // Step 1...
  }
).then(    // B
  function() {
    // Step 2...
  }
).then(    // C
  function() {
    // Step 3...
  }
);

// None of this happens until...
p.succeed();

```

Each call to `then` returns a new promise that is automatically chained to the preceding one. The promise returned by `then` in A resolves when Step 1 completes. The successful completion of A causes Step 2 to execute, and the successful completion of Step 2 resolves the promise returned by `then` in B, triggering Step 3 to execute. Finally, the whole chain of events won't begin until the initial promise `p` resolves.

Handling Errors with Promises

Let's extend our previous example to include an error handler:

JavaScript

```

var p = new Ice.Promise();
p.then(    // A
  function() {
    // Step 1...
  }
).then(    // B
  function() {
    // Step 2...
  }
).exception(
  function(ex) {
    // handle errors
  }
);

```

Here we call the `exception(failureFn)` method to establish an exception handler at the end of the promise chain, which is equivalent to calling `then(undefined, failureFn)`. You'll notice that none of the intermediate steps defines its own failure callback, with the intention

that all errors will be handled in one location. After a call to `p.succeed` triggers execution of the chain, an exception raised by any of these steps propagates through each subsequent promise in the chain until a failure callback is found. If instead the application calls `p.fail`, none of the steps would execute and only the exception handler would be called.

Now let's examine the behavior when an intermediate step defines a failure callback:

JavaScript

```
var p = new Ice.Promise();
p.then(
  function() {
    console.log("step 1");
  },
  function() {
    console.log("fail 1");
  }
).then(
  function() {
    console.log("step 2");
  }
).exception(
  function(ex) {
    console.log("error");
  }
);
p.fail();

// Outputs:
fail 1
step 2
```

The results might surprise you at first. If a failure callback completes without raising an exception, the promise is considered to have resolved successfully and therefore triggers the success callback of the next promise in the chain. On the other hand, if a failure callback raises an exception, it will propagate to the next failure callback in the chain. This behavior allows a failure callback to recover from error situations (if possible) and continue with the normal logic flow, or raise an exception and skip to the next error handler.

If no failure callback is defined in a chain after the point at which an exception occurs, that exception will be silently ignored. For this reason, we always recommend terminating a chain with an exception handler. Furthermore, you should not let any uncaught exceptions be thrown from your final exception handler.

Next we'll illustrate this point by throwing an exception:

JavaScript

```
var p = new Ice.Promise();
p.then(
  function() {
    console.log("step 1");
  },
  function() {
    console.log("fail 1");
    throw new Error();
  }
).then(
  function() {
    console.log("step 2");
  }
).exception(
  function(ex) {
    console.log("error");
  }
);
p.fail();

// Outputs:
fail 1
error
```

Here you can see that the exception raised in the first failure callback bypasses Step 2 and triggers the final exception handler.

Passing Values between Promises

The promise implementation forwards any value returned by a success or failure callback to the next success callback in the chain, as shown below:

JavaScript

```

var p = new Ice.Promise();
p.then(
    function() {
        return "World!";
    }
).then(
    function(arg) {
        console.log("Hello " + arg);
    }
);
p.succeed();

// Outputs:
Hello World!

```

Chaining Asynchronous Events with Promises

Now that we've discussed promise fundamentals, let's explore more realistic use cases. The primary purpose of promises is chaining together a sequence of asynchronous events such that the next step in the chain won't execute until the previous step has completed. Common examples in Ice applications include a series of proxy invocations in which the calls must be made sequentially in a certain order, and proxy invocations in which the results of a preceding call must be obtained before the next call can be made.

Consider the following example:

JavaScript

```

var p = new Ice.Promise();
p.then(
    function() { // Step 1
        var promise = // do something that creates a promise...
        return promise;
    }
).then(
    function() { // Step 2
        var promise = // do something else that creates a promise...
        return promise;
    }
).then(
    function() { // Step 3
        console.log("all done");
    }
);

p.succeed();

```

Steps 1 and 2 each initiate some asynchronous action that creates a promise, and the steps return the promise object as the result of the

callback. Normally the result value would be passed as the argument to the next success callback in the chain, as we discussed earlier. However, when a callback returns a promise, execution of the next success or failure callback becomes dependent on the completion of the returned promise. In the example above, calling `p.succeed` causes Step 1 to execute, but Step 2 won't execute until the promise returned by Step 1 resolves successfully.

Promise API

Instances of `Ice.Promise` support the following methods:

- `then(successFn, failureFn)`
Executes the success function if this promise resolves successfully, or the failure function if this promise fails. `then` returns a new promise whose execution is dependent on the resolution of this promise. If either function argument is undefined, the success or failure status of this promise is passed to the next one in the chain. If a function is undefined and this is the last promise in the chain, the outcome is ignored.
- `exception(failureFn)`
A convenience method equivalent to calling `then(undefined, failureFn)`. `exception` returns a new promise whose execution is dependent on the resolution of this promise.
- `finally(fn)`
Executes the given function when this promise succeeds or fails. The callback function must be prepared to receive any arguments resulting from the success or failure of this promise. `finally` returns a new promise whose execution is dependent on the resolution of the previous promise in the chain (see example below). Exceptions raised by the given callback function will be ignored.
- `delay(ms)`
Returns a new promise whose success or failure callback is invoked after the specified delay (in milliseconds). The results of the previous promise in the chain are forwarded to the next promise in the chain, as if the delay promise was not present.
- `succeed([args])`
Resolves this promise successfully. Any arguments are passed to the success callback of the next promise in the chain. Returns a reference to this promise.
- `fail([args])`
Resolves this promise as failed. Any arguments are passed to the failure callback of the next promise in the chain. Returns a reference to this promise.
- `succeeded()`
Returns true if this promise succeeded, false otherwise.
- `failed()`
Returns true if this promise failed, false otherwise.
- `completed()`
Returns true if this promise has been resolved, false otherwise.

Additionally, the `Promise` type defines the following functions:

- `try(fn)`
Returns a new promise whose execution depends on the completion of the given function. This function allows you to write code similar to the traditional try/catch/finally blocks of synchronous code, as shown below:

JavaScript

```
Ice.Promise.try(
  function() {
    // perform asynchronous actions...

    // return a promise to the last action in the chain...
  }
).exception(
  function(ex) {
    // handle errors
  }
).finally(
  function() {
    // clean up when the last action completes
  }
);
```

The `try` function makes error handling especially convenient because the chained exception handler will be called if an exception is thrown directly by the `try` callback, or if the callback returns a promise that later fails. Note that you could also arrange the `exception` and `finally` blocks this way:

JavaScript

```
Ice.Promise.try(
  function() {
    // perform asynchronous actions...

    // return a promise to the last action in the chain...
  }
).finally(
  function() {
    // clean up when the last action completes
  }
).exception(
  function(ex) {
    // handle errors
  }
);
```

If the `try` callback fails with an exception, the `finally` callback will be invoked and the failure will propagate to the `exception` callback. Of course, the order in which the callbacks are invoked in an error situation differs from the previous example.

- `all(promise1[, promise2, ...])`
Returns a new promise whose execution depends on the completion of all given promises. The promise arguments can be specified individually or supplied as a single array, meaning `all(p1, p2, p3)` is equivalent to `all([p1, p2, p3])`. The returned promise resolves successfully if all of the given promises resolve successfully, and the returned promise fails if any of the given promises fails. In the case that all of the given promises succeed, the result values from each promise's success function are passed as arguments to the success callback of the returned promise in the same order. Here is an example:

JavaScript

```
function asyncAction() {
    // returns a promise...
}

Ice.Promise.all(
    asyncAction(), // Action 1
    asyncAction(), // Action 2
    asyncAction() // Action 3
).then(
    function(results1, results2, results3) {
        // Each argument is an array containing the results of the
        // corresponding action
    }
).exception(
    function(ex) {
        // handle errors
    }
);
```

The success function of the promise returned by `all` does not execute until all of the promise arguments resolve successfully, at which time their results are passed as arguments to the success function. Each result argument is an array containing the results (if any) of the corresponding action's promise.

- `delay([args...,] ms)`
 Similar to the prototype method described earlier, this function returns a promise whose success callback is invoked after the specified delay (in milliseconds). One difference between this function and the prototype method is the delay value must be the last argument, with any preceding arguments passed to the success callback:

JavaScript

```
Ice.Promise.delay("John", 100).then(
    function(name) { // Invoked after 100ms
        console.log("Hi " + name);
    },
    ...
);
```

Completion Callbacks in JavaScript

The `AsyncResult` promise returned by a proxy invocation resolves when the remote operation completes successfully or fails. The semantics of the success and failure functions depend on the proxy's invocation mode:

- **Tway proxies**
 The success or failure function executes after the Ice run time in the client receives a reply from the server.
- **Oneway and datagram proxies**
 The success function executes after the Ice run time passes the message off to the socket. The failure function will only be called if an error occurs while Ice is attempting to marshal or send the message.

- Batch proxies

The success function executes after the Ice run time queues the request. The failure function will only be called if an error occurs while Ice is attempting to marshal the message.

For all asynchronous Ice APIs, the failure function receives two arguments: the exception that caused the failure, and a reference to the `AsyncResult` promise for the failed invocation.

The success callback parameters depend on the operation signature. If the operation has non-void return type, the first parameter of the success callback is the return value. The return value (if any) is followed by a parameter for each out-parameter of the corresponding Slice operation, in the order of declaration. Ice adds a reference to the `AsyncResult` object associated with the request as the final parameter to every success callback. Recall the example we showed earlier:

Slice

```
double op(int inp1, string inp2, out bool outp1, out long outp2);
```

The success callback for `op` must have the following signature:

JavaScript

```
function handleSuccess(returnVal, outp1, outp2, asyncResult)
```

You can omit the `asyncResult` parameter if your function has no use for it.

The failure callback is invoked if the invocation fails because of an Ice run time or user exception. This callback function must have the following signature:

JavaScript

```
function handleAnException(ex, asyncResult)
```

Again, you can omit the `asyncResult` parameter if your function has no use for it.

For example, the code below shows how to invoke the `getName` operation:

JavaScript

```

var proxy = ...;
var empNo = ...;
proxy.getName(empNo).then(
    function(name, asyncResult) {
        console.log("Name of employee #" + empNo + " is " + name);
    }
).exception(
    function(ex, asyncResult) {
        console.log("Failed to get name of employee #" + empNo);
        console.log(ex);
    }
);

```

Let's extend the example add a call to `getAddress`:

JavaScript

```

var proxy = ...;
var empNo = ...;
proxy.getName(empNo).then(
    function(name, asyncResult) {
        console.log("Name of employee #" + empNo + " is " + name);
        return proxy.getAddress(empNo);
    }
).then(
    function(addr, asyncResult) {
        console.log("Address of employee #" + empNo + " is " + addr);
    }
).exception(
    function(ex, asyncResult) {
        console.log(asyncResult.operation + " failed for employee #" +
empNo);
        console.log(ex);
    }
);

```

Notice here that the success callback for `getName` returns the `AsyncResult` promise for `getAddress`, which means the second success callback won't be invoked until `getAddress` completes.

Asynchronous Oneway Invocations in JavaScript

You can invoke operations via oneway proxies asynchronously, provided the operation has `void` return type, does not have any out-parameters, and does not raise user exceptions. If you call the proxy function on a oneway proxy for an operation that returns values or raises a user exception, the proxy function throws an instance of `Error`.

The callback functions look exactly as for a twoway invocation. The failure function is only called if the invocation raised an exception during the proxy function ("on the way out"), and the success function is called as soon as the message is accepted by the local network connection. The success function takes a single argument representing the `AsyncResult` associated with the request.

Asynchronous Batch Requests in JavaScript

Applications that send [batched requests](#) can either flush a batch explicitly or allow the Ice run time to flush automatically. The asynchronous proxy method `ice_flushBatchRequests` initiates an immediate flush of any batch requests queued by that proxy.

In addition, similar methods are available on the communicator and the `Connection` object that is accessible via the `connection` property of `AsyncResult`. These methods flush batch requests sent via the same communicator and via the same connection, respectively.

All versions of `ice_flushBatchRequests` return a promise whose success callback executes as soon as the batch request message is accepted by the local network connection. The success function takes a single argument representing the `AsyncResult` associated with the flush request. Ice only invokes the failure callback if an error occurs while attempting to send the message.

JavaScript Mapping for Classes

On this page:

- [Basic JavaScript Mapping for Classes](#)
- [Inheritance from Ice.Object in JavaScript](#)
- [Class Constructors in JavaScript](#)
- [Class Data Members in JavaScript](#)
- [Class Operations in JavaScript](#)
- [Class Factories in JavaScript](#)

Basic JavaScript Mapping for Classes

A Slice `class` is mapped to a JavaScript type with the same name. For each Slice data member, the JavaScript instance contains a corresponding property (just as for structures and exceptions). Consider the following class definition:

Slice
<pre>class TimeOfDay { short hour; // 0 - 23 short minute; // 0 - 59 short second; // 0 - 59 string format(); // Return time as hh:mm:ss };</pre>

The Slice compiler generates the following code for this definition:

JavaScript
<pre>TimeOfDay = function(hour, minute, second) { ... } TimeOfDay.prototype = new Ice.Object(); TimeOfDay.prototype.constructor = TimeOfDay; // Nothing generated for format()...</pre>

There are a number of things to note about the generated code:

1. The prototype for generated type `TimeOfDay` inherits from `Ice.Object`. This means that all Slice classes implicitly inherit from `Ice.Object`, which is the ultimate ancestor of all classes. Note that `Ice.Object` is *not* the same as `Ice.ObjectPrx`. In other words, you *cannot* pass a class where a proxy is expected and vice versa.
2. The generated type provides a constructor that accepts a value for each data member.
3. The generated type defines a property for each Slice data member.
4. The generated type's prototype does not include any definitions for the class' operations.

There is quite a bit to discuss here, so we will look at each item in turn.

Inheritance from `Ice.Object` in JavaScript

As for Slice interfaces, the generated type for a Slice class implicitly inherits from a common base type, `Ice.Object`. However, as shown in the illustration below, the types inherit from `Ice.Object` instead of `Ice.ObjectPrx` (which is at the base of the inheritance hierarchy for proxies). As a result, you cannot pass a class where a proxy is expected (and vice versa) because the base types for classes and proxies are not compatible.

Inheritance from `Ice.ObjectPrx` and `Ice.Object`.

`Ice.Object` defines a number of member functions:

JavaScript

```

Object.prototype.ice_isA = function(s, current) { ... }
Object.prototype.ice_ping = function(current) { }
Object.prototype.ice_ids = function(current) { ... }
Object.prototype.ice_id = function(current) { ... }
Object.prototype.ice_preMarshal = function() { }
Object.prototype.ice_postMarshal = function() { }
  
```

The member functions of `Ice.Object` behave as follows:

- `ice_isA`
This function returns `true` if the object supports the given `type ID`, and `false` otherwise.
- `ice_ping`
As for interfaces, `ice_ping` provides a basic reachability test for the class.
- `ice_ids`
This function returns a string sequence representing all of the `type IDs` supported by this object, including `::Ice::Object`.
- `ice_id`
This function returns the actual run-time `type ID` for a class. If you call `ice_id` through a reference to a base instance, the returned `type ID` is the actual (possibly more derived) `type ID` of the instance.
- `ice_preMarshal`
The Ice run time invokes this function prior to marshaling the object's state, providing the opportunity for a subtype to validate its declared data members.
- `ice_postUnmarshal`
The Ice run time invokes this function after unmarshaling an object's state. A subtype typically overrides this function when it needs to perform additional initialization using the values of its declared data members.

Class Constructors in JavaScript

The type generated for a Slice class provides a constructor that initializes each data member to a default value appropriate for its type:

Data Member Type	Default Value
<code>string</code>	Empty string
<code>enum</code>	First enumerator in enumeration
<code>struct</code>	Default-constructed value
Numeric	Zero

bool	False
sequence	Null
dictionary	Null
class/interface	Null

If you wish to ensure that data members of primitive and enumerated types are initialized to specific values, you can declare default values in your [Slice definition](#). The constructor initializes each of these data members to its declared value instead.

The constructor accepts one argument for each member of the class. This allows you to create and initialize an instance in a single statement, for example:

JavaScript

```
var tod = new TimeOfDayI(14, 45, 00); // 14:45pm
```

For derived classes, the constructor requires an argument for every member of the class, including inherited members. For example, consider the the definition from [Class Inheritance](#) once more:

Slice

```
class TimeOfDay {
    short hour;           // 0 - 23
    short minute;        // 0 - 59
    short second;        // 0 - 59
};

class DateTime extends TimeOfDay {
    short day;           // 1 - 31
    short month;         // 1 - 12
    short year;          // 1753 onwards
};
```

The constructors generated for these classes are similar to the following:

JavaScript

```

var TimeOfDay = function(hour, minute, second)
{
    this.hour = hour;
    this.minute = minute;
    this.second = second;
};

var DateTime = function(hour, minute, second, day, month, year)
{
    TimeOfDay.call(this, hour, minute, second);
    this.day = day;
    this.month = month;
    this.year = year;
};

```

Pass `undefined` as the value of any [optional data member](#) that you wish to remain unset.

Class Data Members in JavaScript

By default, data members of classes are mapped exactly as for structures and exceptions: for each data member in the Slice definition, the generated type defines a corresponding property.

[Optional data members](#) use the same mapping as required data members, but an optional data member can also be set to `undefined` to indicate that the member is unset. A well-behaved program must compare an optional data member to `undefined` before using the member's value:

JavaScript

```

var v = ...
if(v.optionalMember === undefined)
    console.log("optionalMember is unset")
else
    console.log("optionalMember =", v.optionalMember)

```

Class Operations in JavaScript

Operations of classes are mapped to methods in the generated type. This means that, if a class contains operations (such as the `format` operation of our `TimeOfDay` class), you must provide an implementation of those operations in a type that is derived from the generated type. For example:

JavaScript

```

var TimeOfDayI = function(hour, minute, second)
{
    TimeOfDay.call(this, hour, minute, second);
};
TimeOfDayI.prototype = new TimeOfDay();
TimeOfDayI.prototype.constructor = TimeOfDayI;

TimeOfDayI.prototype.format = function(current)
{
    var result = "";
    result += (this.hour < 10) ? "0" + this.hour : this.hour;
    result += ":";
    result += (this.minute < 10) ? "0" + this.minute : this.minute;
    result += ":";
    result += (this.second < 10) ? "0" + this.second : this.second;
    return result;
};

```

Note that Ice provides an equivalent but much more compact way of defining class implementations:

JavaScript

```

var TimeOfDayI = Ice.Class(TimeOfDay, {
    format: function(current) { ... }
});

```

The `Ice.Class` constructor function creates a new type, establishes the prototype relationship (if a base type is specified), and adds each defined method to the new type's prototype.

Class Factories in JavaScript

Having created a type such as `TimeOfDayI`, we have an implementation and we can instantiate `TimeOfDayI` objects, but we cannot receive it as the return value or as an out-parameter from an operation invocation. To see why, consider the following simple interface:

Slice

```

interface Time {
    TimeOfDay get();
};

```

When a client invokes the `get` operation, the Ice run time must instantiate and return an instance of `TimeOfDay`. However, `TimeOfDay` is conceptually an abstract type because it declares operations and therefore it cannot be instantiated. Unless we tell it, the Ice run time cannot

magically know that we have created a `TimeOfDayI` type that implements the abstract `format` operation of the `TimeOfDay` abstract type. In other words, we must provide the Ice run time with a factory that knows that the `TimeOfDay` abstract type has a `TimeOfDayI` concrete implementation. The `Ice::Communicator` interface provides us with the necessary operations:

Slice

```

module Ice {
    local interface ObjectFactory {
        Object create(string type);
        void destroy();
    };

    local interface Communicator {
        void addObjectFactory(ObjectFactory factory, string id);
        ObjectFactory findObjectFactory(string id);
        // ...
    };
};

```

To supply the Ice run time with a factory for our `TimeOfDayI` type, we must define an object that implements the `create` and `destroy` methods:

JavaScript

```

var factory = {
    create: function(type)
    {
        if(type === TimeOfDay.ice_staticId())
        {
            return new TimeOfDayI();
        }
        return null;
    },
    destroy: function()
    {
        // Nothing to do
    }
};

```

The factory's `create` function is called by the Ice run time when it needs to create a `TimeOfDay` instance. The factory's `destroy` function is called by the Ice run time when its communicator is destroyed.

The `create` function is passed the `type ID` of the class to instantiate. For our `TimeOfDay` class, the type ID is `"::M::TimeOfDay"`. Our implementation of `create` checks the type ID: if it matches, the function instantiates and returns a `TimeOfDayI` object. For other type IDs, the function returns null because it does not know how to instantiate other types of objects.

Note that we used the `ice_staticId` function to obtain the type ID rather than embedding a literal string. Using a literal type ID string in your code is discouraged because it can lead to errors that are only detected at run time. For example, if a `Slice` class or one of its enclosing modules is renamed and the literal string is not changed accordingly, a receiver will fail to unmarshal the object and the Ice run time will raise `NoObjectFactoryException`. By using `ice_staticId` instead, we avoid any risk of a misspelled or obsolete type ID, and we can more easily discover whether a `Slice` class or module has been renamed.

Given a factory implementation, such as the one above, we must inform the Ice run time of the existence of the factory:

JavaScript

```
var communicator = ...;  
communicator.addObjectFactory(factory, TimeOfDay.ice_staticId());
```

Now, whenever the Ice run time needs to instantiate an object with the type ID `"::M::TimeOfDay"`, it calls the `create` function of the registered factory.

The `destroy` operation of the object factory is invoked by the Ice run time when the communicator is destroyed. This gives you a chance to clean up any resources that may be used by your factory. Do not call `destroy` on the factory while it is registered with the communicator — if you do, the Ice run time has no idea that this has happened and, depending on what your `destroy` implementation is doing, may cause undefined behavior when the Ice run time tries to next use the factory.

The run time guarantees that `destroy` will be the last call made on the factory, that is, `create` will not be called once `destroy` has been called.

Note that you cannot register a factory for the same type ID twice: if you call `addObjectFactory` with a type ID for which a factory is registered, the Ice run time throws an `AlreadyRegisteredException`.

Finally, keep in mind that if a Slice class has only data members, but no operations, you need not create and register an object factory to transmit instances of such a class. Only if a class has operations do you have to define and register an object factory.

slice2js Command-Line Options

The Slice-to-JavaScript compiler, `slice2js`, offers the following command-line options in addition to the [standard options](#):

- `--stdout`
Print generated code to standard output.
- `--depend-json`
Print dependency information in JSON format to standard output by default, or to the file specified by the `--depend-file` option. No code is generated when this option is specified. The output consists of the complete list of Slice files that the input Slice files depend on through direct or indirect inclusion.

Server-Side Slice-to-JavaScript Mapping

The mapping for Slice data types to JavaScript is identical on the client side and server side. This means that everything in [Client-Side Slice-to-JavaScript Mapping](#) also applies to the server side. However, for the server side, there are a few additional things you need to know — specifically how to:

- Initialize and finalize the server-side run time
- Implement servants
- Pass parameters and throw exceptions
- Create servants and register them with the Ice run time

Because the mapping for Slice data types is identical for clients and servers, the server-side mapping only adds a few additional mechanisms to the client side: a small API to initialize and finalize the run time, plus a few rules for how to derive servant classes from skeletons and how to register servants with the server-side run time.

Although the examples we present are very simple, they accurately reflect the basics of writing an Ice server. Of course, for more sophisticated servers, you will be using [additional APIs](#), for example, to improve performance or scalability. However, these APIs are all described in [Slice](#), so, to use these APIs, you need not learn any JavaScript mapping rules beyond those we described here.

Support for server-side activities in Ice for JavaScript is currently limited to callbacks over [bidirectional connections](#), which allows a JavaScript client to receive "push notifications" from a server. In this section, we describe the server-related activities of a JavaScript client.

Server-Side JavaScript Mapping for Interfaces

The server-side mapping for interfaces provides an up-call API for the Ice run time: by implementing member functions in a servant class, you provide the hook that gets control flow from the Ice server-side run time into your application code.

On this page:

- [Skeleton Types in JavaScript](#)
- [Servant Types in JavaScript](#)
 - [Normal and idempotent Operations in JavaScript](#)

Skeleton Types in JavaScript

On the client side, interfaces map to [proxy types](#). On the server side, interfaces map to *skeleton* types. A skeleton is a type that conceptually has an abstract member function for each operation on the corresponding interface. For example, consider our [Slice definition](#) for the `Node` interface:

```

Slice

module Filesystem {
    interface Node {
        idempotent string name();
    };
    // ...
};

```

The Slice compiler generates the following definition for this interface:

```

JavaScript

Filesystem.Node = function() { ... };
Filesystem.Node.prototype = new Ice.Object();
Filesystem.Node.prototype.constructor = Filesystem.Node;
// Mapping-internal code here...

```

The important points to note here are:

- As for the client side, Slice modules are mapped to JavaScript scopes with the same name, so the skeleton definitions are part of the `Filesystem` scope.
- For each Slice interface `<interface-name>`, the compiler generates a JavaScript type `<interface-name>` (`Node` in this example). This type extends `Ice.Object` and serves as the actual skeleton; it is the base type from which you derive your servant implementation.

Servant Types in JavaScript

In order to provide an implementation for an Ice object, you must create a servant type that inherits from the corresponding skeleton. For example, to create a servant for the `Node` interface, you could write:

JavaScript

```
var NodeI = Ice.Class(Filesystem.Node, {
  __init__: function(name) {
    this._name = name;
  },
  name: function(current) {
    return this._name;
  }
});
```

By convention, servant types have the name of their interface with an `I`-suffix, so the servant type for the `Node` interface is called `NodeI`. (This is a convention only: as far as the Ice run time is concerned, you can choose any name you prefer for your servant types.) Note that `NodeI` extends `Filesystem.Node`, that is, it derives from its skeleton.

Here we're using the `Ice.Class` convenience function to define our servant. This function establishes the necessary prototype relationship with the given base type and adds a method to the new type's prototype for each property in the supplied object. The value of the `__init__` property (if defined) becomes the new type's constructor.

As far as Ice is concerned, the `NodeI` type must implement only a single function: the `name` method defined by the Slice interface. You can add other methods and data members as you see fit to support your implementation. For example, in the preceding definition, we added a `_name` member and a constructor. (Obviously, the constructor initializes the `_name` member and the `name` method returns its value.) You can ignore the `current` parameter for now.

Normal and idempotent Operations in JavaScript

Whether an operation is an ordinary operation or an `idempotent` operation has no influence on the way the operation is mapped. To illustrate this, consider the following interface:

Slice

```
interface Example {
    void    normalOp();
    idempotent void    idempotentOp();
    idempotent string readonlyOp();
};
```

The corresponding servant methods look like this:

JavaScript

```
var ExampleI = Ice.Class(Example, {
  normalOp:    function(current) { ... },
  idempotentOp: function(current) { ... },
  readonlyOp:  function(current) { ... }
});
```

Note that the signatures of the member functions are unaffected by the `idempotent` qualifier.

Parameter Passing in JavaScript

On this page:

- [Server-Side Parameters in JavaScript](#)

Server-Side Parameters in JavaScript

For each parameter of a Slice operation, the JavaScript mapping generates a corresponding parameter for the method in the servant. In addition, every operation has an additional, trailing parameter of type `Ice.Current`. For example, the `name` operation of the `Node` interface has no parameters, but the `name` method of the servant has a single parameter of type `Ice.Current`. We will ignore this parameter for now.

For a Slice operation that returns multiple values, the implementation returns them in an array consisting of a non-void return value, if any, followed by the `out` parameters in the order of declaration. An operation returning only one value simply returns the value itself.

An operation returns multiple values when it declares multiple `out` parameters, or when it declares a non-void return type and at least one `out` parameter.

To illustrate the rules, consider the following interface that passes string parameters in all possible directions:

Slice

```

module M {
  interface Example {
    string op1(string sin);
    void op2(string sin, out string sout);
    string op3(string sin, out string sout);
  };
};

```

The servant methods would look as follows:

JavaScript

```

var ExampleI = Ice.Class(M.Example, {
  op1: function(sin, current) { ... },
  op2: function(sin, current) { ... },
  op3: function(sin, current) { ... }
});

```

The signatures of the JavaScript methods are identical because they all accept a single `in` parameter, but their implementations differ in the way they return values. For example, we could implement the operations as follows:

JavaScript

```

var ExampleI = Ice.Class(M.Example, {
  op1: function(sin, current) {
    console.log(sin); // In params are initialized
    return "Done";    // Return value
  },
  op2: function(sin, current) {
    console.log(sin); // In params are initialized
    return "Hello World!"; // Out parameter
  },
  op3: function(sin, current) {
    console.log(sin); // In params are initialized
    return ["Done", "Hello World!"];
  }
});

```

Notice that `op1` and `op2` return their string values directly, whereas `op3` returns an array consisting of the return value followed by the `out` parameter.

This code is in no way different from what you would normally write if you were to pass strings to and from a function; the fact that remote procedure calls are involved does not impact on your code in any way. The same is true for parameters of other types, such as proxies, classes, or dictionaries: the parameter passing conventions follow normal JavaScript rules and do not require special-purpose API calls.

See Also

- [Server-Side JavaScript Mapping for Interfaces](#)
- [Raising Exceptions in JavaScript](#)
- [The Current Object](#)

Raising Exceptions in JavaScript

To throw an exception from an operation implementation, you simply instantiate the exception, initialize it, and throw it. For example:

```

JavaScript

```

// ...
write: function(text, current) {
 try {
 // Try to write file contents here...
 }
 catch(err) {
 var ex = new GenericError("Exception during write
operation");
 ex.ice_cause = err; // Not returned to client but may be
useful
 throw ex;
 }
}

```

```

If you throw an arbitrary JavaScript error (such as an instance of `Error`), the Ice run time catches the exception and then returns an `UnknownException` to the client. Similarly, if you throw an "impossible" user exception (a user exception that is not listed in the exception specification of the operation), the client receives an `UnknownUserException`.

If you throw an Ice run-time exception, such as `MemoryLimitException`, the client receives an `UnknownLocalException`. For that reason, you should never throw system exceptions from operation implementations. If you do, all the client will see is an `UnknownLocalException`, which does not tell the client anything useful.

Three run-time exceptions are [treated specially](#) and not changed to `UnknownLocalException` when returned to the client: `ObjectNotExistException`, `OperationNotExistException`, and `FacetNotExistException`.

Object Incarnation in JavaScript

Having created a servant such as the rudimentary `NodeI` type, you can instantiate the type to create a concrete servant that can receive invocations from a client. However, merely instantiating a servant is insufficient to incarnate an object. Specifically, to provide an implementation of an Ice object, you must take the following steps:

1. Instantiate a servant class.
2. Create an identity for the Ice object incarnated by the servant.
3. Inform the Ice run time of the existence of the servant.
4. Pass a proxy for the object to a client so the client can reach it.

On this page:

- [Instantiating a JavaScript Servant](#)
- [Creating an Identity in JavaScript](#)
- [Activating a JavaScript Servant](#)
- [UUIDs as Identities in JavaScript](#)
- [Creating Proxies in JavaScript](#)
 - [Proxies and Servant Activation in JavaScript](#)
 - [Direct Proxy Creation in JavaScript](#)

Instantiating a JavaScript Servant

Instantiating a servant means to allocate an instance:

```

JavaScript

var servant = new NodeI("Fred");
```

This code creates a new `NodeI` instance.

Creating an Identity in JavaScript

Each Ice object requires an identity. That identity must be unique for all servants using the same object adapter.

```

The Ice object model assumes that all objects (regardless of their adapter) have a globally unique identity.
```

An Ice object identity is a structure with the following Slice definition:

```

Slice

module Ice {
  struct Identity {
    string name;
    string category;
  };
  // ...
};
```

The full identity of an object is the combination of both the `name` and `category` fields of the `Identity` structure. For now, we will leave the `category` field as the empty string and simply use the `name` field. (The `category` field is most often used in conjunction with [servant locators](#).)

To create an identity, we simply assign a key that identifies the servant to the `name` field of the `Identity` structure:

JavaScript

```
var id = new Ice.Identity();
id.name = "Fred"; // Not unique, but good enough for now
```

Activating a JavaScript Servant

Merely creating a servant instance does nothing: the Ice run time becomes aware of the existence of a servant only once you explicitly tell the object adapter about the servant. To activate a servant, you invoke the `add` operation on the object adapter. Assuming that we have access to the object adapter in the `_adapter` variable, we can write:

JavaScript

```
this._adapter.add(servant, id);
```

Note the two arguments to `add`: the servant and the object identity. Calling `add` on the object adapter adds the servant and the servant's identity to the adapter's servant map and links the proxy for an Ice object to the correct servant instance in the server's memory as follows:

1. The proxy for an Ice object, apart from addressing information, contains the identity of the Ice object. When a client invokes an operation, the object identity is sent with the request to the server.
2. The object adapter receives the request, retrieves the identity, and uses the identity as an index into the servant map.
3. If a servant with that identity is active, the object adapter retrieves the servant from the servant map and dispatches the incoming request into the correct member function on the servant.

Assuming that the object adapter is in the [active state](#), client requests are dispatched to the servant as soon as you call `add`.

UUIDs as Identities in JavaScript

The Ice object model assumes that object identities are globally unique. One way of ensuring that uniqueness is to use UUIDs (Universally Unique Identifiers) as identities. Ice for JavaScript provides a helper function that we can use to create such identities:

JavaScript

```
var uuid = Ice.generateUUID();
console.log(uuid);
```

When executed, this code prints a unique string such as `5029a22c-e333-4f87-86b1-cd5e0f0ce509`. Each call to `generateUUID` creates a string that differs from all previous ones.

You can use a UUID such as this to create object identities. For convenience, the object adapter has an operation `addWithUUID` that generates a UUID and adds a servant to the servant map in a single step. Using this operation, we can create an identity and register a servant with that identity in a single step as follows:

JavaScript

```
this._adapter.addWithUUID(new NodeI("Fred"));
```

Creating Proxies in JavaScript

Once we have activated a servant for an Ice object, the server can process incoming client requests for that object. However, clients can only access the object once they hold a proxy for the object.

At present, Ice for JavaScript only supports server-side activity over [bidirectional connections](#). There are two ways of using bidirectional connections:

- In conjunction with a [Glacier2 router](#), which requires very little additional code in the client aside from ensuring that the object adapter is correctly configured to use the router. This is the simplest and most common way of employing bidirectional connections.
- [Manually configuring a connection](#) for bidirectional use.

The remaining discussion in this section applies when using a Glacier2 router.

Proxies and Servant Activation in JavaScript

The `add` and `addWithUUID` servant activation operations on the object adapter return a proxy for the corresponding Ice object. This means we can write:

```

JavaScript

var proxy = NodePrx.uncheckedCast(this._adapter.addWithUUID(new
NodeI("Fred")));
```

Here, `addWithUUID` both activates the servant and returns a proxy for the Ice object incarnated by that servant in a single step.

Note that we need to use an `uncheckedCast` here because `addWithUUID` returns a proxy of type `Ice.ObjectPrx`.

Direct Proxy Creation in JavaScript

The object adapter offers an operation to create a proxy for a given identity:

```

Slice

module Ice {
  local interface ObjectAdapter {
    Object* createProxy(Identity id);
    // ...
  };
};
```

Note that `createProxy` creates a proxy for a given identity whether a servant is activated with that identity or not. In other words, proxies have a life cycle that is quite independent from the life cycle of servants:

```

JavaScript

var id = new Ice.Identity();
id.name = Ice.generateUUID();
var o = this._adapter.createProxy(id);
```

This creates a proxy for an Ice object with the identity returned by `generateUUID`. Obviously, no servant yet exists for that object so, if we return the proxy to a peer and the peer invokes an operation on the proxy, the peer will receive an `ObjectNotExistException`. (We examine these life cycle issues in more detail in [Object Life Cycle](#).)

Asynchronous Method Dispatch (AMD) in JavaScript

JavaScript is single-threaded, therefore it is very important to consider how servant implementation decisions affect the overall application. In a JavaScript program with a graphical user interface, spending too much time in the implementation of a Slice operation can delay the processing of UI events and adversely impact the user experience.

Asynchronous Method Dispatch (AMD), the server-side equivalent of *AMI*, allows a server to receive a request but then suspend its processing. When processing resumes and the results are available, the server sends a response explicitly using a callback object provided by the Ice run time.

AMD is transparent to the client, that is, there is no way for a client to distinguish a request that, in the server, is processed synchronously from a request that is processed asynchronously.

One use case that requires AMD is nested invocations. Since all [outgoing invocations](#) have asynchronous semantics, an operation implementation whose results depend on the outcome of a nested invocation must postpone its response until the nested invocation completes.

An alternate use case for AMD is an operation that requires further processing after completing the client's request. In order to minimize the client's delay, the operation returns the results and then continues to perform additional work.

On this page:

- [Enabling AMD with Metadata in JavaScript](#)
- [AMD Mapping in JavaScript](#)
 - [Callback object for AMD](#)
 - [Servant method for AMD](#)
- [AMD Exceptions in JavaScript](#)
- [AMD Example in JavaScript](#)

Enabling AMD with Metadata in JavaScript

To enable asynchronous dispatch, you must add an ["amd"] metadata directive to your Slice definitions. The directive applies at the interface and the operation level. If you specify ["amd"] at the interface level, all operations in that interface use asynchronous dispatch; if you specify ["amd"] for an individual operation, only that operation uses asynchronous dispatch. In either case, the metadata directive *replaces* synchronous dispatch, that is, a particular operation implementation must use synchronous or asynchronous dispatch and cannot use both.

Consider the following Slice definitions:

Slice

```
["amd"] interface I {
    bool isValid();
    float computeRate();
};

interface J {
    ["amd"] void startProcess();
    int endProcess();
};
```

In this example, both operations of interface `I` use asynchronous dispatch, whereas, for interface `J`, `startProcess` uses asynchronous dispatch and `endProcess` uses synchronous dispatch.

Specifying metadata at the operation level (rather than at the interface or class level) minimizes complexity: although the asynchronous model is more flexible, it is also more complicated to use. It is therefore in your best interest to limit the use of the asynchronous model to those operations that need it, while using the simpler synchronous model for the rest.

AMD Mapping in JavaScript

The AMD mapping differs from the default synchronous model in two ways:

1. A callback object is passed as the first argument to a servant method
2. The name of the servant method requires an `_async` prefix

Callback object for AMD

A servant method receives a callback object that it uses to notify the Ice run time about the completion of an operation. The object defines two methods:

JavaScript

```
function ice_response(<params>)
function ice_exception(ex)
```

The `ice_response` function allows the server to report the successful completion of the operation. If the operation's Slice definition has a non-void return type, the first parameter to `ice_response` is the return value. Parameters corresponding to the operation's out-parameters follow the return value, in the order of declaration.

The `ice_exception` function allows the server to raise an exception. The Ice run time [validates](#) the exception value using the same semantics as for synchronous dispatch.

Neither `ice_response` nor `ice_exception` throws any exceptions to the caller.

Servant method for AMD

The servant method, whose name has the suffix `_async`, always has a `void` return type. The first parameter is the callback object described above. The remaining parameters comprise the in-parameters of the operation, in the order of declaration.

For example, suppose we have defined the following operation:

Slice

```
interface I {
  ["amd"] int foo(short s, out long l);
};
```

The callback object's `ice_response` method has the signature shown below:

JavaScript

```
function ice_response(retval, l)
```

The servant method for asynchronous invocation of operation `foo` would have this signature:

JavaScript

```
foo_async: function(cb, s) { ... };
```

AMD Exceptions in JavaScript

There are two processing contexts in which the logical implementation of an AMD operation may need to report an exception: the dispatch context (the call sequence that invokes the servant method), and the response context (the call sequence that sends the response).

These are not necessarily two different contexts: it is legal to send the response from the dispatch context.

Although we recommend that the callback object be used to report all exceptions to the client, it is legal for the implementation to raise an exception instead, but only from the dispatch context.

As you would expect, an exception raised from a response context cannot be caught by the Ice run time; the application's run time environment determines how such an exception is handled. Therefore, a response context must ensure that it traps all exceptions and sends the appropriate response using the callback object. Otherwise, if a response context is terminated by an uncaught exception, the request may never be completed and the client might wait indefinitely for a response.

Whether raised in a dispatch context or reported via the callback object, user exceptions are [validated](#) and local exceptions may undergo [translation](#).

AMD Example in JavaScript

To demonstrate the use of AMD in Ice, consider an operation that must make a nested invocation:

Slice

```

module Demo {

    exception RequestFailed {
        string reason;
    };

    interface TaxManager {
        float computeTax(float amount)
            throws RequestFailed;
    };

    interface ShoppingCart {
        ["amd"] float computeTotal()
            throws RequestFailed;
    };
};

```

In this over-simplified example, a shopping cart object must query a tax manager object in order to compute the total amount owed by the customer.

Our servant class derives from `Demo.ShoppingCart` and supplies a definition for the `computeTotal_async` method:

JavaScript

```

var ShoppingCartI = Ice.Class(Demo.ShoppingCart, {
  __init__: function() {
    this._subtotal = 0.0;
  },
  computeTotal_async: function(cb, current) {
    var taxManager = ... // get TaxManager proxy
    var subtotal = this._subtotal;
    taxManager.computeTax(subtotal).then(
      function(tax) {
        cb.ice_response(subtotal + tax);
      },
      function(ex) {
        if(ex instanceof Demo.RequestFailed)
          cb.ice_exception(ex); // Relay RequestFailed
        exception from computeTax
        else
          cb.ice_exception(new Demo.RequestFailed("failed: " +
            ex.toString()));
      });
  }
});

```

The implementation of `computeTotal_async` makes a nested invocation of `computeTax`. The success and failure callbacks use the AMD callback object to complete the invocation of the `computeTotal` operation.

Client-Side Slice-to-Objective-C Mapping

The client-side Slice-to-Objective-C mapping defines how Slice data types are translated to Objective-C types, and how clients invoke operations, pass parameters, and handle errors. Much of the Objective-C mapping is intuitive. For example, Slice dictionaries map to Cocoa framework dictionaries, so there is little new you have to learn in order to use Slice dictionaries in Objective-C.

The Objective-C mapping is thread-safe. For example, you can concurrently invoke operations on an object from different threads without the risk of race conditions or corrupting data structures in the Ice run time, but you must still synchronize access to application data from different threads. For example, if you have two threads sharing a sequence, you cannot safely have one thread insert into the sequence while another thread is iterating over the sequence. However, you only need to concern yourself with concurrent access to your own data — the Ice run time itself is fully thread safe, and none of the Ice API calls require you to acquire or release a lock before you safely can make the call.

Much of what appears in this chapter is reference material. We suggest that you skim the material on the initial reading and refer back to specific sections as needed. However, we recommend that you read at least the mappings for [exceptions](#), [interfaces](#), and [operations](#) in detail because these sections cover how to call operations from a client, pass parameters, and handle exceptions.

In order to use the Objective-C mapping, you should need no more than the Slice definition of your application and knowledge of the Objective-C mapping rules. In particular, looking through the generated code in order to discern how to use the Objective-C mapping is likely to be confusing because the generated code is not necessarily meant for human consumption and, occasionally, contains various cryptic constructs to deal with mapping internals. Of course, occasionally, you may want to refer to the generated code to confirm a detail of the mapping, but we recommend that you otherwise use the material presented here to see how to write your client-side code.

ICE, ICEMX, GLACIER2, ICESTORM, ICEGRID Prefixes

All of the APIs for the Ice run time are prefixed by `ICE`, to avoid clashes with definitions for other libraries or applications. Parts of the Ice API are generated from Slice definitions; other parts provide special-purpose definitions that do not have a corresponding Slice definition. Regardless of the way they are defined, the `ICE` prefix universally applies to all entry points in the Ice run time. We will incrementally cover the contents of the Ice API throughout the remainder of the manual.

The APIs for IceMX, Glacier2, IceStorm and IceGrid are also prefixed with respectively ICEMX, GLACIER2, ICESTORM and ICEGRID.

Objective-C Mapping for Modules

Because Objective-C does not support namespaces, a Slice module maps to a prefix for the identifiers defined inside the modules. By default, the prefix is the same as the name of the module:

Slice
<pre>module example { enum Color { Red, Green, Blue }; };</pre>

With this definition, the Slice identifier `Color` maps to the Objective-C identifier `exampleColor`.

For nested modules, by default, the module identifiers are concatenated. For example, consider the following Slice definition:

Slice
<pre>module outer { module inner { enum Color { Red, Green, Blue }; }; };</pre>

With this definition, the Slice identifier `Color` becomes `outerinnerColor` in Objective-C.

You can use a metadata directive to change the default mapping to a different prefix. For example:

Slice
<pre>["objc:prefix:OUT"] module outer { enum Vehicle { Car, Truck, Bicycle }; module inner { enum Color { Red, Green, Blue }; }; };</pre>

With this definition, `Vehicle` maps to `OUTVehicle`. However, `Color` still maps to `outerinnerColor`, that is, the metadata directive applies only to types defined in the `outer` module, but not to types that are defined in nested modules. If you want to assign a prefix for types in the nested module, you must use a separate metadata directive, for example:

Slice

```
["objc:prefix:OUT"]
module outer {
    enum Vehicle { Car, Truck, Bicycle };

    ["objc:prefix:IN"]
    module inner {
        enum Color { Red, Green, Blue };
    };
};
```

With this definition, `Vehicle` maps to `OUTVehicle`, and `Color` maps to `INColor`.

For the remainder of the examples in this chapter, we assume that Slice definitions are enclosed by a module `Example` that is annotated with the metadata directive `["objc:prefix:EX"]`.

Objective-C Mapping for Identifiers

Objective-C identifiers are derived from Slice identifiers. The exact Objective-C identifier that is generated depends on the context. For types that are nested in modules (and hence have global visibility in Objective-C), the generated Objective-C identifiers are prefixed with their `module prefix`. Slice identifiers that do not have global visibility (such as operation names and structure members) do not use the module prefix and are preserved without change. For example, consider the following Slice definition:

Slice
<pre>["objc:prefix:EX"] module Example { struct Point { double x; double y; }; };</pre>

This maps to the following Objective-C definition:

Objective-C
<pre>@interface EXPoint : NSObject <NSCopying> { @private ICEDouble x; ICEDouble y; } @property(nonatomic, assign) ICEDouble x; @property(nonatomic, assign) ICEDouble y; // More definitions here... @end</pre>

If a Slice identifier is the same as an Objective-C keyword, the corresponding Objective-C identifier has an underscore suffix. For example, Slice `while` maps to Objective-C `while_`.

In some cases, the Objective-C mapping generates more than one identifier for a given Slice construct. For example, an interface `Intf` generates the identifiers `EXIntf` and `EXIntfPrx`. If a Slice identifier happens to be an Objective-C keyword, the underscore suffix applies only where necessary, so an interface `while` generates `EXWhile` and `EXWhilePrx`.

Note that Slice operation and member names can clash with the name of an inherited method, property, or instance variable. For example:

Slice
<pre>exception Failed { string reason; // Clashes with NSError };</pre>

This is a legal Slice definition. However, the generated exception class derives from `NSException`, which defines a `reason` method. To avoid hiding the method in the base class, the generated exception class maps the Slice `reason` member to the Objective-C property `reason_`, just as it would for a keyword.

This escape mechanism applies to all generated classes that directly or indirectly derive from `NSObject` or `NSException`.

Internal Identifiers in Objective-C

Any methods that contain two or more adjacent underscores (such as `read__` and `op_____`) are internal to the Objective-C mapping implementation and are not for use by application code.

Objective-C Mapping for Built-In Types

The Slice built-in types are mapped to Objective-C types as shown below.

Slice	Objective-C
bool	BOOL
byte	ICEByte
short	ICEShort
int	ICEInt
long	ICELong
float	ICEFloat
double	ICEDouble
string	NSString or NSMutableString

Slice `bool` maps to Objective-C `BOOL`. The remaining integral and floating-point types map to Objective-C type definitions instead of native types. This allows the Ice run time to provide a definition as appropriate for each target architecture. (For example, `ICELong` might be defined as `long` on one architecture and as `long long` on another.)

Note that `ICEByte` is a typedef for `unsigned char`. This guarantees that byte values are always in the range 0..255, and it ensures that right-shifting an `ICEByte` does not cause sign-extension.

Whether a Slice string maps to `NSString` or `NSMutableString` depends on the context. `NSMutableString` is used in some cases for operation parameters; otherwise, if a string is a data member of a Slice structure, class, or exception, it maps to `NSString`. (We will discuss these differences in more detail as we cover the mapping of the relevant Slice language features.)

Objective-C Mapping for Enumerations

A Slice enumeration maps to the corresponding enumeration in Objective-C. For example:

Slice
<pre>["objc:prefix:EX"] module Example { enum Fruit { Apple, Pear, Orange }; };</pre>

The generated Objective-C definition is:

Objective-C
<pre>typedef enum { EXApple, EXPear, EXOrange } EXFruit;</pre>

Objective-C Mapping for Structures

On this page:

- [Basic Objective-C Mapping for Structures](#)
- [Mapping for Data Members in Objective-C](#)
- [Creating and Initializing Structures in Objective-C](#)
- [Copying Structures in Objective-C](#)
- [Deallocating Structures in Objective-C](#)
- [Structure Comparison and Hashing in Objective-C](#)

Basic Objective-C Mapping for Structures

A Slice `structure` maps to an Objective-C class.

For each Slice data member, the generated Objective-C class has a corresponding property. For example, here is our `Employee` structure once more:

Slice
<pre>struct Employee { long number; string firstName; string lastName; };</pre>

The Slice-to-Objective-C compiler generates the following definition for this structure:

Objective-C
<pre>@interface EXEmployee : NSObject <NSCopying> { @private ICELong number; NSString *firstName; NSString *lastName; } @property(nonatomic, assign) ICELong number; @property(nonatomic, retain) NSString *firstName; @property(nonatomic, retain) NSString *lastName; -(id) init:(ICELong)number firstName:(NSString *)firstName lastName:(NSString *)lastName; +(id) employee:(ICELong)number firstName:(NSString *)firstName lastName:(NSString *)lastName; +(id) employee; // This class also overrides copyWithZone, // hash, isEqual, and dealloc. @end</pre>

Mapping for Data Members in Objective-C

For each data member in the Slice definition, the Objective-C class contains a corresponding private instance variable of the same name, as well as a property definition that allows you to set and get the value of the corresponding instance variable. For example, given an instance of `EXEmployee`, you can write the following:

```

Objective-C

ICELong number;
EXEmployee *e = ...;
[e setNumber:99];
number = [e number];

// Or, more concisely with dot notation:

e.number = 99;
number = e.number;
```

Properties that represent data members always use the `nonatomic` property attribute. This avoids the overhead of locking each data member during access. The second property attribute is `assign` for integral and floating-point types and `retain` for all other types (such as strings, structures, and so on.)

Note that, for types that have immutable and mutable variants (strings, sequences, and dictionaries), the corresponding data member uses the immutable variant. This allows the application to assign an immutable object to the data member. You can safely cast the data member to the mutable variant if the structure was created by the Ice run time: the unmarshaling code always creates and assigns the mutable version to the data member.

Creating and Initializing Structures in Objective-C

Structures provide the typical (inherited) `init` method:

```

Objective-C

EXEmployee *e = [[EXEmployee alloc] init];
// ...
[e release];
```

As usual, `init` initializes the instance variables of the structure with zero-filled memory, with the following exceptions:

- A string data member is initialized to an empty string
- An enumerator data member is initialized to the first enumerator
- A structure data member is initialized to a default-constructed value

You can also declare default values in your [Slice definition](#), in which case this `init` method initializes each data member with its declared value instead.

In addition, a structure provides a second `init` method that accepts one parameter for each data member of the structure:

Objective-C

```
-(id) initWith:(ICELong)number firstName:(NSString *)firstName
        lastName:(NSString *)lastName;
```

Note that the first parameter is always unlabeled; the second and subsequent parameters have a label that is the same as the name of the corresponding Slice data member. The additional `initWith:` method allows you to instantiate a structure and initialize its data members in a single statement:

Objective-C

```
EXEmployee *e = [[EXEmployee alloc] initWith:99 firstName:@"Brad"
        lastName:@"Cox"];
// ...
[e release];
```

`initWith:` applies the memory management policy of the corresponding properties, that is, it calls `retain` on the `firstName` and `lastName` arguments.

Each structure also provides two convenience constructors that mirror the `initWith:` methods: a parameter-less convenience constructor and one that has a parameter for each Slice data member:

Objective-C

```
+(id) employee;
+(id) employee:(ICELong)number firstName:(NSString *)firstName
        lastName:(NSString *)lastName;
```

The convenience constructors have the same name as the mapped Slice structure (without the module prefix). As usual, they allocate an instance, perform the same initialization actions as the corresponding `initWith:` methods, and call `autorelease` on the return value:

Objective-C

```
EXEmployee *e = [EXEmployee employee:99 firstName:@"Brad"
        lastName:@"Cox"];

// No need to call [e release] here.
```

Copying Structures in Objective-C

Structures implement the `NSCopying` protocol. Structures are copied by assigning instance variables of value type and calling `retain` on each instance variable of non-value type. In other words, the copy is shallow:

Objective-C

```
EXEmployee *e = [EXEmployee employee:99 firstName:@"Brad"
lastName:@"Cox"];
EXEmployee *e2 = [e copy];
NSAssert(e.number == e2.number);
NSAssert([e.firstName == e2.firstName]); // Same instance
// ...
[e2 release];
```

Note that, if you assign an `NSMutableString` to a structure member and use the structure as a dictionary key, you must not modify the string inside the structure without copying it because doing so will corrupt the dictionary.

Deallocating Structures in Objective-C

Each structure implements a `dealloc` method that calls `release` on each instance variable with a `retain` property attribute. This means that structures take care of the memory management of their contents: releasing a structure automatically releases all its instance variables.

Structure Comparison and Hashing in Objective-C

Structures implement `isEqual`, so you can compare them for equality. Two structures are equal if all their instance variables are equal. For value types, equality is determined by the `==` operator; for non-value types other than classes, equality is determined by the corresponding instance variable's `isEqual` method. **Classes** are compared by comparing their identity: two class members are equal if they both point at the same instance.

The `hash` method returns a hash value is that is computed from the hash value of all of the structure's instance variables.

Objective-C Mapping for Sequences

The Objective-C mapping uses different mappings for [sequences](#) of value types (such as `sequence<byte>`) and non-value types (such as `sequence<string>`).

On this page:

- [Mapping for Sequences of Value Types in Objective-C](#)
- [Mapping of Sequences of Non-Value Types in Objective-C](#)

Mapping for Sequences of Value Types in Objective-C

The following Slice types are value types:

- Integral types (`bool`, `byte`, `short`, `int`, `long`)
- Floating point types (`float`, `double`)
- Enumerated types

Sequences of these types map to a type definition. For example:

Slice
<pre>enum Fruit { Apple, Pear, Orange }; sequence<byte> ByteSeq; sequence<int> IntSeq; sequence<Fruit> FruitSeq;</pre>

The three Slice sequences produce the following Objective-C definitions:

Objective-C
<pre>typedef enum { EXApple, EXPear, EXOrange } EXFruit; typedef NSData EXByteSeq; typedef NSMutableData EXMutableByteSeq; typedef NSData EXIntSeq; typedef NSMutableData EXMutableIntSeq; typedef NSData EXFruitSeq; typedef NSMutableData EXMutableFruitSeq;</pre>

As you can see, each sequence definition creates a pair of type definitions, an immutable version named `<module-prefix><Slice-name>`, and a mutable version named `<module-prefix>Mutable<Slice-name>`. This constitutes the entire public API for sequences of value types, that is, sequences of value types simply map to `NSData` or `NSMutableData`. The `NS(Mutable)Data` sequences contain an array of the corresponding element type in their internal byte array.

We chose to map sequences of value types to `NSData` instead of `NSArray` because of the large overhead of placing each sequence element into an `NSNumber` container instance.

For example, here is how you could initialize a byte sequence of 1024 elements with values that are the modulo 128 of the element index in reverse order:

Objective-C

```
int limit = 1024;
NSMutableByteSeq *bs = [NSMutableData dataWithLength:limit];
ICEByte *p = (ICEByte *)[bs bytes];
while (--limit > 0) {
    *p++ = limit % 0x80;
}
```

Naturally, you do not need to initialize the sequence using a loop. For example, if the data is available in a buffer, you could use the `dataWithBytes:length` or `dataWithBytesNoCopy:length` methods of `NSData` instead.

Here is one way to retrieve the bytes of the sequence:

Objective-C

```
const ICEByte* p = (const ICEByte *)[bs bytes];
const ICEByte* limitp = p + [bs length];
while (p < limitp) {
    printf("%d\n", *p++);
}
```

For sequences of types other than `byte` or `bool`, you must keep in mind that the length of the `NSData` array is not the same as the number of elements. The following example initializes an integer sequence with the first few primes and prints out the contents of the sequence:

Objective-C

```
const int primes[] = { 1, 2, 3, 5, 7, 9, 11, 13, 17, 19, 23 };
NSMutableIntSeq *is = [NSMutableData dataWithBytes:primes
length:sizeof(primes)];

const ICEInt *p = (const ICEInt *)[is bytes];
int limit = [is length] / sizeof(*p);
int i;
for(i = 0; i < limit; ++i) {
    printf("%d\n", p[i]);
}
```

The code to manipulate a sequence of enumerators is very similar. For portability, you should not assume a particular size for enumerators. That is, instead of relying on all enumerators having the size of, for example, an `int`, it is better to use `sizeof(EXFruit)` to ensure that you are not overstepping the bounds of the sequence.

Mapping of Sequences of Non-Value Types in Objective-C

Sequences of non-value types, such as sequences of `string`, structures, classes, and so on, map to mutable and immutable type definitions of `NSArray`. For example:

Slice

```
sequence<string> Page;
sequence<Page> Book;
```

This maps to:

Objective-C

```
typedef NSArray EXPage;
typedef NSMutableArray EXMutablePage;

typedef NSArray EXBook;
typedef NSMutableArray EXMutableBook;
```

You use such sequences as you would use any other `NSArray` in your code. For example:

Objective-C

```
EXMutablePage *page1 = [NSArray arrayWithObjects:
    @"First line of page one",
    @"Second line of page one",
    nil];

EXMutablePage *page2 = [NSArray arrayWithObjects:
    @"First line of page two",
    @"Second line of page two",
    nil];

EXMutableBook *book = [NSMutableArray array];
[book addObject:page1];
[book addObject:page2];
[book addObject:[NSArray array]]; // Empty page
```

This creates a book with three pages; the first two pages contain two lines each, and the third page is empty. You can print the contents of the book as follows:

Objective-C

```

int pageNum = 0;
for (EXPage *page in book) {
    ++pageNum;
    int lineNumber = 0;
    if ([page count] == 0) {
        printf("page %d: <empty>\n", pageNum);
    } else {
        for (NSString *line in page) {
            ++lineNum;
            printf("page %d, line %d: %s\n",
                pageNum, lineNumber, [line UTF8String]);
        }
    }
}

```

This prints:

```

page 1, line 1: First line of page one
page 1, line 2: Second line of page one
page 2, line 1: First line of page two
page 2, line 2: Second line of page two
page 3: <empty>

```

If you have a sequence of proxies or a sequence of classes, to transmit a null proxy or class inside a sequence, you must insert an `NSNull` value into the `NSArray`. In addition, the mapping also allows you to use `NSNull` as the element value of an `NSArray` for elements of type string, structure, sequence, or dictionary. For example, instead of inserting an empty `NSArray` into the book sequence in the preceding example, we could also have inserted `NSNull`:

Objective-C

```

EXMutableBook *book = [NSMutableArray array];
[book addObject:page1];
[book addObject:page2];
[book addObject:[NSNull null]]; // Empty page

```

Objective-C Mapping for Dictionaries

Here is the definition of our `EmployeeMap` once more:

Slice
<pre>dictionary<long, Employee> EmployeeMap;</pre>

The following code is generated for this definition:

Objective-C
<pre>typedef NSDictionary EXEmployeeMap; typedef NSMutableDictionary EXMutableEmployeeMap;</pre>

Similar to [sequences](#), Slice dictionaries map to type definitions for `NSDictionary` and `NSMutableDictionary`, with the names `<module-prefix><Slice-name>` and `<module-prefix>Mutable<Slice-name>`.

As a result, you can use the dictionary like any other `NSDictionary`, for example:

Objective-C
<pre>EXMutableEmployeeMap *em = [EXMutableEmployeeMap dictionary]; EXEmployee *e = [EXEmployee employee]; e.number = 42; e.firstName = @"Stan"; e.lastName = @"Lippman"; [em setObject:e forKey:[NSNumber numberWithInt:e.number]]; e = [EXEmployee employee]; e.number = 77; e.firstName = @"Herb"; e.lastName = @"Sutter"; [em setObject:e forKey:[NSNumber numberWithInt:e.number]];</pre>

To put a value type into a dictionary (either as the key or the value), you must use `NSNumber` as the object to hold the value. If you have a dictionary that uses a Slice enumeration as the key or the value, you must insert the enumerator as an `NSNumber` that holds an `int`.

To insert a null proxy or null class instance into a dictionary as a value, you must insert `NSNull`.

As a convenience feature, the Objective-C mapping also allows you to insert `NSNull` as the value of a dictionary if the value type of the dictionary is a string, structure, sequence, or dictionary. If you send such a dictionary to a receiver, the Ice run time marshals an empty string, default-initialized structure, empty sequence, or empty dictionary as the corresponding value to the receiver, respectively.

Objective-C Mapping for Constants

Slice constant definitions map to corresponding Objective-C constant definitions. For example:

Slice	
<code>const bool</code>	<code>AppendByDefault = true;</code>
<code>const byte</code>	<code>LowerNibble = 0x0f;</code>
<code>const string</code>	<code>Advice = "Don't Panic!";</code>
<code>const short</code>	<code>TheAnswer = 42;</code>
<code>const double</code>	<code>PI = 3.1416;</code>
<code>enum Fruit { Apple, Pear, Orange };</code>	
<code>const Fruit</code>	<code>FavoriteFruit = Pear;</code>

Here are the generated definitions for these constants:

Objective-C	
<code>static const BOOL</code>	<code>EXAppendByDefault = YES;</code>
<code>static const ICEByte</code>	<code>EXLowerNibble = 15;</code>
<code>static NSString * const</code>	<code>EXAdvice = @"Don't Panic!";</code>
<code>static const ICEShort</code>	<code>EXTheAnswer = 42;</code>
<code>static const ICEDouble</code>	<code>EXPI = 3.1416;</code>
<code>typedef enum {</code>	<code>EXApple, EXPear, EXOrange</code>
<code>} EXFruit;</code>	
<code>static const EXFruit</code>	<code>EXFavoriteFruit = EXPear;</code>

All constants are initialized directly in the generated header file, so they are compile-time constants and can be used in contexts where a compile-time constant expression is required, such as to dimension an array or as the `case` label of a `switch` statement.

Slice string literals that contain non-ASCII characters or universal character names are mapped to Objective-C string literals with these characters replaced by their UTF-8 encoding as octal escapes. For example:

Slice	
<code>const string</code>	<code>Egg = "æuf";</code>
<code>const string</code>	<code>Heart = "c\u0153ur";</code>
<code>const string</code>	<code>Banana = "\U0001F34C";</code>

is mapped to:

Objective-C	
<code>static NSString * const</code>	<code>demoEgg = @"\305\223uf";</code>
<code>static NSString * const</code>	<code>demoHeart = @"c\305\223ur";</code>
<code>static NSString * const</code>	<code>demoBanana = @"\360\237\215\214";</code>

Objective-C Mapping for Exceptions

This page describes the Objective-C mapping for exceptions.

On this page:

- [Exception Inheritance Hierarchy in Objective-C](#)
- [Mapping for Exception Data Members in Objective-C](#)
- [Objective-C Mapping for User Exceptions](#)
- [Objective-C Mapping for Run-Time Exceptions](#)
 - [Creating and Initializing Run-Time Exceptions in Objective-C](#)
- [Copying and Deallocating Exceptions in Objective-C](#)
- [Exception Comparison and Hashing in Objective-C](#)

Exception Inheritance Hierarchy in Objective-C

Here again is a fragment of the Slice definition for our world time server:

Slice
<pre>exception GenericError { string reason; }; exception BadTimeVal extends GenericError {}; exception BadZoneName extends GenericError {};</pre>

These exception definitions map as follows:

Objective-C
<pre>@interface EXGenericError : ICEUserException { @private NSString *reason_; } @property(n nonatomic, retain) NSString *reason_; // ... @end @interface EXBadTimeVal : EXGenericError // ... @end @interface EXBadZoneName : EXGenericError // ... @end</pre>

Each Slice exception is mapped to an Objective-C class. For each exception member, the corresponding class contains a private instance variable and a property. (Obviously, because `BadTimeVal` and `BadZoneName` do not have members, the generated classes for these

exceptions also do not have members.)

The inheritance structure of the Slice exceptions is preserved for the generated classes, so `EXBadTimeVal` and `EXBadZoneName` inherit from `EXGenericError`.

In turn, `EXGenericError` derives from `ICEUserException`:

Objective-C

```

@interface ICEException : NSException
-(NSString* *)ice_name;
@end

@interface ICEUserException : ICEException
// ...
@end

@interface ICELocalException : ICEException
// ...
@end

```

Note that `ICEUserException` itself derives from `ICEException`, which derives from `NSException`. Similarly, run-time exceptions derive from a common base class `ICELocalException` that derives from `ICEException`, so we have the inheritance structure shown below:

Inheritance structure for exceptions.

`ICEException` provides a single method, `ice_name`, that returns the Slice type ID of the exception with the leading `::` omitted. For example, the return value of `ice_name` for our Slice `GenericError` is `Example::GenericError`.

Mapping for Exception Data Members in Objective-C

As we mentioned [earlier](#), each data member of a Slice exception generates a corresponding Objective-C property. Here is an example that

extends our `GenericError` with yet another exception:

Slice
<pre>exception GenericError { string reason; }; exception FileError extends GenericError { string name; int errorCode; };</pre>

The generated properties for these exceptions are as follows:

Objective-C
<pre>@interface EXGenericError : ICEUserException { @private NSString *reason_; } @property(nonatomic, retain) NSString *reason_; // ... @end @interface EXFileError : EXGenericError { @private NSString *name_; ICEInt errorCode; } @property(nonatomic, retain) NSString *name_; @property(nonatomic, assign) ICEInt errorCode; // ... @end</pre>

This is exactly the same mapping as for [structure members](#), with one difference: the `name` and `reason` members map to `name_` and `reason_` properties, whereas — as for structures — `errorCode` maps to `errorCode`. The trailing underscore for `reason_` and `name_` prevents a name collision with the `name` and `reason` methods that are defined by `NSError`: if you call the `name` method, you receive the name that is stored by `NSError`; if you call the `name_` method, you receive the value of the `name_` instance variable of `EXFileError`:

Objective-C

```
@try {
    // Do something that can throw ExFileError...
}
@catch(EXFileError *ex)
{
    // Print the value of the Slice reason, name,
    // and errorCode members.
    printf("reason: %s, name: %s, errorCode: %d\n",
        [ex.reason_ UTF8String],
        [ex.name_ UTF8String],
        ex.errorCode);

    // Print the NSError name.
    printf("NSError name: %s\n", [[ex name] UTF8String]);
}
```

The same escape mechanism applies if you define exception data members named `callStackReturnAddresses`, `raise`, or `userInfo`.

Objective-C Mapping for User Exceptions

Initialization of exceptions follows the same pattern as for [structures](#): each exception (apart from the inherited no-argument `init` method) provides an `init` method that accepts one argument for each data member of the exception, and two convenience constructors. For example, the generated methods for our `EXGenericError` exception look as follows:

Objective-C

```
@interface EXGenericError : ICEUserException
// ...

-(id) init:(NSString *)reason;
+(id) genericError;
+(id) genericError:(NSString *)reason;
@endif
```

If a user exception has no data members (and its base exceptions do not have data members either), only the inherited `init` method and the no-argument convenience constructor are generated.

The no-argument `init` method and the no-argument convenience constructor initialize the instance variables of the exception with zero-filled memory, with the following exceptions:

- A string data member is initialized to an empty string
- An enumerator data member is initialized to the first enumerator
- A structure data member is initialized to a default-constructed value

If you declare default values in your [Slice definition](#), the inherited `init` method and the no-argument convenience constructor initialize each data member with its declared value instead.

If an exception has a base exception with data members, its `init` method and convenience constructor accept one argument for each Slice data member, in base-to-derived order. For example, here are the methods for the `FileError` exception we defined [above](#):

Objective-C

```

@interface EXFileError : EXGenericError
// ...

-(id) init:(NSString *)reason name:(NSString *)name
        errorCode:(ICEInt)errorCode;

+(id) fileError;
+(id) fileError:(NSString *)reason name:(NSString *)name
        errorCode:(ICEInt)errorCode;

@end

```

Note that `init` and the second convenience constructor accept three arguments; the first initializes the `EXGenericError` base, and the remaining two initialize the instance variables of `EXFileError`.

Objective-C Mapping for Run-Time Exceptions

The Ice run time throws [run-time exceptions](#) for a number of pre-defined error conditions. All run-time exceptions directly or indirectly derive from `ICELocalException` which, in turn, derives from `ICEException`. (See the above illustration for an example of an inheritance diagram.)

By catching exceptions at the appropriate point in the hierarchy, you can handle exceptions according to the category of error they indicate:

- `NSException`
This is the root of the complete inheritance tree. Catching `NSException` catches all exceptions, whether they relate to Ice or the Cocoa framework.
- `ICEException`
Catching `ICEException` catches both user and run-time exceptions.
- `ICEUserException`
This is the root exception for all user exceptions. Catching `ICEUserException` catches all user exceptions (but not run-time exceptions).
- `ICELocalException`
This is the root exception for all run-time exceptions. Catching `ICELocalException` catches all run-time exceptions (but not user exceptions).
- `ICETimeoutException`
This is the base exception for both operation-invocation and connection-establishment timeouts.
- `ICEConnectTimeoutException`
This exception is raised when the initial attempt to establish a connection to a server times out.

For example, an `ICEConnectTimeoutException` can be handled as `ICEConnectTimeoutException`, `ICETimeoutException`, `ICELocalException`, `ICEException`, or `NSException`.

You will probably have little need to catch run-time exceptions as their most-derived type and instead catch them as `ICELocalException`; the fine-grained error handling offered by the remainder of the hierarchy is of interest mainly in the implementation of the Ice run time. Exceptions to this rule are the exceptions related to [facet](#) and [object](#) life cycles, which you may want to catch explicitly. These exceptions are `ICEFacetNotExistException` and `ICEObjectNotExistException`, respectively.

Creating and Initializing Run-Time Exceptions in Objective-C

`ICELocalException` provides two properties that return the file name and line number at which an exception was raised:

Objective-C

```
@interface ICELocalException : ICEException
{
// ...

@property(nonatomic, readonly) NSString* file;
@property(nonatomic, readonly) int line;

-(id)init:(const char*)file line:(int)line;
+(id)localException:(const char*)file line:(int)line;
@end
```

The `init` method and the convenience constructor accept the file name and line number as arguments.

Concrete run-time exceptions that derived from `ICEException` provide a corresponding `init` method and convenience constructor. For example, here is the Slice definition of `ObjectNotExistException`:

Slice

```
local exception RequestFailedException {
    Identity id;
    string facet;
    string operation;
};

local exception ObjectNotExistException
extends RequestFailedException {};
```

The Objective-C mapping for `ObjectNotExistException` is:

Objective-C

```
@interface ICEObjectNotExistException : ICERequestFailedException
// ...
-(id) init:(const char*)file__p line:(int)line__p;
-(id) init:(const char*)file__p
        line:(int)line__p
        id:(ICEIdentity *)id_
        facet:(NSString *)facet
        operation:(NSString *)operation;
+(id) objectNotExistException:(const char*)file__p
        line:(int)line__p;
+(id) objectNotExistException:(const char*)file__p
        line:(int)line__p
        id:(ICEIdentity *)id_
        facet:(NSString *)facet
        operation:(NSString *)operation;

@end
```

In other words, as for user exceptions, run-time exceptions provide `init` methods and convenience constructors that accept arguments in base-to-derived order. This means that all run-time exceptions require a file name and line number when they are instantiated. For example, you can throw an `ICEObjectNotExistException` as follows:

Objective-C

```
@throw [ICEObjectNotExistException
objectNotExistException:__FILE__ line:__LINE__];
```

If you throw this exception in the context of an executing operation on the server side, the `id_`, `facet`, and `operation` instance variables are automatically initialized by the Ice run time.

When you instantiate a run-time exception, the base `NSEException` is initialized such that its `name` method returns the same string as `ice_name`; the `reason` and `userInfo` methods return `nil`.

Copying and Deallocating Exceptions in Objective-C

User exceptions and run-time exceptions implement the `NSCopying` protocol, so you can copy them. The semantics are the same as for `structures`.

Similarly, like structures, exceptions implement a `dealloc` method that takes care of deallocating the instance variables when an exception is released.

Exception Comparison and Hashing in Objective-C

Exceptions do not override `isEqual` or `hash`, so these methods have the behavior inherited from `NSObject`.

Objective-C Mapping for Interfaces

The mapping of Slice [interfaces](#) revolves around the idea that, to invoke a remote operation, you call a member function on a local class instance that represents the remote object. This makes the mapping easy and intuitive to use because, for all intents and purposes (apart from error semantics), making a remote procedure call is no different from making a local procedure call.

Proxy Classes and Proxy Protocols in Objective-C

On the client side, interfaces map to a protocol with member functions that correspond to the operations on those interfaces. Consider the following simple interface:

```

Slice

["objc:prefix:EX"]
module Example {
    interface Simple {
        void op();
    }
};

```

The Slice compiler generates the following definitions for use by the client:

```

Objective-C

@interface EXSimplePrx : ICEObjectPrx
// Mapping-internal methods here...
@end

@protocol EXSimplePrx <ICEObjectPrx>
-(void) op;
-(void) op:(ICEContext *)context;
@end;

```

As you can see, the compiler generates a proxy protocol `EXSimplePrx` and a proxy class `EXSimplePrx`. In general, the generated name for both protocol and class is `<module-prefix><interface-name>Prx`.

In the client's address space, an instance of `EXSimplePrx` is the local ambassador for a remote instance of the `Simple` interface in a server and is known as a *proxy class instance*. All the details about the server-side object, such as its address, what protocol to use, and its object identity are encapsulated in that instance.

Note that `EXSimplePrx` derives from `ICEObjectPrx`, and that `EXSimplePrx` adopts the `ICEObjectPrx` protocol. This reflects the fact that all Slice interfaces implicitly derive from `Ice::Object`. For each operation in the interface, the proxy protocol has two methods whose name is derived from the operation. For the preceding example, we find that the operation `op` is mapped to two methods, `op` and `op:`.

The second method has a trailing parameter of type `ICEContext`. This parameter is for use by the Ice run time to store information about how to deliver a request; normally, you do not need to supply a value here and can pretend that the trailing parameter does not exist. (We examine the `ICEContext` parameter in detail in [Request Contexts](#). The parameter is also used by `IceStorm`.)

Proxy Instantiation and Casting in Objective-C

Client-side application code never manipulates proxy class instances directly. In fact, you are not allowed to instantiate a proxy class directly. Instead, proxy instances are always instantiated on behalf of the client by the Ice run time, so client code never has any need to instantiate a proxy directly.

Proxies are immutable: once the run time has instantiated a proxy, that proxy continues to denote the same remote object and cannot be changed. This means that, if you want to keep a copy of a proxy, it is sufficient to call `retain` on the proxy. (You can also call `copy` on a proxy because `ICEObjectPrx` implements `NSCopying`. However, calling `copy` has the same effect as calling `retain`.)

Proxies are always passed and returned as type `id<module-prefix><interface-name>Prx>`. For example, for the preceding `Simple` interface, the proxy type is `id<EXSimplePrx>`.

The `ICEObjectPrx` base class provides class methods that allow you to cast a proxy from one type to another, as described below.

Using a Checked Cast in Objective-C

A `checkedCast` tests whether the object denoted by a proxy implements the specified interface:

```
Objective-C
+(id) checkedCast:(id<ICEObjectPrx>)proxy;
```

If so, the cast returns a proxy to the specified interface; otherwise, if the object denoted by the proxy does not implement the specified interface, the cast returns `nil`. Checked casts are typically used to safely down-cast a proxy to a more derived interface. For example, assuming we have `Slice` interfaces `Base` and `Derived`, you can write the following:

```
Objective-C
id<EXBasePrx> base = ...; // Initialize base proxy
id<EXDerivedPrx> derived = [EXDerivedPrx checkedCast:base];
if(derived != nil)
{
    // base implements run-time type Derived
    // use derived...
} else {
    // Base has some other, unrelated type
}
```

The expression `[EXDerivedPrx checkedCast:base]` tests whether `base` points at an object of type `Derived` (or an object with a type that is derived from `Derived`). If so, the cast succeeds and `derived` is set to point at the same object as `base`. Otherwise, the cast fails and `derived` is set to `nil`. (Proxies that "point nowhere" are represented by `nil`.)

Calling `checkedCast` on a proxy that is already of the desired proxy type returns immediately that proxy. Otherwise, `checkedCast` always calls `ice_isA` on the target object, and upon success, creates a new instance of the desired proxy class.

The message effectively asks the server "is the object denoted by this proxy of type `Derived`?" The reply from the server is communicated to the application code in form of a successful (non-`nil`) or unsuccessful (`nil`) result. Sending a remote message is necessary because, as a rule, there is no way for the client to find out what the actual run-time type of a proxy is without confirmation from the server. (For example, the server may replace the implementation of the object for an existing proxy with a more derived one.) This means that you have to be prepared for a `checkedCast` to fail. For example, if the server is not running, you will receive an `ICEConnectionRefusedException`; if the server is running, but the object denoted by the proxy no longer exists, you will receive an `ICEObjectNotExistException`.

Using an Unchecked Cast in Objective-C

In some cases, it is known that an object supports a more derived interface than the static type of its proxy. For such cases, you can use an

unchecked down-cast:

```
Objective-C
```

```
+(id) uncheckedCast:(id<ICEObjectPrx>)proxy;
```

Here is an example:

```
Objective-C
```

```
id<EXBasePrx> base;
base = ...; // Initialize base to point at a Derived
id<EXDerivedPrx> derived = [EXDerivedPrx uncheckedCast:base];
// Use derived...
```

An `uncheckedCast` provides a down-cast *without* consulting the server as to the actual run-time type of the object. You should use an `uncheckedCast` only if you are certain that the proxy indeed supports the more derived type: an `uncheckedCast`, as the name implies, is not checked in any way; it does not contact the object in the server and, if the proxy does not support the specified interface, the cast does not return null. If you use the proxy resulting from an incorrect `uncheckedCast` to invoke an operation, the behavior is undefined. Most likely, you will receive an `ICEOperationNotExistException`, but, depending on the circumstances, the Ice run time may also report an exception indicating that unmarshaling has failed, or even silently return garbage results.

Despite its dangers, `uncheckedCast` is still useful because it avoids the cost of sending a message to the server. And, particularly during *initialization*, it is common to receive a proxy of type `id<ICEObjectPrx>`, but with a known run-time type. In such cases, an `uncheckedCast` saves the overhead of sending a remote message.

Note that an `uncheckedCast` is *not* the same as an ordinary cast. The following is incorrect and has undefined behavior:

```
Objective-C
```

```
id<EXDerivedPrx> derived = (id<EXDerivedPrx>)base; // Wrong!
```

Both `checkedCast` and `uncheckedCast` call `autorelease` on the proxy they return so, if you want to prevent the proxy from being deallocated once the enclosing `autorelease` pool is drained, you must call `retain` on the returned proxy.

Using Proxy Methods in Objective-C

The `ICEObjectPrx` provides a variety of [methods for customizing a proxy](#). Since proxies are immutable, each of these "factory methods" returns a copy of the original proxy that contains the desired modification. For example, you can obtain a proxy configured with a ten-second timeout as shown below:

```
Objective-C
```

```
id<ICEObjectPrx> proxy = [communicator stringWithProxy:...];
proxy = [proxy ice_timeout:10000];
```

A factory method returns a new (autoreleased) proxy object if the requested modification differs from the current proxy, otherwise it returns the original proxy. The returned proxy is always of the same type as the source proxy, except for the factory methods `ice_facet` and `ice_identity`. Calls to either of these methods may produce a proxy for an object of an unrelated type, therefore they return a base proxy that you must subsequently down-cast to an appropriate type.

Object Identity and Proxy Comparison in Objective-C

Proxy objects support comparison with `isEqual`. Note that `isEqual` uses *all* of the information in a proxy for the comparison. This means that not only the object identity must match for a comparison to succeed, but other details inside the proxy, such as the protocol and endpoint information, must be the same as well. In other words, comparison with `isEqual` tests for proxy identity, not object identity. A common mistake is to write code along the following lines:

```

Objective-C
id<ICEObjectPrx> p1 = ...;    // Get a proxy...
id<ICEObjectPrx> p2 = ...;    // Get another proxy...

if (![p1 isEqual:p2]) {
    // p1 and p2 denote different objects    // WRONG!
} else {
    // p1 and p2 denote the same object    // Correct
}

```

Even though `p1` and `p2` differ, they may denote the same Ice object. This can happen if, for example, `p1` and `p2` embed the same object identity, but use a different protocol to contact the target object. Similarly, the protocols might be the same, but could denote different endpoints (because a single Ice object can be contacted via several different transport endpoints). In other words, if two proxies compare equal with `isEqual`, we know that the two proxies denote the same object (because they are identical in all respects); however, if two proxies compare unequal with `isEqual`, we know absolutely nothing: the proxies may or may not denote the same object.

To compare the object identities of two proxies, you can use additional methods provided by proxies:

```

Objective-C
@protocol ICEObjectPrx <NSObject, NSCopying>
// ...
-(NSComparisonResult) compareIdentity:(id<ICEObjectPrx>)p;
-(NSComparisonResult) compareIdentityAndFacet:(id<ICEObjectPrx>)p;
@end

```

The `compareIdentity` method compares the object identities embedded in two proxies while ignoring other information, such as facet and transport information. To include the `facet name` in the comparison, use `compareIdentityAndFacet` instead.

`compareIdentity` and `compareIdentityAndFacet` allow you to correctly compare proxies for object identity. The example below demonstrates how to use `compareIdentity`:

```

Objective-C
id<ICEObjectPrx> p1 = ...;    // Get a proxy...
id<ICEObjectPrx> p2 = ...;    // Get another proxy...

if ([p1 compareIdentity:p2] != NSOrderedSame) {
    // p1 and p2 denote different objects    // Correct
} else {
    // p1 and p2 denote the same object    // Correct
}

```

Basic Objective-C Mapping for Operations

As we saw in the [mapping for interfaces](#), for each operation on an interface, the proxy protocol contains two corresponding methods with the same name as the operation.

To invoke an operation, you call it via the proxy object. For example, here is part of the definitions for our file system:

Slice

```
["objc:prefix:FS"]
module Filesystem {
    interface Node {
        idempotent string name();
    };
    // ...
};
```

The proxy protocol for the `Node` interface looks as follows:

Objective-C

```
@protocol FSNodePrx <ICEObjectPrx>
-(NSMutableString *) name;
-(NSMutableString *) name:(ICEContext *)context;
@end;
```

The `name` method returns a value of type `NSMutableString`. Given a proxy to an object of type `Node`, the client can invoke the operation as follows:

Objective-C

```
id<EXNodePrx> node = ...;           // Initialize proxy
NSString *name = [node name];      // Get name via RPC
```

The `name` method sends the operation invocation to the server, waits until the operation is complete, and then unmarshals the return value and returns it to the caller.

Because the `name` method autoreleases the return value, it is safe to ignore the return value. For example, the following code contains no memory leak:

Objective-C

```
id<EXNodePrx> node = ...;           // Initialize proxy
[node name];                        // Useless, but no leak
```

If you ignore the return value, no memory leak occurs because the next time the enclosing autorelease pool is drained, the memory will be reclaimed.

Normal and idempotent Operations in Objective-C

You can add an `idempotent` qualifier to a Slice operation. As far as the corresponding proxy protocol methods are concerned, `idempotent` has no effect. For example, consider the following interface:

Slice

```
interface Ops {
    string op1();
    idempotent string op2();
    idempotent void op3(string s);
};
```

The proxy protocol for this interface looks like this:

Objective-C

```
@protocol EXOpsPrx <ICEObjectPrx>
-(NSMutableString *) op1;
-(NSMutableString *) op1:(ICEContext *)context;
-(NSMutableString *) op2;
-(NSMutableString *) op2:(ICEContext *)context;
-(void) op3:(NSString *)s;
-(void) op3:(NSString *)s context:(ICEContext *)context;
@end;
```

For brevity, we will not show the methods with the additional trailing `context` parameter for the remainder of this discussion. Of course, the compiler generates the additional methods regardless.

Because `idempotent` affects an aspect of call dispatch, not interface, it makes sense for the mapping to be unaffected by the `idempotent` keyword.

Passing Parameters in Objective-C

In-Parameters in Objective-C

The parameter passing rules for the Objective-C mapping are very simple: value type parameters are passed by value and non-value type parameters are passed by pointer. Semantically, the two ways of passing parameters are identical: the Ice run time guarantees not to change the value of an in-parameter.

Here is an interface with operations that pass parameters of various types from client to server:

Slice

```

struct NumberAndString {
    int x;
    string str;
};

sequence<string> StringSeq;

dictionary<long, StringSeq> StringTable;

interface ClientToServer {
    void op1(int i, float f, bool b, string s);
    void op2(NumberAndString ns, StringSeq ss, StringTable st);
    void op3(ClientToServer* proxy);
};

```

The Slice compiler generates the following code for this definition:

Objective-C

```

@interface EXNumberAndString : NSObject <NSCopying>
// ...
@property(nonatomic, assign) ICEInt x;
@property(nonatomic, retain) NSString *str;
// ...
@end

typedef NSArray EXStringSeq;
typedef NSMutableArray EXMutableStringSeq;

typedef NSDictionary EXStringTable;
typedef NSMutableDictionary EXMutableStringTable;

@protocol EXClientToServerPrx <ICEObjectPrx>
-(void) op1:(ICEInt)i f:(ICEFloat)f b:(BOOL)b s:(NSString *)s;
-(void) op2:(EXNumberAndString *)ns ss:(EXStringSeq *)ss
st:(NSDictionary *)st;
-(void) op3:(id<EXClientToServerPrx>)proxy;
@end;

```

Given a proxy to a `ClientToServer` interface, the client code can pass parameters as in the following example:

Objective-C

```

id<EXClientToServerPrx> p = ...;           // Get proxy...

[p op1:42 f:3.14 b:YES s:@"Hello world!"]; // Pass literals

ICEInt i = 42;
ICEFloat f = 3.14;
BOOL b = YES;
NSString *s = @"Hello world!";

[p op1:i f:f b:b s:s];                    // Pass simple vars

EXNumberAndString *ns = [EXNumberAndString numberAndString:42
str:@"The Answer"];
EXMutableStringSeq *ss = [ExMutableStringSeq array];
[ss addObject:@"Hello world!"];
EXStringTable *st = [EXMutableStringTable dictionary];
[ss setObject:ss forKey:[NSNumber numberWithInt:0]];

[p op2:ns ss:ss st:st];                    // Pass complex vars

[p op3:p];                                 // Pass proxy

```

You can pass either literals or variables to the various operations. The Ice run time simply marshals the value of the parameters to the server and leaves parameters otherwise untouched, so there are no memory-management issues to consider.

Note that the invocation of `op3` is somewhat unusual: the caller passes the proxy it uses to invoke the operation to the operation as a parameter. While unusual, this is legal (and no memory management issues arise from doing this.)

Passing `nil` and `NSNull` in Objective-C

The Slice language supports the concept of null ("points nowhere") for only two of its types: proxies and classes. For either type, `nil` represents a null proxy or class. For other Slice types, such as strings, the concept of a null string simply does not apply. (There is no such thing as a null string, only the empty string.) However, strings, structures, sequences, and dictionaries are all passed by pointer, which raises the question of how the Objective-C mapping deals with `nil` values.

As a convenience feature, the Objective-C mapping permits passing of `nil` as a parameter for the following types:

- Proxies (`nil` sends a null proxy.)
- Classes (`nil` sends a null class instance.)
- Strings (`nil` sends an empty string.)
- Structures (`nil` sends a default-initialized structure.)
- Sequences (`nil` sends an empty sequence.)
- Dictionaries (`nil` sends an empty dictionary.)

It is impossible to add `nil` to an `NSArray` or `NSDictionary`, so the mapping follows the usual convention that an `NSArray` element or `NSDictionary` value that is conceptually `nil` is represented by `NSNull`. For example, to send a sequence of proxies, some of which are null proxies, you must insert `NSNull` values into the sequence.

As a convenience feature, if you have a sequence with elements of type string, structure, sequence, or dictionary, you can use `NSNull` as the element value. For elements that are `NSNull`, the Ice run time marshals an empty string, default-initialized structure, empty sequence, or empty dictionary to the receiver.

Similarly, for dictionaries with value type string, structure, sequence, or dictionary, you can use `NSNull` as the value to send the corresponding empty value (or default-initialized value, in the case of structures).

Out-Parameters in Objective-C

The Objective-C mapping passes out-parameters by pointer (for value types) and by pointer-to-pointer (for non-value types). Here is the [Slice definition](#) once more, modified to pass all parameters in the `out` direction:

```

Slice

```

struct NumberAndString {
 int x;
 string str;
};

sequence<string> StringSeq;

dictionary<long, StringSeq> StringTable;

interface ServerToClient {
 void op1(out int i, out float f, out bool b, out string s);
 void op2(out NumberAndString ns,
 out StringSeq ss,
 out StringTable st);
 void op3(out ClientToServer* proxy);
};

```

```

The Slice compiler generates the following code for this definition:

```

Objective-C

```

@protocol EXServerToClientPrx <ICEObjectPrx>
-(void) op1:(ICEInt *)i f:(ICEFloat *)f b:(BOOL *)b
s:(NSMutableString **)s;
-(void) op2:(EXNumberAndString **)ns ss:(EXMutableStringSeq **)ss
 st:(EXMutableStringTable **)st;
-(void) op3:(id<EXClientToServerPrx> *)proxy;
@end

```

```

Note that, for types that come in immutable and mutable variants (strings, sequences, and dictionaries), the corresponding out-parameter uses the mutable variant.

Given a proxy to a `ServerToClient` interface, the client code can pass parameters as in the following example:

Objective-C

```
id<EXServerToClientPrx> p = ...; // Get proxy...

ICEInt i;
ICEFloat f;
BOOL b;
NSMutableString *s;

[p op1:&i f:&f b:&b s:&s];
// i, f, b, and s contain updated values now

EXNumberAndString *ns;
EXStringSeq *ss;
EXStringTable *st;

[p op2:&ns ss:&ss st:&st];
// ns, ss, and st contain updated values now

[p op3:&p];
// p has changed now!
```

Again, there are no surprises in this code: the caller simply passes pointers to pointer variables to a method; once the operation completes, the values of those variables will have been set by the server.

Memory Management for Out-Parameters in Objective-C

When the Ice run time returns an out-parameter to the caller, it does not make any assumptions about the previous value of that parameter (if any). In other words, if you pass an initialized string as an out-parameter, the value you pass is simply discarded and the corresponding variable is assigned a new instance. As an example, consider the following operation:

Slice

```
void getString(out string s);
```

You could call this as follows:

Objective-C

```
NSMutableString *s = @"Hello";
[p getString:&s];
// s now points at the returned string.
```

All out-parameters are autoreleased by the Ice run time before they are returned. This is convenient because it does just the right thing with respect to memory management. For example, the following code does not leak memory:

Objective-C

```
NSMutableString *s = @"Hello";
[p getString:&s];
[p getString:&s]; // No leak here.
```

However, because the pointer value of out-parameters is simply assigned by the proxy method, you must be careful not to pass a variable as an out-parameter if that variable was not released or autoreleased:

Objective-C

```
NSMutableString *s = [[NSMutableString alloc] initWithString:@"Hello"];
[p getString:&s]; // Bad news!
```

This code leaks the initial string because the proxy method assigns the passed pointer without calling `release` on it first. (In practice, this is rarely a problem because there is no need to initialize out-parameters and, if an out-parameter was initialized by being passed as an out-parameter to an operation earlier, its value will have been autoreleased by the proxy method already.)

It is worth having another look at the final call of the [code example](#) we saw earlier:

Objective-C

```
[p op3:&p];
```

Here, `p` is the proxy that is used to dispatch the call. That same variable `p` is also passed as an out-parameter to the call, meaning that the server will set its value. In general, passing the same parameter as both an input and output parameter is safe (with the caveat we just discussed).

Receiving Return Values in Objective-C

The Objective-C mapping returns return values in much the same way as out-parameters: value types are returned by value, and non-value types are returned by pointer. As an example, consider the following operations:

Slice

```
struct NumberAndString {
    int x;
    string str;
};

interface Ops {
    int getInt();
    string getString();
    NumberAndString getNumberAndString();
};
```

The proxy protocol looks as follows:

Objective-C

```
@protocol EXOpsPrx <ICEObjectPrx>
-(ICEInt) getInt;
-(NSString *) getString;
-(EXNumberAndString *) getNumberAndString;
@end
```

Note that, for types with mutable and immutable variants (strings, sequences, and dictionaries), the formal return type is the mutable variant. As for out-parameters, anything returned by pointer is autoreleased by the Ice run time. This means that the following code works fine and does not contain memory management errors:

Objective-C

```
EXNumberAndString *ns = [NSNumberAndString numberAndString];
ns.x = [p getInt];
ns.str = [p getString]; // Autoreleased by getString,
                        // retained by ns.str.

[p getNumberAndString]; // No leak here.
```

The return value of `getString` is autoreleased by the proxy method but, during the assignment to the property `str`, the generated code calls `retain`, so the structure keeps the returned string alive in memory, as it should. Similarly, ignoring the return value from an invocation is safe because the returned value is autoreleased and will be reclaimed when the enclosing autorelease pool is drained.

Chained Invocations in Objective-C

Consider the following simple interface containing two operations, one to set a value and one to get it:

Slice

```
interface Name {
    string getName();
    void setName(string name);
};
```

Suppose we have two proxies to interfaces of type `Name`, `p1` and `p2`, and chain invocations as follows:

Objective-C

```
[p2 setName:[p1 getName]]; // No leak here.
```

This works exactly as intended: the value returned by `p1` is transferred to `p2`. There are no memory-management or exception safety issues with this code.

nil Out-Parameters and Return Values in Objective-C

If an out-parameter or return value is a proxy or class, and the operation returns a null proxy or class, the proxy method returns `nil`. If a proxy or class is returned as part of a sequence or dictionary, the corresponding entry is `NSNull`.

For strings, structures, sequences, and dictionaries, the Ice run time *never* returns `nil` or `NSNull` (even if the server passed `nil` or `NSNull` as the value). Instead, the unmarshaling code always instantiates an empty string, empty sequence, or empty dictionary, and it always initializes structure members during unmarshaling, so structures that are returned from an operation invocation never contain a `nil` instance variable (except for proxy and class instance variables).

Optional Parameters in Objective-C

The Objective-C mapping uses the `id` type for optional parameters. As a result, there's no compile time check for optional parameters. Instead, Ice performs a run-time type check and if the optional parameter does not match the expected type an `NSException` with the `NSInvalidArgumentException` name is raised. Slice types that map to an Objective-C class use the same mapping as required parameters. Slice built-in basic types (except string) are boxed into an `NSNumber` value. The `ICENone` singleton value can also be passed as the value of an optional parameter or return value.

Consider the following operation:

Slice
<pre>optional(1) int execute(optional(2) string aString, optional(3) int anInt, out optional(4) float outFloat);</pre>

A client can invoke this operation as shown below:

Objective-C
<pre>id f; id i; i = [proxy execute:@"--file log.txt" anInt:@14 outFloat:&f] i = [proxy execute:ICENone anInt:@14 outFloat:&f] // aString is unset if(i == ICENone) { NSLog(@"return value is not set"); } else { int v = [i intValue]; NSLog(@"return value is set to %d", v); }</pre>

Passing `nil` for an optional parameter is the same as passing `nil` for a required parameter, the optional parameter is considered to be set to `nil`. For Slice built-in basic types (except string), the optional parameter is considered to be set to 0 or `NO` for booleans.

A well-behaved program must not assume that an optional parameter always has a value. It should compare the value to `ICENone` to determine whether the optional parameter is set.

Exception Handling in Objective-C

Any operation invocation may throw a [run-time exception](#) and, if the operation has an exception specification, may also throw [user exceptions](#). Suppose we have the following simple interface:

Slice
<pre>exception Tantrum { string reason; }; interface Child { void askToCleanUp() throws Tantrum; };</pre>

Slice exceptions are thrown as Objective-C exceptions, so you can simply enclose one or more operation invocations in a `try-catch` block:

Objective-C
<pre>id<EXChildPrx> child = ...; // Get proxy... @try { [child askToCleanUp]; // Give it a try... } @catch (EXTantrum *t) { printf("The child says: %s\n", t.reason_); }</pre>

Typically, you will catch only a few exceptions of specific interest around an operation invocation; other exceptions, such as unexpected run-time errors, will typically be dealt with by exception handlers higher in the hierarchy. For example:

Objective-C

```

void run()
{
    id<EXChildPrx> child = ...;           // Get proxy...
    @try {
        [child askToCleanUp];           // Give it a try...
    } @catch (EXTantrum *t) {
        printf("The child says: %s\n", t.reason);
        [child scold];                  // Recover from error...
    }
    [child praise];                     // Give positive feedback...
}

int
main(int argc, char* argv[])
{
    int status = 1;
    @try {
        // ...
        run();
        // ...
        status = 0;
    } @catch (ICEException *e) {
        printf("Unexpected run-time error: %s\n", [e ice_name]);
    }
    // ...
    return status;
}

```

This code handles a specific exception of local interest at the point of call and deals with other exceptions generically. (This is also the strategy we used for our [first simple application](#).)

Exceptions and Out-Parameters in Objective-C

If an operation throws an exception, the Ice run time makes no guarantee for the value of out-parameters. Individual out-parameters may have the old value, the new value, or a value that is indeterminate, such that parts of the out-parameter have been assigned and others have not. However, no matter what their state, the values will be "safe" for memory-management purposes, that is, any out-parameters that were successfully unmarshaled are autoreleased.

Exceptions and Return Values in Objective-C

For return values, the Objective-C mapping provides the guarantee that a variable receiving the return value of an operation will not be overwritten if an exception is thrown.

Objective-C Mapping for Local Interfaces

The Ice run time defines APIs using [Slice](#). These APIs are provided as part of the Ice run time library and cannot be invoked remotely. (Doing so would not make any sense.) Therefore, the Slice interfaces for the Ice run time are defined as [local interfaces](#).

Unlike the mapped Objective-C interfaces for non-local Slice interfaces, the mapped Objective-C for local Slice interfaces do not adopt the `<interface-name>Prx` protocol. (Doing so would be misleading because proxies imply that the target object can be remote.) Instead, the protocol for local interfaces has the same name as the interface. For example, the `Ice::Communicator` interface is mapped simply as:

```

Objective-C

@protocol ICECommunicator
...
@end
```

Because `Communicator` is a local interface, objects of type `ICECommunicator` are passed as `id<ICECommunicator>` (*not* `ICECommunicator*` or `id<ICECommunicatorPrx>`).

Basic Objective-C Mapping for Classes

A Slice `class` is mapped similar to a structure and exception.

The generated class contains an instance variable and a property for each Slice data member. Consider the following class definition:

Slice

```
class TimeOfDay {
    short hour;           // 0 - 23
    short minute;        // 0 - 59
    short second;        // 0 - 59
    string format();     // Return time as hh:mm:ss
};
```

The Slice compiler generates the following code for this definition:

Objective-C

```

@interface EXTimeOfDay : ICEObject
{
    ICEShort hour;
    ICEShort minute;
    ICEShort second;
}

@property(nonatomic, assign) ICEShort hour;
@property(nonatomic, assign) ICEShort minute;
@property(nonatomic, assign) ICEShort second;

-(id) init:(ICEShort)hour minute:(ICEShort)minute
second:(ICEShort)second;
+(id) timeOfDay;
+(id) timeOfDay:(ICEShort)hour minute:(ICEShort)minute
second:(ICEShort)second;
@end

```

There are a number of things to note about the generated code:

1. The generated class `EXTimeOfDay` derives from `ICEObject`, which is the parent of all classes. Note that `ICEObject` is *not* the same as `ICEObjectPrx`. In other words, you *cannot* pass a class where a proxy is expected and vice versa.
2. The generated class contains a property for each Slice data member.
3. The generated class provides an `init` method that accepts one argument for each data member, and it provides the same two convenience constructors as structures and exceptions.

Derivation from `ICEObject` in Objective-C

All classes ultimately derive from a common base class, `ICEObject`. Note that this is not the same as implementing the `ICEObjectPrx` protocol (which is implemented by proxies). As a result, you cannot pass a class where a proxy is expected (and vice versa) because the base types for classes and proxies are not compatible.

`ICEObject` defines a number of methods:

Objective-C

```

@protocol ICEObject <NSObject>
-(BOOL) ice_isA:(NSString*)typeId current:(ICECurrent*)current;
-(void) ice_ping:(ICECurrent*)current;
-(NSString*) ice_id:(ICECurrent*)current;
-(NSArray*) ice_ids:(ICECurrent*)current;
@end

@interface ICEObject NSObject <ICEObject, NSCopying>
-(BOOL) ice_isA:(NSString*)typeId;
-(void) ice_ping;
-(NSString*) ice_id;
-(NSArray*) ice_ids;
+(NSString*) ice_staticId;
-(void) ice_preMarshal;
-(void) ice_postUnmarshal;
-(BOOL) ice_dispatch:(id<ICERequest>)request;
-(id) initWithDelegate:(id)delegate;
+(id) objectWithDelegate:(id)delegate;
@end

```

The methods are split between the `ICEObject` protocol and class because classes can be servants.

The methods of `ICEObject` behave as follows:

- `ice_isA`
This function returns YES if the object supports the given `type ID`, and NO otherwise.
- `ice_ping`
`ice_ping` provides a basic reachability test for the class. If it completes without raising an exception, the class exists and is reachable. Note that `ice_ping` is normally only invoked on the proxy for a class that might be remote because a class instance that is local (in the caller's address space) can always be reached.
- `ice_ids`
This function returns a string sequence representing all of the `type IDs` supported by this object, including `::Ice::Object`.
- `ice_id`
This function returns the actual run-time `type ID` for a class. If you call `ice_id` via a pointer to a base instance, the returned `type ID` is the actual (possibly more derived) `type ID` of the instance.
- `ice_staticId`
This function returns the static `type ID` of a class.
- `ice_preMarshal`
The Ice run time invokes this function prior to marshaling the object's state, providing the opportunity for a subclass to validate its declared data members.
- `ice_postUnmarshal`
The Ice run time invokes this function after unmarshaling an object's state. A subclass typically overrides this function when it needs to perform additional initialization using the values of its declared data members.
- `ice_dispatch`
This function dispatches an incoming request to a servant. It is used in the implementation of `dispatch interceptors`.

- `initWithDelegate`
These constructors enable the implementation of servants with a [delegate](#).

Class Data Members in Objective-C

By default, data members of classes are mapped exactly as for structures and exceptions: for each data member in the Slice definition, the generated class contains a corresponding property.

Class Constructors in Objective-C

Classes provide the usual `init` method and a parameter-less convenience constructor that perform default initialization of the object's instance variables. These methods initialize the instance variables with zero-filled memory, with the following exceptions:

- A string data member is initialized to an empty string
- An enumerator data member is initialized to the first enumerator
- A structure data member is initialized to a default-constructed value

If you declare default values in your [Slice definition](#), the `init` method and convenience constructor initialize each data member with its declared value instead.

In addition, if a class has data members, it provides an `init` method and a convenience constructor that accept one argument for each data member. This allows you to allocate and initialize a class instance in a single statement (instead of first having to allocate and default-initialize the instance and then assign to its properties).

For derived classes, the `init` method and the convenience constructor have one parameter for each of the base class's data members, plus one parameter for each of the derived class's data members, in base-to-derived order. For example:

Slice

```

class Base {
    int i;
};

class Derived extends Base {
    string s;
};

```

This generates:

Objective-C

```

@interface EXBase : ICEObject
// ...

@property(nonatomic, assign) ICEInt i;

-(id) init:(ICEInt)i;
+(id) base;
+(id) base:(ICEInt)i;
@end

@interface EXDerived : EXBase
// ...

@property(nonatomic, retain) NSString *s;

-(id) init:(ICEInt)i s:(NSString *)s;
+(id) derived;
+(id) derived:(ICEInt)i s:(NSString *)s;
@end

```

Derived Classes in Objective-C

Note that, in the preceding example, the derivation of the Slice definitions is preserved for the generated classes: `EXBase` derives from `ICEObject`, and `EXDerived` derives from `EXBase`. This allows you to treat and pass classes polymorphically: you can always pass an `EXDerived` instance where an `EXBase` instance is expected.

Passing Classes as Parameters in Objective-C

Classes are passed by pointer, like any other Objective-C object. For example, here is an operation that accepts a `Base` as an in-parameter and returns a `Derived`:

Slice

```
Derived getDerived(Base d);
```

The corresponding proxy method looks as follows:

Objective-C

```
-(EXDerived *) getDerived:(EXBase *)d;
```

To pass a null instance, you simply pass `nil`.

Operations of Classes in Objective-C

If you look back at the code that is generated for the `EXTimeOfDay` class, you will notice that there is no indication at all that the class has a `format` operation. As opposed to proxies, classes do not implement any protocol that would define which operations are available. This means that you can partially implement the operations of a class. For example, you might have a Slice class with five operations that is returned from a server to a client. If the client uses only one of the five operations, the client-side code needs to implement only that one operation and can leave the remaining four operations without implementation. (If the class were to implement a mandatory protocol, the client-side code would have to implement all operations in order to avoid a compiler warning.)

Of course, you must implement those operations that you actually intend to call. The mapping of operations for classes follows the *server-side* mapping for operations on interfaces: parameter types and labels are exactly the same. (See [Parameter Passing in Objective-C](#) for details.) In a nutshell, the server-side mapping is the same as the client-side mapping except that, for types that have mutable and immutable variants, they map to the immutable variant where the client-side mapping uses the mutable variant, and vice versa.

For example, here is how we could implement the `format` operation of our `TimeOfDay` class:

Objective-C

```

@interface TimeOfDayI : EXTimeOfDay
@end

@implementation TimeOfDayI
-(NSString *) format
{
    return [NSString stringWithFormat:@"%02d:%02d:%02d",
self.hour, self.minute, self.second];
}
@end

```

By convention, the implementation of classes with operations has the same name as the Slice class with an `I`-suffix. Doing this is not mandatory — you can call your implementation class anything you like. However, if you do not want to use the `I`-suffix naming, we recommend that you adopt another naming convention and follow it consistently.

Note that `TimeOfDayI` derives from `EXTimeOfDay`. This is because, as we will see in a moment, the Ice run time will instantiate a `TimeOfDayI` instance whenever it receives a `TimeOfDay` instance over the wire and expects that instance to provide the properties of `EXTimeOfDay`.

Class Factories in Objective-C

Having created a class such as `TimeOfDayI`, we have an implementation and we can instantiate the `TimeOfDayI` class, but we cannot receive it as the return value or as an out-parameter from an operation invocation. To see why, consider the following simple interface:

Slice

```

interface Time {
    TimeOfDay get();
};

```

When a client invokes the `get` operation, the Ice run time must instantiate and return an instance of the `TimeOfDayI` class. However, unless we tell it, the Ice run time cannot magically know that we have created a `TimeOfDayI` class that implements a `format` method. To allow the Ice run time to instantiate the correct object, we must provide a factory that knows that the Slice `TimeOfDay` class is implemented

by our `TimeOfDayI` class. The `Ice::Communicator` interface provides us with the necessary operations:

```

Slice

["objc:prefix:ICE"]
module Ice {
    local interface ObjectFactory {
        Object create(string type);
        void destroy();
    };

    local interface Communicator {
        void addObjectFactory(ObjectFactory factory, string id);
        ObjectFactory findObjectFactory(string id);
        // ...
    };
};

```

To supply the Ice run time with a factory for our `TimeOfDayI` class, we must implement the `ObjectFactory` interface:

```

Slice

module Ice {
    local interface ObjectFactory {
        Object create(string type);
        void destroy();
    };
};

```

The object factory's `create` operation is called by the Ice run time when it needs to instantiate a `TimeOfDay` class. The factory's `destroy` operation is called by the Ice run time when its communicator is destroyed. A possible implementation of our object factory is:

```

Objective-C

@interface ObjectFactory<ICEObjectFactory>
@end

@implementation ObjectFactory
-(ICEObject*) create:(NSString *)type
{
    NSAssert([type isEqualToString:@"::Example::TimeOfDay"]);
    return [[TimeOfDayI alloc] init];
}
@end

```

The `create` method is passed the `type ID` of the class to instantiate. For our `TimeOfDay` class, the type ID is `"::Example::TimeOfDay"`.

Our implementation of `create` checks the type ID: if it is `"::Example::TimeOfDay"`, it instantiates and returns a `TimeOfDayI` object. For other type IDs, it asserts because it does not know how to instantiate other types of objects.

Note that your factory *must not* autorelease the returned instance. The Ice run time takes care of the necessary memory management activities on your behalf.

Given a factory implementation, such as our `ObjectFactory`, we must inform the Ice run time of the existence of the factory:

Objective-C

```
id<ICECommunicator> ice = ...;
ObjectFactory *factory = [[[ObjectFactory alloc] init] autorelease];
[ic addObjectFactory:factory sliceId:@"::Example::TimeOfDay"];
```

Now, whenever the Ice run time needs to instantiate a class with the type ID `"::Example::TimeOfDay"`, it calls the `create` method of the registered `ObjectFactory` instance.

The `destroy` operation of the object factory is invoked by the Ice run time when the communicator is destroyed. This gives you a chance to clean up any resources that may be used by your factory. Do not call `destroy` on the factory while it is registered with the communicator — if you do, the Ice run time has no idea that this has happened and, depending on what your `destroy` implementation is doing, may cause undefined behavior when the Ice run time tries to next use the factory.

The run time guarantees that `destroy` will be the last call made on the factory, that is, `create` will not be called concurrently with `destroy`, and `create` will not be called once `destroy` has been called. However, the Ice run time may make concurrent calls to `create`.

Note that you cannot register a factory for the same type ID twice: if you call `addObjectFactory` with a type ID for which a factory is registered, the Ice run time throws an `AlreadyRegisteredException`.

Finally, keep in mind that if a class has only data members, but no operations, you need not (but can) create and register an object factory to transmit instances of such a class. Only if a class has operations do you have to define and register an object factory.

Using a Category to Implement Operations in Objective-C

An alternative to registering a class factory is to use an Objective-C category to implement operations. For example, we could have implemented our `format` method using a category instead:

Objective-C

```
@interface EXTimeOfDay (TimeOfDayI)
@end

@implementation EXTimeOfDay (TimeOfDayI)
-(NSString *) format
{
    return [NSString stringWithFormat:@"%0.2d:%0.2d:%0.2d",
self.hour, self.minute, self.second];
}
@end
```

In this case, there is no need to derive from the generated `EXTimeOfDay` class because we provide the `format` implementation as a category. There is also no need to register a class factory: the Ice run time instantiates an `EXTimeOfDay` instance when a `TimeOfDay` instance arrives over the wire, and the `format` method is found at run time when it is actually called.

This is a viable alternative approach to implement class operations. However, keep in mind that, if the operation implementation requires use of instance variables that are not defined as part of the Slice definitions of a class, you cannot use this approach because Objective-C categories do not permit you to add instance variables to a class.

Copying of Classes in Objective-C

Classes implement `NSCopying`. The behavior is the same as for structures: instance variables of value type are copied by assignment, instance variables of pointer type are copied by calling `retain`, that is, the copy is shallow. To illustrate this, consider the following class definition:

```

class Node {
    int i;
    string s;
    Node next;
};

```

We can initialize two instances of type `EXNode` as follows:

```

NSString lastString = [NSString stringWithString:@"last"];
EXNode *last = [EXNode node:99 s:lastString next:nil];

NSString firstString = [NSString stringWithString:@"first"];
EXNode *first = [EXNode node:1 s:firstString next:last];

```

This creates the situation shown below:

Two instances of type `EXNode`.

Now we create a copy of the first node by calling `copy`:

Objective-C

```
EXNode *copy = [[first copy] autorelease];
```

This creates the situation shown here:

EXNode instances after calling copy on first.

As you can see, the first node is copied, but the last node (pointed at by the `next` instance variable of the first node) is not copied; instead, `first` and `copy` now both have their `next` instance variable point at the same last node, and both point at the same string.

Cyclic References in Objective-C

One thing to be aware of are cyclic references among classes. As an example, we can easily create a cycle by executing the following statements:

Objective-C

```
EXNode *first = [EXNode node];
EXNode *last = [EXNode node];
first.next = last;
last.next = first;
```

This makes the `next` instance variable of the two classes point at each other, creating the cycle shown below:

Two nodes with cyclic references.

There is no problem with sending this class graph as a parameter. For example, you could pass either `first` or `last` as a parameter to an operation and, in the server, the Ice run time will faithfully rebuild the corresponding graph, preserving the cycle. However, if a server returns such a graph from an operation invocation as the return value or as an out-parameter, all class instances that are part of a cycle are leaked. The same is true on the client side: if you receive such a graph from an operation invocation and do not explicitly break the cycle, you will leak all instances that form part of the cycle.

Because it is difficult to break cycles manually (and, on the server side, for return values and out-parameters, it is impossible to break them), we recommend that you avoid cyclic references among classes.

A future version of the Objective-C run time may provide a garbage collection facility similar to the one provided with the C++ mapping.

Objective-C Mapping for Interfaces by Value

Slice permits you to pass an *interface* by value:

Slice
<pre> interface ClassBase { void someOp(); // ... }; interface Processor { ClassBase process(ClassBase b); }; class SomeClass implements ClassBase { // ... }; </pre>

Note that `process` accepts and returns a value of type `ClassBase`. This is *not* the same as passing `id<ClassBasePrx>`, which is a *proxy* to an object of type `ClassBase` that is possibly remote. Instead, what is passed here is an *interface*, and the interface is passed by *value*.

The immediate question is "what does this mean?" After all, interfaces are abstract and, therefore, it is impossible to pass an interface by value. The answer is that, while an interface cannot be passed, what *can* be passed is a class that implements the interface. That class is type-compatible with the formal parameter type and, therefore, can be passed by value. In the preceding example, `SomeClass` implements `ClassBase` and, hence, can be passed to and returned from the `process` operation.

The Objective-C mapping maps interface-by-value parameters to `ICEObject*`, regardless of the type of the interface. For example, the proxy protocol for the `process` operation is:

Objective-C
<pre> -(ICEObject *) process:(ICEObject *)b; </pre>

This means that you can pass a class of any type to the operation, even if it is not type-compatible with the formal parameter type, because all classes derive from `ICEObject`. However, an invocation of `process` is still type-safe at run time: the Ice run time verifies that the class instance that is passed implements the specified interface; if not, the invocation throws an `ICEMarshalException`.

Passing interfaces by value as `ICEObject*` is a consequence of the decision to not generate a formal protocol for classes. (If such a protocol would exist, the formal parameter type could be `id<ProtocolName>`. However, as we described for the [class mapping](#), a protocol would require the implementation of a class to implement all of its operations, which can be inconvenient. Because it is rare to pass interfaces by value (more often, the formal parameter type will be a base *class* instead of a base *interface*), the minor loss of static type safety is an acceptable trade-off.

Objective-C Mapping for Optional Data Members

The Objective-C mapping for [optional data members](#) in Slice classes and [exceptions](#) adds an extra boolean instance variable as well as two selectors for testing if the optional is set and clearing its value. The argument for the optional data member in the convenience constructor is mapped according to the [optional parameter mapping](#) for Slice operations. Consider the following Slice definition:

Slice
<pre>class C { string name; optional(2) string alternateName; optional(5) bool active; };</pre>

The generated Objective-C code provides the following API:

Objective-C
<pre>@interface testC : ICEObject { NSString *name; NSString *alternateName; BOOL has_alternateName__; BOOL active; BOOL has_active__; } @property(nonatomic, ICE_STRONG_ATTR) NSString *name; @property(nonatomic, ICE_STRONG_ATTR) NSString *alternateName; @property(nonatomic, assign) BOOL active; -(id) init:(NSString*)name alternateName:(id)alternateName active:(id)active; +(id) c:(NSString*)name alternateName:(id)alternateName active:(id)active; +(id) c; -(void)setAlternateName:(NSString*)alternateName_p; -(BOOL)hasAlternateName; -(void)clearAlternateName; -(void)setActive:(BOOL)active_p; -(BOOL)hasActive; -(void)clearActive; @end</pre>

Note that calling a `get` method or accessing the property when the value is not currently set returns an undefined value.

Asynchronous Method Invocation (AMI) in Objective-C

Asynchronous Method Invocation (AMI) is the term used to describe the client-side support for the asynchronous programming model. AMI supports both oneway and twoway requests, but unlike their synchronous counterparts, AMI requests never block the calling thread. When a client issues an AMI request, the Ice run time hands the message off to the local transport buffer or, if the buffer is currently full, queues the request for later delivery. The application can then continue its activities and poll or wait for completion of the invocation, or receive a callback when the invocation completes.

AMI is transparent to the server: there is no way for the server to tell whether a client sent a request synchronously or asynchronously.

Basic Asynchronous API in Objective-C

Consider the following simple Slice definition:

Slice

```

module Demo {
    interface Employees {
        string getName(int number);
    };
};

```

Proxy Methods for AMI in Objective-C

Besides the synchronous proxy methods, the Objective-C mapping generates the following asynchronous proxy methods:

Objective-C

```

-(id<ICEAsyncResult>) begin_getName:(ICEInt)number;

-(id<ICEAsyncResult>) begin_getName:(ICEInt)number
context:(ICEContext *)context;

-(id<ICEAsyncResult>) begin_getName:(ICEInt)number
response:(void(^)(NSMutableString*))response_
exception:(void(^)(ICEException*))exception_;

-(id<ICEAsyncResult>) begin_getName:(ICEInt)number
context:(ICEContext *)context
response:(void(^)(NSMutableString*))response_
exception:(void(^)(ICEException*))exception_;

-(id<ICEAsyncResult>) begin_getName:(ICEInt)number
response:(void(^)(NSMutableString*))response_
exception:(void(^)(ICEException*))exception_
sent:(void(^)(BOOL))sent_;

-(id<ICEAsyncResult>) begin_getName:(ICEInt)number
context:(ICEContext *)context
response:(void(^)(NSMutableString*))response_
exception:(void(^)(ICEException*))exception_
sent:(void(^)(BOOL))sent_;

-(NSMutableString *) end_getName:(id<ICEAsyncResult>)result;

```

As you can see, the single `getName` operation results in several `begin_getName` methods as well as an `end_getName` method. The `begin_` methods optionally accept a [per-invocation context](#) and [callbacks](#).

- The `begin_getName` methods send (or queue) an invocation of `getName`. These methods do not block the calling thread.
- The `end_getName` method collects the result of the asynchronous invocation. If, at the time the calling thread calls `end_getName`, the result is not yet available, the calling thread blocks until the invocation completes. Otherwise, if the invocation completed some time before the call to `end_getName`, the method returns immediately with the result.

A client could call these methods as follows:

Objective-C

```

id<EXEmployeesPrx> e = [EXEmployeesPrx checkedCast:...];
id<ICEAsyncResult> r = [e begin_getName:99]

// Continue to do other things here...

NSString* name = [e end_getName:r];

```

Because `begin_getName` does not block, the calling thread can do other things while the operation is in progress.

Note that `begin_getName` returns a value of type `id<ICEAsyncResult>`. This value contains the state that the Ice run time requires to keep track of the asynchronous invocation. You must pass the `id<ICEAsyncResult>` that is returned by the `begin_` method to the corresponding `end_` method.

The `begin_` method has one parameter for each in-parameter of the corresponding Slice operation. The `end_` method accepts the `id<ICEAsyncResult>` object as its only argument and returns the out-parameters using the [same semantics](#) as for regular synchronous invocations. For example, consider the following operation:

```
Slice
```

```
double op(int inp1, string inp2, out bool outp1, out long outp2);
```

The `begin_op` and `end_op` methods have the following signature:

```
Objective-C
```

```
-(id<ICEAsyncResult>) begin_op:(ICEInt)inp1 inp2:(NSString *)inp2;
-(ICEDouble) end_op:(BOOL*)outp1 outp2:(ICELong*)outp2
result:(id<ICEAsyncResult>)result;
```

The call to `end_op` returns the out-parameters as follows:

```
Objective-C
```

```
BOOL outp1;
ICELong outp2;
ICEDouble doubleValue = [p end_op:&outp1 outp2:&outp2 result:result];
```

Exception Handling for AMI in Objective-C

If an invocation raises an exception, the exception is thrown by the `end_` method, even if the actual error condition for the exception was encountered during the `begin_` method ("on the way out"). The advantage of this behavior is that all exception handling is located with the code that calls the `end_` method (instead of being present twice, once where the `begin_` method is called, and again where the `end_` method is called).

There is one exception to the above rule: if you destroy the communicator and then make an asynchronous invocation, the `begin_` method throws `ICECommunicatorDestroyedException`. This is necessary because, once the run time is finalized, it can no longer throw an exception from the `end_` method.

The only other exception that is thrown by the `begin_` and `end_` methods is `NSException` with the `NSInvalidArgumentException` name. This exception indicates that you have used the API incorrectly. For example, the `begin_` method throws this exception if you call an operation that has a return value or out-parameters on a oneway proxy. Similarly, the `end_` method throws this exception if you use a different proxy to call the `end_` method than the proxy you used to call the `begin_` method, or if the `id<ICEAsyncResult>` you pass to the `end_` method was obtained by calling the `begin_` method for a different operation.

The `ICEAsyncResult` Protocol in Objective-C

The `id<ICEAsyncResult>` that is returned by the `begin_` method encapsulates the state of the asynchronous invocation:

Objective-C

```

@protocol ICEAsyncResult <NSObject>
-(id<ICECommunicator>) getCommunicator;
-(id<ICEConnection>) getConnection;
-(id<ICEObjectPrx>) getProxy;

-(BOOL) isCompleted;
-(void) waitForCompleted;

-(BOOL) isSent;
-(void) waitForSent;

-(BOOL) sentSynchronously;
-(NSString*) getOperation;
@end

```

The methods have the following semantics:

- `getCommunicator`
This method returns the communicator that sent the invocation.
- `getConnection`
This method returns the connection that was used for the invocation. Note that, for typical asynchronous proxy invocations, this method returns a nil value because the possibility of automatic retries means the connection that is currently in use could change unexpectedly. The `getConnection` method only returns a non-nil value when the `ICEAsyncResult` is obtained by calling `begin_flushBatchRequests` on a `Connection` object.
- `getProxy`
This method returns the proxy that was used to call the `begin_` method, or nil if the `ICEAsyncResult` was not obtained via an asynchronous proxy invocation.
- `getOperation`
This method returns the name of the operation.
- `isCompleted`
This method returns true if, at the time it is called, the result of an invocation is available, indicating that a call to the `end_` method will not block the caller. Otherwise, if the result is not yet available, the method returns false.
- `waitForCompleted`
This method blocks the caller until the result of an invocation becomes available.
- `isSent`
When you call the `begin_` method, the Ice run time attempts to write the corresponding request to the client-side transport. If the transport cannot accept the request, the Ice run time queues the request for later transmission. `isSent` returns true if, at the time it is called, the request has been written to the local transport (whether it was initially queued or not). Otherwise, if the request is still queued, `isSent` returns false.
- `waitForSent`
This method blocks the calling thread until a request has been written to the client-side transport.
- `sentSynchronously`
This method returns true if a request was written to the client-side transport without first being queued. If the request was initially queued, `sentSynchronously` returns false (independent of whether the request is still in the queue or has since been written to the client-side transport).

Polling for Completion in Objective-C

The `ICEAsyncResult` methods allow you to poll for call completion. Polling is useful in a variety of cases. As an example, consider the following simple interface to transfer files from client to server:

Slice

```
interface FileTransfer
{
    void send(int offset, ByteSeq bytes);
};
```

The client repeatedly calls `send` to send a chunk of the file, indicating at which offset in the file the chunk belongs. A naïve way to transmit a file would be along the following lines:

Objective-C

```
NSInputStream* stream = ...
id<EXFileTransferPrx> ft = [EXFileTransferPrx checkedCast:...];
int chunkSize = ...;
int offset = 0;
while([stream hasBytesAvailable])
{
    char bytes[chunkSize];
    int l = [stream read:bytes maxLength:sizeof(bytes)];
    if(l > 0)
    {
        [ft send:offset bytes:[ByteSeq dataWithBytes:bytes length:l]];
        offset += l;
    }
}
```

This works, but not very well: because the client makes synchronous calls, it writes each chunk on the wire and then waits for the server to receive the data, process it, and return a reply before writing the next chunk. This means that both client and server spend much of their time doing nothing — the client does nothing while the server processes the data, and the server does nothing while it waits for the client to send the next chunk.

Using asynchronous calls, we can improve on this considerably:

Objective-C

```

NSInputStream* stream = ...
id<EXFileTransferPrx> ft = [EXFileTransferPrx checkedCast:...];
int chunkSize = ...;
int offset = 0;
NSMutableArray* results = [NSMutableArray arrayWithCapacity:5];
int numRequests = 5;
while([stream hasBytesAvailable])
{
    char bytes[chunkSize];
    int l = [stream read:bytes maxLength:sizeof(bytes)];
    if(l > 0)
    {
        // Send up to numRequests + 1 chunks asynchronously.
        id<ICEAsyncResult> r =
            [ft begin_send:offset bytes:[ByteSeq dataWithBytes:bytes
length:l]];
        offset += l;

        // Wait until this request has been passed to the
        // transport.
        [r waitForSent];
        [results addObject:r];

        // Once there are more than numRequests, wait for the
        // least recent one to complete.
        while([results count] > numRequests)
        {
            r = [results objectAtIndex:0];
            [results removeObjectAtIndex:0];
            [r waitForCompleted];
        }
    }
}

// Wait for any remaining requests to complete.
for(id<ICEAsyncResult> r in results)
{
    [r waitForCompleted];
}

```

With this code, the client sends up to `numRequests + 1` chunks before it waits for the least recent one of these requests to complete. In other words, the client sends the next request without waiting for the preceding request to complete, up to the limit set by `numRequests`. In effect, this allows the client to "keep the pipe to the server full of data": the client keeps sending data, so both client and server continuously do work.

Obviously, the correct chunk size and value of `numRequests` depend on the bandwidth of the network as well as the amount of time taken by the server to process each request. However, with a little testing, you can quickly zoom in on the point where making the requests larger or queuing more requests no longer improves performance. With this technique, you can realize the full bandwidth of the link to within a

percent or two of the theoretical bandwidth limit of a native socket connection.

Completion Callbacks in Objective-C

The `begin_` method accepts three optional callback arguments that allow you to be notified asynchronously when a request completes. Here is the signature of the `begin_getName` method that we saw [earlier](#):

Objective-C

```

-(id<ICEAsyncResult>) begin_getName:(ICEInt)number
    response:(void(^)(NSMutableString*))response_
    exception:(void(^)(ICEException*))exception_;

-(id<ICEAsyncResult>) begin_getName:(ICEInt)number
    context:(ICEContext *)context
    response:(void(^)(NSMutableString*))response_
    exception:(void(^)(ICEException*))exception_;

-(id<ICEAsyncResult>) begin_getName:(ICEInt)number
    response:(void(^)(NSMutableString*))response_
    exception:(void(^)(ICEException*))exception_
    sent:(void(^)(BOOL))sent_;

-(id<ICEAsyncResult>) begin_getName:(ICEInt)number
    context:(ICEContext *)context
    response:(void(^)(NSMutableString*))response_
    exception:(void(^)(ICEException*))exception_
    sent:(void(^)(BOOL))sent_;

```

The value you pass for the response callback (`response`), the exception callback (`exception`), or the sent callback (`sent`) argument must be an Objective-C block. The response callback is invoked when the request completes successfully, and the exception callback is invoked when the operation raises an exception. (The sent callback is primarily used for [flow control](#).)

For example, consider the following callbacks for an invocation of the `getName` operation:

Objective-C

```

void(^getNameCB)(NSMutableString*) = ^(NSMutableString* name)
{
    NSLog(@"Name is: %@", name);
};

void(^failureCB)(ICEException*) = ^(ICEException* ex)
{
    NSLog(@"Exception is: %@", [ex description]);
};

```

The response callback parameters depend on the operation signature. If the operation has a non-void return type, the first parameter of the response callback is the return value. The return value (if any) is followed by a parameter for each out-parameter of the corresponding Slice

operation, in the order of declaration.

The exception callback is called if the invocation fails because of an Ice run time exception, or if the operation raises a user exception.

To inform the Ice run time that you want to receive callbacks for the completion of the asynchronous call, you pass the callbacks to the `begin_` method:

Objective-C

```
e = [EmployeesPrx checkedCast:...]  
  
[e begin_getName:99 response:getNameCB exception:failureCB];
```

You can also pass the Objective-C blocks directly to the call:

Objective-C

```
[e begin_getName:99  
  response: ^(NSMutableString* name)  
            {  
                NSLog(@"Name is: %@", name);  
            }  
  exception: ^(ICEException* ex)  
            {  
                NSLog(@"Exception is: %@", [ex description]);  
            }  
];
```

Ice enforces the following semantics at run time regarding which callbacks can be optionally specified with a `nil` value:

- You must supply an exception callback.
- You may omit the response callback for an operation that returns no data (that is, an operation with a void return type and no out-parameters).

Memory Management

The Ice run time creates an `NSAutoReleasePool` object before dispatching a completion callback. The pool is released once the dispatch is complete

Oneway Invocations in Objective-C

You can invoke operations via oneway proxies asynchronously, provided the operation has `void` return type, does not have any out-parameters, and does not raise user exceptions. If you call the `begin_` method on a oneway proxy for an operation that returns values or raises a user exception, the `begin_` method throws `NSException` with the `NSInvalidArgumentException` name.

The callback signatures look exactly as for a twoway invocation, but the response block is never called and may be `nil`.

Flow Control in Objective-C

Asynchronous method invocations never block the thread that calls the `begin_` method: the Ice run time checks to see whether it can write

the request to the local transport. If it can, it does so immediately in the caller's thread. (In that case, `[ICEAsyncResult sentSynchronously]` returns true.) Alternatively, if the local transport does not have sufficient buffer space to accept the request, the Ice run time queues the request internally for later transmission in the background. (In that case, `[ICEAsyncResult sentSynchronously]` returns false.)

This creates a potential problem: if a client sends many asynchronous requests at the time the server is too busy to keep up with them, the requests pile up in the client-side run time until, eventually, the client runs out of memory.

The API provides a way for you to implement flow control by counting the number of requests that are queued so, if that number exceeds some threshold, the client stops invoking more operations until some of the queued operations have drained out of the local transport.

You can supply a sent callback to be notified when the request was successfully sent:

```

Objective-C

```
void(^sentCB)(BOOL) = ^(BOOL sentSynchronously)
{
 ...
}
```

```

You inform the Ice run time that you want to be notified when a request has been passed to the local transport as usual:

```

Objective-C

```
[e begin_getName:99 response:getNameCB exception:failureCB sent:sentCB];
```

```

If the Ice run time can immediately pass the request to the local transport, it does so and invokes the sent callback from the thread that calls the `begin_` method. On the other hand, if the run time has to queue the request, it calls the sent callback from a different thread once it has written the request to the local transport. The boolean `sentSynchronously` parameter indicates whether the request was sent synchronously or was queued.

The sent callback allows you to limit the number of queued requests by counting the number of requests that are queued and decrementing the count when the Ice run time passes a request to the local transport.

Batch Requests in Objective-C

Applications that send [batched requests](#) can either flush a batch explicitly or allow the Ice run time to flush automatically. The proxy method `ice_flushBatchRequests` performs an immediate flush using the synchronous invocation model and may block the calling thread until the entire message can be sent. Ice also provides asynchronous versions of this method so you can flush batch requests asynchronously.

`begin_ice_flushBatchRequests` and `end_ice_flushBatchRequests` are proxy methods that flush any batch requests queued by that proxy.

In addition, similar methods are available on the communicator and the `Connection` object that is returned by `[ICEAsyncResult getConnection]`. These methods flush batch requests sent via the same communicator and via the same connection, respectively.

Concurrency in Objective-C

The Ice run time always invokes your callback methods from a separate thread, with one exception: it calls the sent callback from the thread calling the `begin_` method if the request could be sent synchronously. In the sent callback, you know which thread is calling the callback by looking at the `sentSynchronously` parameter.

slice2objc Command-Line Options

The Slice-to-Objective-C compiler, `slice2objc`, offers the following command-line options in addition to the [standard options](#):

- `--include-dir DIR`
Modifies `#import` directives in source files to prepend the path name of each header file with the directory `DIR`.
- `--dll-export MACRO`
Use `MACRO` to control the export of symbols from dynamic shared libraries. This option allows you to export symbols from the generated code and place such generated code in a shared library. Compiling a Slice definition with:

```
$ slice2objc --dll-export WIDGET_API x.ice
```

adds the provided `MACRO` name (`WIDGET_API` in our example) to the declaration of interfaces and protocols that need to be exported.

The generated code also defines the provided `MACRO` as `__attribute__((visibility ("default")))`.

This option is useful when you create a shared library and compile your Objective-C code with `-fvisibility=hidden` to reduce the number of symbols exported.

Example of a File System Client in Objective-C

This page presents a very simple client to access a server that implements the file system we developed in [Slice for a Simple File System](#). The Objective-C code shown here hardly differs from the code you would write for an ordinary Objective-C program. This is one of the biggest advantages of using Ice: accessing a remote object is as easy as accessing an ordinary, local Objective-C object. This allows you to put your effort where you should, namely, into developing your application logic instead of having to struggle with arcane networking APIs. This is true for the [server side](#) as well, meaning that you can develop distributed applications easily and efficiently.

We now have seen enough of the client-side Objective-C mapping to develop a complete client to access our remote file system. For reference, here is the Slice definition once more:

Slice

```

["objc:prefix:FS"]
module Filesystem {
    exception GenericError {
        string reason;
    };

    interface Node {
        idempotent string name();
    };

    sequence<string> Lines;

    interface File extends Node {
        idempotent Lines read();
        idempotent void write(Lines text) throws GenericError;
    };

    sequence<Node*> NodeSeq;

    interface Directory extends Node {
        idempotent NodeSeq list();
    };
};

```

To exercise the file system, the client does a recursive listing of the file system, starting at the root directory. For each node in the file system, the client shows the name of the node and whether that node is a file or directory. If the node is a file, the client retrieves the contents of the file and prints them.

The body of the client code looks as follows:

Objective-C

```

#import <Ice/Ice.h>
#import <Filesystem.h>

#import <Foundation/NSAutoreleasePool.h>
#import <stdio.h>

static void
listRecursive(id<FSDirectoryPrx> dir, int depth)
{
    // ...
}

int
main(int argc, char* argv[])
{
    NSAutoreleasePool * pool = [[NSAutoreleasePool alloc] init];
    int status = 1;
    id<ICECommunicator> communicator;
    @try
    {
        communicator = [ICEUtil createCommunicator:&argc argv:argv];

        // Create a proxy for the root directory
        //
        id<FSDirectoryPrx> rootDir = [FSDirectoryPrx checkedCast:
            [communicator stringToProxy:
@"RootDir:default -p 10000"]];
        if (!rootDir)
            [NSException raise:@"invalid proxy" format:@"nil"];

        // Recursively list the contents of the root directory
        //
        printf("Contents of root directory:\n");
        listRecursive(rootDir, 0);

        status = 0;
    } @catch (NSException *ex) {
        NSLog(@"%@ \n", [ex name]);
    }

    @try {
        [communicator destroy];
    } @catch (NSException* ex) {
        NSLog(@"%@ \n", [ex name]);
    }

    [pool release];
    return status;
}

```

1. The code imports a few header files:
 - `Ice/Ice.h`: Always included in both client and server source files, provides definitions that are necessary for accessing the Ice run time.
 - `Filesystem.h`: The header that is generated by the Slice compiler from the Slice definitions in `Filesystem.ice`.
 - `NSAutoreleasePool.h`: The client uses an autorelease pool to reclaim memory before it exits.
 - `stdio.h`: The implementation of `listRecursive` prints to `stdout`.
2. The structure of the code in `main` follows what we saw in [Hello World Application](#). After initializing the run time, the client creates a proxy to the root directory of the file system. For this example, we assume that the server runs on the local host and listens using the default protocol (TCP/IP) at port 10000. The object identity of the root directory is known to be `RootDir`.
3. The client down-casts the proxy to `DirectoryPrx` and passes that proxy to `listRecursive`, which prints the contents of the file system.

Most of the work happens in `listRecursive`:

Objective-C

```

// Print the specified number of tabs.

static void
printIndent(int depth)
{
    while (depth-- > 0)
        putchar('\t');
}

// Recursively print the contents of directory "dir" in tree
// fashion.  For files, show the contents of each file.
// The "depth" parameter is the current nesting level
// (for indentation).

static void
listRecursive(id<FSDirectoryPrx> dir, int depth)
{
    ++depth;
    FSNodeSeq *contents = [dir list];

    for (id<FSNodePrx> node in contents) {
        id<FSDirectoryPrx> dir = [FSDirectoryPrx checkedCast:node];
        id<FSFilePrx> file = [FSFilePrx uncheckedCast:node];
        printIndent(depth);
        printf("%s%s\n", [[node name] UTF8String],
            (dir ? " (directory):" : " (file):"));
        if (dir) {
            listRecursive(dir, depth);
        } else {
            FSLines *text = [file read];
            for (NSString *line in text) {
                printIndent(depth);
                printf("\t%s\n", [line UTF8String]);
            }
        }
    }
}

```

The function is passed a proxy to a directory to list, and an indent level. (The indent level increments with each recursive call and allows the code to print the name of each node at an indent level that corresponds to the depth of the tree at that node.) `listRecursive` calls the `list` operation on the directory and iterates over the returned sequence of nodes:

1. The code does a `checkedCast` to narrow the `Node` proxy to a `Directory` proxy, as well as an `uncheckedCast` to narrow the `Node` proxy to a `File` proxy. Exactly one of those casts will succeed, so there is no need to call `checkedCast` twice: if the `Node` *is-a* `Directory`, the code uses the `id<FSDirectoryPrx>` returned by the `checkedCast`; if the `checkedCast` fails, we *know* that the `Node` *is-a* `File` and, therefore, an `uncheckedCast` is sufficient to get an `id<FSFilePrx>`. In general, if you know that a down-cast to a specific type will succeed, it is preferable to use an `uncheckedCast` instead of a `checkedCast` because an `uncheckedCast` does not incur any network traffic.

2. The code prints the name of the file or directory and then, depending on which cast succeeded, prints "(directory)" or "(file)" following the name.
3. The code checks the type of the node:
 - If it is a directory, the code recurses, incrementing the indent level.
 - If it is a file, the code calls the `read` operation on the file to retrieve the file contents and then iterates over the returned sequence of lines, printing each line.

Assume that we have a small file system consisting of two files and a directory as follows:

A small file system.

The output produced by the client for this file system is:

```

Contents of root directory:
  README (file):
    This file system contains a collection of poetry.
  Coleridge (directory):
    Kubla_Khan (file):
      In Xanadu did Kubla Khan
      A stately pleasure-dome decree:
      Where Alph, the sacred river, ran
      Through caverns measureless to man
      Down to a sunless sea.
  
```

Note that, so far, our client (and server) are not very sophisticated:

- The protocol and address information are hard-wired into the code.
- The client makes more remote procedure calls than strictly necessary; with minor redesign of the Slice definitions, many of these calls can be avoided.

We will see how to address these shortcomings in our discussions of [IceGrid](#) and [object life cycle](#).

Server-Side Slice-to-Objective-C Mapping

The mapping for Slice data types to Objective-C is identical on the client side and server side, except for operation parameters, which map slightly differently for types that have mutable and immutable variants (strings, sequence, and dictionaries). This means that the mappings in the [Client-Side Slice-to-Objective-C Mapping](#) also apply to the server side. However, for the server side, there are a few additional things you need to know — specifically, how to:

- Initialize and finalize the server-side run time
- Implement servants
- Pass parameters and throw exceptions
- Create servants and register them with the Ice run time.

Although the examples we present are very simple, they accurately reflect the basics of writing an Ice server. Of course, for more sophisticated servers, you will be using [additional APIs](#), for example, to improve performance or scalability. However, these APIs are all described in Slice, so, to use these APIs, you need not learn any Objective-C mapping rules beyond those described here.

The Server-Side main Function in Objective-C

This page discusses how to initialize and finalize the server-side run time.

On this page:

- [Initializing and Finalizing the Server-Side Run Time](#)
- [Alternative Ways to Create a Communicator in Objective-C](#)

Initializing and Finalizing the Server-Side Run Time

The main entry point to the Ice run time is represented by the local interface `ICECommunicator`. As for the client side, you must initialize the Ice run time by calling `createCommunicator` (a class method of the `ICEUtil` class) before you can do anything else in your server. `createCommunicator` returns an instance of type `id<ICECommunicator>`:

Objective-C

```

int
main(int argc, char* argv[])
{
    // ...
    id<ICECommunicator> communicator =
    [ICEUtil createCommunicator:&argc argv:argv];
    // ...
}

```

`createCommunicator` accepts a *pointer* to `argc` as well as `argv`. The class method scans the argument vector for any **command-line options** that are relevant to the Ice run time; any such options are removed from the argument vector so, when `createCommunicator` returns, the only options and arguments remaining are those that concern your application. If anything goes wrong during initialization, `createCommunicator` throws an exception.

Before leaving your `main` function, you *must* call `Communicator::destroy`. The `destroy` operation is responsible for finalizing the Ice run time. In particular, `destroy` waits for any operation implementations that are still executing in the server to complete. In addition, `destroy` ensures that any outstanding threads are joined with and reclaims a number of operating system resources, such as file descriptors and memory. Never allow your `main` function to terminate without calling `destroy` first; doing so has undefined behavior.

The general shape of our server-side `main` function is therefore as follows:

Objective-C

```

#import <Ice/Ice.h>

int
main(int argc, char* argv[])
{
    NSAutoreleasePool * pool = [[NSAutoreleasePool alloc] init];

    int status = 1;
    id<ICECommunicator> communicator = nil;
    @try {
        communicator = [ICEUtil createCommunicator:&argc argv:argv];

        // Server code here...

        status = 0;
    } @catch (NSEException* ex) {
        NSLog(@"%@", ex);
    }

    @try {
        [communicator destroy];
    } @catch (NSEException* ex) {
        NSLog(@"%@", ex);
    }

    [pool release];
    return status;
}

```

Note that the code places the call to `createCommunicator` into a `try` block and takes care to return the correct exit status to the operating system. Also note that the code creates and releases an autorelease pool. This ensures that memory will be released before the program terminates.

The `catch` handler for `NSEException` ensures that the communicator is destroyed regardless of whether the program terminates normally or due to an exception.

You must *not* release the communicator that is returned by `createCommunicator`. As for any operation that returns a pointer, the Ice run time calls `autorelease` on the returned instance, so you do not have to release it yourself.

This is also the reason why `createCommunicator` is not called `initialize` (as it is for other language mappings) — `initialize` would suggest that the return value must be released because the method name begins with `init`.

Alternative Ways to Create a Communicator in Objective-C

`createCommunicator` is provided in several versions that accept different arguments. Here is the complete list:

- `(id<ICECommunicator>) createCommunicator: (int*)argc argv:(char*[])argv initData:(ICEInitializationData*)initData;`

This is the designated initializer — the remaining versions of `createCommunicator` are implemented in terms of this initializer. As

for the version we saw in the preceding section, this version accepts a pointer to `argc` as well as `argv` and removes Ice-related `command-line options` from the argument vector. The `initData` argument allows you to pass additional initialization information to the Ice run time (see below).

- `+(id<ICECommunicator>) createCommunicator;`
This is equivalent to calling:
`[ICEUtil createCommunicator:nil argv:nil initData:nil];`
- `+(id<ICECommunicator>) createCommunicator: (int*)argc argv:(char*[])argv;`
This is equivalent to calling
`[ICEUtil createCommunicator:&argc argv:argv initData:nil];`
- `+(id<ICECommunicator>) createCommunicator: (ICEInitializationData*)initData`
This is equivalent to calling
`[ICEUtil createCommunicator:nil argv:nil initData:initData];`

The `initData` argument is of type `ICEInitializationData`. Even though it has no Slice definition, this class behaves as if it were a Slice structure with the following definition:

Slice

```

#include <Properties.ice>
#include <Logger.ice>

["objc:prefix:ICE"]
module Ice {
    dictionary<string, string> PrefixDict;

    local struct InitializationData {
        Ice::Properties properties;
        Ice::Logger logger;
    };
};

```

The `properties` member allows you to explicitly set `property values` for the communicator to be created. This is useful, for example, if you want to ensure that a particular property setting is always used by the communicator.

The `logger` member sets the `logger` that the Ice run time uses to log messages. If you do not set a logger (leaving the `logger` member as `nil`), the run time installs a default logger that calls `NSLog` to log messages.

Server-Side Objective-C Mapping for Interfaces

The server-side mapping for interfaces provides an up-call API for the Ice run time: by implementing methods in a servant class, you provide the hook that gets the thread of control from the Ice server-side run time into your application code.

On this page:

- [Skeleton Classes in Objective-C](#)
- [Servant Classes in Objective-C](#)
 - [Derived Servants in Objective-C](#)
 - [Delegate Servants in Objective-C](#)
 - [Memory Management](#)

Skeleton Classes in Objective-C

On the client side, interfaces map to [proxy protocols and classes](#). On the server side, interfaces map to *skeleton* protocols and classes. A skeleton is a class that has a method for each operation on the corresponding interface. For example, consider our [Slice definition](#) for the `Node` interface:

Slice

```
["objc:prefix:FS"]
module Filesystem {
    interface Node {
        idempotent string name();
    };
    // ...
};
```

The Slice compiler generates the following definition for this interface:

Objective-C

```
@protocol FSNode <ICEObject>
-(NSString *) name:(ICECurrent *)current;
@end

@interface FSNode : ICEObject
// ...
@end
```

As you can see, the server-side API consists of a protocol and a class, known as the *skeleton protocol* and *skeleton class*. The methods of the skeleton class are internal to the mapping, so they do not concern us here. The skeleton protocol defines one method for each Slice operation. As for the client-side mapping, the method name is the same as the name of the corresponding Slice operation. If the Slice operation has parameters or a return value, these are reflected in the generated method, just as they are for the client-side mapping. In addition, each method has an additional trailing parameter of type `ICECurrent`. This parameter provides additional information about an invocation to your server-side code.

As for the client-side mapping, the generated code reflects the fact that all Slice interfaces and classes ultimately derive from `Ice::Object`. As you can see, the generated protocol incorporates the `ICEObject` protocol, and the generated class derives from the `ICEObject` class.

Servant Classes in Objective-C

The Objective-C mapping supports two different ways to implement servants. You can implement a servant by deriving from the skeleton class and implementing the methods for the Slice operations in your derived class. Alternatively, you can use a delegate servant, which need not derive from the skeleton class.

Derived Servants in Objective-C

To provide an implementation for an Ice object, you can create a servant class that derives from the corresponding skeleton class. For example, to create a servant for the `Node` interface, you could write:

Objective-C

```

@interface NodeI : FSNode <FSNode>
{
    @private
        NSString *myName;
}

+(id) nodei:(NSString *)name;
@end

```

By convention, servant classes have the name of their interface with an `I`-suffix, so the servant class for the `Node` interface is called `NodeI`. (This is a convention only: as far as the Ice run time is concerned, you can choose any name you prefer for your servant classes.)

Note that `NodeI` derives from `FSNode`, that is, it derives from its skeleton class. In addition, it adopts the `FSNode` protocol. Adopting the protocol is not strictly necessary; however, if you do write your servants this way, the compiler emits a warning if you forget to implement one or more Slice operations for the corresponding interface, so we suggest that you make it a habit to always have your servant class adopt its skeleton protocol.

As far as Ice is concerned, the `NodeI` class must implement the single `name` method that is defined by its skeleton protocol. That way, the Ice run time gets a servant that can respond to the operation that is defined by its Slice interface. You can add other methods and instance variables as you see fit to support your implementation. For example, in the preceding definition, we added a `myName` instance variable and property, a convenience constructor, and `dealloc`. Not surprisingly, the convenience constructor initializes the `myName` instance variable, the `name` method returns the value of that variable, and `dealloc` releases it:

Objective-C

```

@implementation NodeI

+(id) nodei:(NSString *)name
{
    NodeI *instance = [[[NodeI alloc] init] autorelease];
    instance.myName = [[name copy] retain];
    return instance;
}

-(NSString *) name:(ICECurrent *)current
{
    return myName;
}

-(void) dealloc
{
    [myName release];
    [super dealloc];
}
@end

```

Delegate Servants in Objective-C

An alternate way to implement a servant is to use a delegate. `ICEObject` provides two constructors to do this:

Objective-C

```

@interface ICEObject : NSObject <ICEObject, NSCopying>
// ...
-(id) initWithDelegate:(id)delegate;
+(id) objectWithDelegate:(id)delegate;
@end

```

The `delegate` parameter specifies an object to which the servant will delegate operation invocations. That object need not derive from the skeleton class; the only requirement on the delegate is that it must have an implementation of the methods corresponding to the Slice operations that are called by clients. As for derived servants, we suggest that the delegate adopt the skeleton protocol, so the compiler will emit a warning if you forget to implement one or more Slice operations in the delegate.

The implementation of the Slice operations in a delegate servant is exactly the same as for a derived servant.

Delegate servants are useful if you need to derive your servant implementation from a base class in order to access some functionality. In that case, you cannot also derive the servant from the generated skeleton class. A delegate servant gets around Objective-C's single inheritance limitation and saves you having to write a servant class that forwards each operation invocation to the delegate.

Another use case are different interfaces that share their implementation. As an example, consider the following Slice definitions:

Slice

```
interface Intf1 {
    void op1();
};

interface Intf2 {
    void op2();
};
```

If `op1` and `op2` are substantially similar in their implementation and share common state, it can be convenient to implement the servants for `Intf1` and `Intf2` using a common delegate class:

Objective-C

```
@interface Intf1AndIntf2 : NSObject<EXIntf1, EXIntf2>
    +(id) intf1AndIntf2;
@end

@implementation Intf1AndIntf2
    +(id) intf1AndIntf2 { /*...*/ }
    -(void) op1:(ICECurrent*)current { /*...*/ }
    -(void) op2:(ICECurrent*)current { /*...*/ }
@end
```

See [Instantiating an Objective-C Servant](#) for an example of how to instantiate delegate servants.

Delegate servants do not permit you to override operations that are inherited from `ICEObject` (such as `ice_ping`). Therefore, if you want to override `ice_ping`, for example, to implement a [default servant](#), you must use a derived servant.

Memory Management

The Ice run time creates an `NSAutoReleasePool` object before dispatching server-side invocations. The pool is released once the dispatch is complete.

Parameter Passing in Objective-C

This page shows how to implement parameters for Slice operations in Objective-C.

On this page:

- [Implementing Parameters for Slice Operations in Objective-C](#)
- [Memory Management for Operations in Objective-C](#)

Implementing Parameters for Slice Operations in Objective-C

For each parameter of a Slice operation, the Objective-C mapping generates a corresponding parameter for the method in the skeleton. In addition, every method has an additional, trailing parameter of type `ICECurrent`. For example, the `name` operation of the `Node` interface has no parameters, but the `name` method of the `Node` skeleton protocol has a single parameter of type `ICECurrent`. We will ignore this parameter for now.

Parameter passing on the server side follows the rules for the client side (with one exception):

- In-parameters and the return value are passed by value or by pointer, depending on the parameter type.
- Out-parameters are passed by pointer-to-pointer.

The exception to the client-side rules concerns types that come in mutable and immutable variants (strings, sequences, and dictionaries). For these, the server-side mapping passes the mutable variant where the client-side passes the immutable variant, and vice versa.

To illustrate the rules, consider the following interface that passes string parameters in all possible directions:

Slice

```
interface Intf {
    string op(string sin, out string sout);
};
```

The generated skeleton protocol for this interface looks as follows:

Objective-C

```
@protocol EXIntf <ICEObject>
-(NSString *) op:(NSMutableString *)sin
                sout:(NSString **)sout
                current:(ICECurrent *)current;

@end
```

As you can see, the in-parameter `sin` is of type `NSMutableString`, and the out parameter and return value are passed as `NSString` (the opposite of the client-side mapping). This means that in-parameters are passed to the servant as their mutable variant, and it is safe for you to modify such in-parameters. This is useful, for example, if a client passes a sequence to the operation, and the operation returns the sequence with a few minor changes. In that case, there is no need for the operation implementation to copy the sequence. Instead, you can simply modify the passed sequence as necessary and return the modified sequence to the client.

Here is an example implementation of the operation:

Objective-C

```

-(NSString *) op:(NSMutableString *)sin
               sout:(NSString **)sout
               current:(ICECurrent *)current
{
    printf("%s\n", [sin UTF8String]); // In-params are initialized
    *sout = [sin appendString:@"appended"]; // Assign out-param
    return @"Done"; // Return a string
}

```

Memory Management for Operations in Objective-C

To avoid leaking memory, you must be aware of how the Ice run time manages memory for operation implementations:

- In-parameters are passed to the servant already autoreleased.
- Out-parameters and return values must be returned by the servant as autoreleased values.

This follows the usual Objective-C convention: the allocator of a value is responsible for releasing it. This is what the Ice run time does for in-parameters, and what you are expected to do for out-parameters and return values. These rules also mean that it is safe to return an in-parameter as an out-parameter or return value. For example:

Objective-C

```

-(NSString *) op:(NSMutableString *)sin
               sout:(NSString **)sout
               current:(ICECurrent *)current
{
    *sout = sin; // Works fine.
    return sin; // Works fine.
}

```

The Ice run time creates and releases a separate autorelease pool for each invocation. This means that the memory for parameters is reclaimed as soon as the run time has marshaled the operation results back to the client.

See Also

- [Server-Side Objective-C Mapping for Interfaces](#)
- [Raising Exceptions in Objective-C](#)
- [The Current Object](#)

Raising Exceptions in Objective-C

To throw an exception from an operation implementation, you simply allocate the exception, initialize it, and throw it. For example:

Objective-C

```

-(void) write:(NSMutableArray *)text current:(ICECurrent *)current
{
    // Try to write the file contents here...
    // Assume we are out of space...
    if (error)
        @throw [FSGenericError genericError:@"file too large"];
}

```

As for out-parameters and return values, you must take care to throw an autoreleased exception.

If you throw an arbitrary Objective-C exception that does not derive from `ICEException`, the client receives an `UnknownException`. Similarly, if you throw an "impossible" user exception (a user exception that is not listed in the exception specification of the operation), the client receives an `UnknownUserException`.

If you throw a run-time exception, such as `MemoryLimitException`, the client receives an `UnknownLocalException`. For that reason, you should never throw system exceptions from operation implementations. If you do, all the client will see is an `UnknownLocalException`, which does not tell the client anything useful.

Three run-time exceptions are [treated specially](#) and not changed to `UnknownLocalException` when returned to the client: `ObjectNotExistException`, `OperationNotExistException`, and `FacetNotExistException`.

- [Parameter Passing in Objective-C](#)

Object Incarnation in Objective-C

Having created a servant class such as the rudimentary `NodeI` class, you can instantiate the class to create a concrete servant that can receive invocations from a client. However, merely instantiating a servant class is insufficient to incarnate an object. Specifically, to provide an implementation of an Ice object, you must follow these steps:

1. [Instantiate a servant class.](#)
2. [Create an identity](#) for the Ice object incarnated by the servant.
3. [Inform the Ice run time](#) of the existence of the servant.
4. [Pass a proxy for the object](#) to a client so the client can reach it.

On this page:

- [Instantiating an Objective-C Servant](#)
- [Creating an Identity in Objective-C](#)
- [Activating an Objective-C Servant](#)
- [UUIDs as Identities in Objective-C](#)
- [Creating Proxies in Objective-C](#)
 - [Proxies and Servant Activation in Objective-C](#)
 - [Direct Proxy Creation in Objective-C](#)

Instantiating an Objective-C Servant

Instantiating a servant means to allocate an instance on the heap:

Objective-C

```
NodeI *servant = [NodeI nodei:@"Fred"];
```

This code creates a new `NodeI` instance. For this example, we used the convenience constructor we saw [earlier](#). Of course, you are not obliged to define such a constructor but, if you do not, you must explicitly call `release` or `autorelease` on the servant.

For a [delegate servant](#), instantiation would look as follows:

Objective-C

```
Intf1AndIntf2 *delegate = [Intf1AndIntf2 intf1AndIntf2];
ICEObject *servant = [ICEObject objectWithDelegate:delegate];
```

Creating an Identity in Objective-C

Each Ice object requires an identity. That identity must be unique for all servants using the same object adapter.

The Ice object model assumes that all objects (regardless of their adapter) have a [globally unique identity](#).

An Ice object identity is a structure with the following Slice definition:

Slice

```
[ "objc:prefix:ICE" ]
module Ice {
    struct Identity {
        string name;
        string category;
    };
    // ...
};
```

The full identity of an object is the combination of both the `name` and `category` fields of the `Identity` structure. For now, we will leave the `category` field as the empty string and simply use the `name` field. (The `category` field is most often used in conjunction with `servant locators`.)

To create an identity, we simply assign a key that identifies the servant to the `name` field of the `Identity` structure:

Objective-C

```
ICEIdentity ident = [ICEIdentity identity:"Fred" category:nil];
```

Activating an Objective-C Servant

Merely creating a servant instance does nothing: the Ice run time becomes aware of the existence of a servant only once you explicitly tell the object adapter about the servant. To activate a servant, you invoke the `add` operation on the object adapter. Assuming that we have access to the object adapter in the `adapter` variable, we can write:

Objective-C

```
[adapter add:servant identity:ident];
```

Note the two arguments to `add`: the servant and the object identity. Calling `add` on the object adapter adds the servant and the servant's identity to the adapter's servant map and links the proxy for an Ice object to the correct servant instance in the server's memory as follows:

1. The proxy for an Ice object, apart from addressing information, contains the identity of the Ice object. When a client invokes an operation, the object identity is sent with the request to the server.
2. The object adapter receives the request, retrieves the identity, and uses the identity as an index into the servant map.
3. If a servant with that identity is active, the object adapter retrieves the servant pointer from the servant map and dispatches the incoming request into the correct method on the servant.

Assuming that the object adapter is in the `active state`, client requests are dispatched to the servant as soon as you call `add`.

Putting the preceding points together, we can write a simple method that instantiates and activates one of our `NodeI` servants. For this example, we use a simple method on our servant called `activate` that activates a servant in an object adapter with the passed identity:

Objective-C

```

-(void) activate:(id<ICEObjectAdapter>)a
           name:(NSString *)name
{
    ICEIdentity ident = [ICEIdentity identity:name category:nil];
    [a add:self identity:ident];
}

```

UUIDs as Identities in Objective-C

The Ice object model assumes that object identities are globally unique. One way of ensuring that uniqueness is to use UUIDs (Universally Unique Identifiers) as identities. The `ICEUtil` class contains a helper function to create such identities:

Objective-C

```

@interface ICEUtil : NSObject
+(id) generateUUID;
// ...
@end

```

When executed, this method returns a unique string such as `5029a22c-e333-4f87-86b1-cd5e0fcce509`. Each call to `generateUUID` creates a string that differs from all previous ones. You can use a UUID such as this to create object identities. For convenience, the object adapter has an operation `addWithUUID` that generates a UUID and adds a servant to the servant map in a single step:

Objective-C

```

-(id<ICEObjectPrx>) addWithUUID:(ICEObject *)servant

```

Note that the operation returns the proxy for the servant just activated.

Creating Proxies in Objective-C

Once we have activated a servant for an Ice object, the server can process incoming client requests for that object. However, clients can only access the object once they hold a proxy for the object. If a client knows the server's address details and the object identity, it can create a proxy from a string, as we saw in our [first example](#). However, creation of proxies by the client in this manner is usually only done to allow the client access to initial objects for bootstrapping. Once the client has an initial proxy, it typically obtains further proxies by invoking operations.

The object adapter contains all the details that make up the information in a proxy: the addressing and protocol information, and the object identity. The Ice run time offers a number of ways to create proxies. Once created, you can pass a proxy to the client as the return value or as an out-parameter of an operation invocation.

Proxies and Servant Activation in Objective-C

The `add` and `addWithUUID` servant activation operations on the object adapter return a proxy for the corresponding Ice object, as we saw earlier. This means we can write:

Objective-C

```
NodeI *servant = [NodeI nodei:name];
id<FSNodePrx> proxy = [FSNodePrx uncheckedCast:
[adapter addWithUUID:servant]];

// Pass proxy to client...
```

Here, `addWithUUID` both activates the servant and returns a proxy for the Ice object incarnated by that servant in a single step.

Note that we need to use an `uncheckedCast` here because `addWithUUID` returns a proxy of type `id<ICEObjectPrx>`.

Direct Proxy Creation in Objective-C

The object adapter offers an operation to create a proxy for a given identity:

Slice

```
["objc:prefix:ICE"]
module Ice {
    local interface ObjectAdapter {
        Object* createProxy(Identity id);
        // ...
    };
};
```

Note that `createProxy` creates a proxy for a given identity whether a servant is activated with that identity or not. In other words, proxies have a life cycle that is quite independent from the life cycle of servants:

Objective-C

```
ICEIdentity *ident = [ICEIdentity identity];
ident.name = [ICEUtil generateUUID];
id<ICEObjectPrx> o = [adapter createProxy:ident];
```

This creates a proxy for an Ice object with the identity returned by `generateUUID`. Obviously, no servant yet exists for that object so, if we return the proxy to a client and the client invokes an operation on the proxy, the client will receive an `ObjectNotExistException`. (We examine these life cycle issues in more detail in [Object Life Cycle](#).)

Example of a File System Server in Objective-C

This page presents the source code for a C++ server that implements our [file system](#) and communicates with the [client](#) we wrote earlier. The code here is fully functional, apart from the required interlocking for threads.

The server is remarkably free of code that relates to distribution: most of the server code is simply application logic that would be present just the same for a non-distributed version. Again, this is one of the major advantages of Ice: distribution concerns are kept away from application code so that you can concentrate on developing application logic instead of networking infrastructure.

The server code presented here is not quite correct as it stands: if two clients access the same file in parallel, each via a different thread, one thread may read the lines instance variable while another thread updates it. Obviously, if that happens, we may write or return garbage or, worse, crash the server. However, it is trivial to make the read and write operations thread-safe with a few lines of code. We discuss how to write thread-safe servant implementations in [The Ice Threading Model](#).

On this page:

 - [Implementing DirectoryI in Objective-C](#)

Implementing a File System Server in Objective-C

We have now seen enough of the server-side Objective-C mapping to implement a server for our [file system](#). (You may find it useful to review these Slice definitions before studying the source code.)

Our server is composed of three source files:

- `Server.m`
This file contains the server main program.
- `FileI.m`
This file contains the implementation for the `File` servants.
- `DirectoryI.m`
This file contains the implementation for the `Directory` servants.

Server main Program in Objective-C

Our server main program, in the file `Server.m`, uses the structure we saw in an [earlier example](#):

Objective-C

```
#import <Ice/Ice.h>
#import <FileI.h>
#import <DirectoryI.h>

#import <Foundation/NSAutoreleasePool.h>

int
main(int argc, char* argv[])
{
    NSAutoreleasePool * pool = [[NSAutoreleasePool alloc] init];

    int status = 1;
    id<ICECommunicator> communicator = nil;
```

```

@try {
    communicator = [ICEUtil createCommunicator:&argc argv:argv];

    id<ICEObjectAdapter> adapter =
[communicator createObjectAdapterWithEndpoints:
        @"SimpleFilesystem"
        endpoints:@"default -p 10000"];

    // Create the root directory (with name "/" and no parent)
    //
    DirectoryI *root = [DirectoryI directoryi:@"/" parent:nil];
    [root activate:adapter];

    // Create a file called "README" in the root directory
    //
    FileI *file = [FileI filei:@"README" parent:root];
    NSMutableArray *text = [NSMutableArray arrayWithObject:
        @"This file system contains a collection of poetry."];
    [file write:text current:nil];
    [file activate:adapter];

    // Create a directory called "Coleridge" in the root dir
    //
    DirectoryI *coleridge =
[DirectoryI directoryi:@"Coleridge" parent:root];
    [coleridge activate:adapter];

    // Create a file called "Kubla_Khan"
    // in the Coleridge directory
    //
    file = [FileI filei:@"Kubla_Khan" parent:coleridge];
    text = [NSMutableArray arrayWithObjects:
        @"In Xanadu did Kubla Khan",
        @"A stately pleasure-dome decree:",
        @"Where Alph, the sacred river, ran",
        @"Through caverns measureless to man",
        @"Down to a sunless sea.",
        nil];
    [file write:text current:nil];
    [file activate:adapter];

    // All objects are created, allow client requests now
    //
    [adapter activate];

    // Wait until we are done
    //
    [communicator waitForShutdown];

    status = 0;

```

```
} @catch (NSEException* ex) {  
    NSLog(@"%@", ex);  
}  
  
@try {  
    [communicator destroy];  
} @catch (NSEException* ex) {  
    NSLog(@"%@", ex);  
}  
  
[pool release];
```

```

    return status;
}

```

There is quite a bit of code here, so let us examine each section in detail:

Objective-C

```

#import <Ice/Ice.h>
#import <FileI.h>
#import <DirectoryI.h>

#import <Foundation/NSAutoreleasePool.h>

```

The code includes the header `Ice/Ice.h`, which contains the definitions for the Ice run time, and the files `FileI.h` and `DirectoryI.h`, which contain the definitions of our servant implementations. Because we use an autorelease pool, we need to include `Foundation/NSAutoreleasePool.h` as well.

The next part of the source code is mostly boiler plate that we saw previously: we create an object adapter, and, towards the end, activate the object adapter and call `waitForShutdown`, which blocks the calling thread until you call `shutdown` or `destroy` on the communicator. (Ice does not make any demands on the main thread, so `waitForShutdown` simply blocks the calling thread; if you want to use the main thread for other purposes, you are free to do so.)

Objective-C

```

int
main(int argc, char* argv[])
{
    NSAutoreleasePool * pool = [[NSAutoreleasePool alloc] init];

    int status = 1;
    id<ICECommunicator> communicator = nil;
    @try {
        communicator = [ICEUtil createCommunicator:&argc argv:argv];

        id<ICEObjectAdapter> adapter =
[communicator createObjectAdapterWithEndpoints:
                    @"SimpleFilesystem"
                    endpoints:@"default -p 10000"];

        // ...

        // All objects are created, allow client requests now
        //
        [adapter activate];

        // Wait until we are done
        //
        [communicator waitForShutdown];

        status = 0;
    } @catch (NSEException* ex) {
        NSLog(@"%@", ex);
    }

    @try {
        [communicator destroy];
    } @catch (NSEException* ex) {
        NSLog(@"%@", ex);
    }

    [pool release];
    return status;
}

```

The interesting part of the code follows the adapter creation: here, the server instantiates a few nodes for our file system to create the structure shown below:

A small file system.

As we will see shortly, the servants for our directories and files are of type `DirectoryI` and `FileI`, respectively. The constructor for either type of servant accepts two parameters: the name of the directory or file to be created and the servant for the parent directory. (For the root directory, which has no parent, we pass a `nil` parent.) Thus, the statement

Objective-C

```
DirectoryI *root = [DirectoryI directoryi:@"/" parent:nil];
```

creates the root directory, with the name "/" and no parent directory.

Here is the code that establishes the structure in the above illustration shown:

Objective-C

```

// Create the root directory (with name "/" and no parent)
//
DirectoryI *root = [DirectoryI directoryi:@"/" parent:nil];
[root activate:adapter];

// Create a file called "README" in the root directory
//
FileI *file = [FileI filei:@"README" parent:root];
NSMutableArray *text = [NSMutableArray arrayWithObject:
    @"This file system contains a collection of poetry."];
[file write:text current:nil];
[file activate:adapter];

// Create a directory called "Coleridge" in the root dir
//
DirectoryI *coleridge =
[DirectoryI directoryi:@"Coleridge" parent:root];
[coleridge activate:adapter];

// Create a file called "Kubla_Khan"
// in the Coleridge directory
//
file = [FileI filei:@"Kubla_Khan" parent:coleridge];
text = [NSMutableArray arrayWithObjects:
    @"In Xanadu did Kubla Khan",
    @"A stately pleasure-dome decree:",
    @"Where Alph, the sacred river, ran",
    @"Through caverns measureless to man",
    @"Down to a sunless sea.",
    nil];
[file write:text current:nil];
[file activate:adapter];

```

We first create the root directory and a file `README` within the root directory. (Note that we pass the servant for the root directory as the parent pointer when we create the new node of type `FileI`.)

After creating each servant, the code calls `activate` on the servant. (We will see the definition of this member function shortly.) The `activate` member function adds the servant to the ASM.

The next step is to fill the file with text:

Objective-C

```

// Create the root directory (with name "/" and no parent)
//
DirectoryI *root = [DirectoryI directoryi:@"/" parent:nil];
[root activate:adapter];

// Create a file called "README" in the root directory
//
FileI *file = [FileI filei:@"README" parent:root];
NSMutableArray *text = [NSMutableArray arrayWithObject:
    @"This file system contains a collection of poetry."];
[file write:text current:nil];
[file activate:adapter];

// Create a directory called "Coleridge" in the root dir
//
DirectoryI *coleridge =
[DirectoryI directoryi:@"Coleridge" parent:root];
[coleridge activate:adapter];

// Create a file called "Kubla_Khan"
// in the Coleridge directory
//
file = [FileI filei:@"Kubla_Khan" parent:coleridge];
text = [NSMutableArray arrayWithObjects:
    @"In Xanadu did Kubla Khan",
    @"A stately pleasure-dome decree:",
    @"Where Alph, the sacred river, ran",
    @"Through caverns measureless to man",
    @"Down to a sunless sea.",
    nil];
[file write:text current:nil];
[file activate:adapter];

```

Recall that [Slice sequences](#) map to `NSArray` or `NSMutableArray`, depending on the parameter direction. Here, we instantiate that array and add a line of text to it.

Finally, we call the `Slice write` operation on our `FileI` servant by simply writing:

Objective-C

```
[file write:text current:nil];
```

This statement is interesting: the server code invokes an operation on one of its own servants. Because the call happens via the pointer to the servant (of type `FileI`) and *not* via a proxy (of type `id<FilePrx>`), the Ice run time does not know that this call is even taking place —

such a direct call into a servant is not mediated by the Ice run time in any way and is dispatched as an ordinary Objective-C function call. The operation implementation in the servant expects a `current` object. In this case, we pass `nil` (which is fine because the operation implementation does not use it anyway).

In similar fashion, the remainder of the code creates a subdirectory called `Coleridge` and, within that directory, a file called `Kubla_Khan` to complete the structure in the above illustration.

Servant Class Definitions in Objective-C

We must provide servants for the concrete interfaces in our Slice specification, that is, we must provide servants for the `File` and `Directory` interfaces in the Objective-C classes `FileI` and `DirectoryI`. This means that our servant classes look as follows:

```

Objective-C

```

#import <Filesystem.h>

@interface FileI : FSFile <FSFile>
// ...
@end

@interface DirectoryI : FSDirectory <FSDirectory>
// ...
@end

```

```

Each servant class derives from its skeleton class and adopts its skeleton protocol.

We now can think about how to implement our servants. One thing that is common to all nodes is that they have a name and a parent directory. As we saw earlier, we pass these details to a convenience constructor, which also takes care of calling `autorelease` on the new servant.

In addition, we will use UUIDs as the object identities for files and directories. This relieves us of the need to otherwise come up with a unique identity for each servant (such as path names, which would only complicate our implementation). Because the `list` operation returns proxies to nodes, and because each proxy carries the identity of the servant it denotes, this means that our servants must store their own identity, so we can create proxies to them when clients ask for them.

For `File` servants, we also need to store the contents of the file, leading to the following definition for the `FileI` class:

Objective-C

```

#import <Filesystem.h>

@class DirectoryI;

@interface FileI : FSFile <FSFile>
{
    @private
    NSString *myName;
    DirectoryI *parent;
    ICEIdentity *ident;
    NSArray *lines;
}

@property(nonatomic, retain) NSString *myName;
@property(nonatomic, retain) DirectoryI *parent;
@property(nonatomic, retain) ICEIdentity *ident;
@property(nonatomic, retain) NSArray *lines;

+(id) filei:(NSString *)name parent:(DirectoryI *)parent;
-(void) write:(NSMutableArray *)text current:(ICECurrent *)current;
-(void) activate:(id<ICEObjectAdapter>)a;
@end

```

The instance variables store the name, parent node, identity, and the contents of the file. The `filei` convenience constructor instantiates the servant, remembers the name and parent directory, assigns a new identity, and calls `autorelease`.

Note that the only Slice operation we have defined here is the `write` method. This is necessary because, as we saw previously, the code in `Server.m` calls this method to initialize the files it creates.

For directories, the requirements are similar. They also need to store a name, parent directory, and object identity. Directories are also responsible for keeping track of the child nodes. We can store these nodes in an array of proxies. This leads to the following definition:

Objective-C

```

#import <Filesystem.h>

@interface DirectoryI : FSDirectory <FSDirectory>
{
    @private
    NSString *myName;
    DirectoryI *parent;
    ICEIdentity *ident;
    NSMutableArray *contents;
}
@property(nonatomic, retain) NSString *myName;
@property(nonatomic, retain) DirectoryI *parent;
@property(nonatomic, retain) ICEIdentity *ident;
@property(nonatomic, retain) NSMutableArray *contents;

+(id) directoryi:(NSString *)name parent:(DirectoryI *)parent;
-(void) addChild:(id<FSNodePrx>)child;
-(void) activate:(id<ICEObjectAdapter>)a;
@end

```

Because the code in `Server.m` does not call any Slice operations on directory servants, we have not declared any of the corresponding methods. (We will see the purpose of the `addChild` method shortly.) As for files, the convenience constructor creates the servant, remembers the name and parent, and assigns an object identity, as well as calling `autorelease`.

Servant Implementation in Objective-C

Let us now turn to how to implement each of the methods for our servants.

Implementing FileI in Objective-C

The implementation of the `name`, `read`, and `write` operations for files is trivial, returning or updating the corresponding instance variable:

Objective-C

```

-(NSString *) name:(ICECurrent *)current
{
    return myName;
}

-(NSArray *) read:(ICECurrent *)current
{
    return lines;
}

-(void) write:(NSMutableArray *)text current:(ICECurrent *)current
{
    self.lines = text;
}

```

Note that this constitutes the complete implementation of the Slice operations for files.

Here is the convenience constructor:

Objective-C

```

+(id) filei:(NSString *)name parent:(DirectoryI *)parent
{
    FileI *instance = [[[FileI alloc] init] autorelease];
    if(instance == nil)
    {
        return nil;
    }
    instance.myName = name;
    instance.parent = parent;
    instance.ident = [ICEIdentity
identity:[ICEUtil generateUUID] category:nil];
    return instance;
}

```

After allocating and autoreleasing the instance, the constructor initializes the instance variables. The only interesting part of this code is how we create the identity for the servant. `generateUUID` is a class method of the `ICEUtil` class that returns a UUID. We assign this UUID to the `name` member of the identity.

We saw earlier that the server calls `activate` after it creates each servant. Here is the implementation of this method:

Objective-C

```

-(void) activate:(id<ICEObjectAdapter>)a
{
    id<FSNodePrx> thisNode =
    [FSNodePrx uncheckedCast:[a add:self identity:ident]];
    [parent addChild:thisNode];
}

```

This is how our code informs the Ice run time of the existence of a new servant. The call to `add` on the object adapter adds the servant and object identity to the adapter's servant map. In other words, this step creates the link between the object identity (which is embedded in proxies), and the actual Objective-C class instance that provides the behavior for the Slice operations.

`add` returns a proxy to the servant, of type `id<ICEObjectPrx>`. Because the `contents` instance variable of directory servants stores proxies of type `id<FSNodePrx>` (and `addChild` expects a proxy of that type), we down-cast the returned proxy to `id<FSNodePrx>`. In this case, because we know that the servant we just added to the adapter is indeed a servant that implements the operations on the Slice `Node` interface, we can use an `uncheckedCast`.

The call to `addChild` connects the new file to its parent directory.

Finally, we need a `dealloc` function so we do not leak the memory for the servant's instance variables:

Objective-C

```

-(void) dealloc
{
    [myName release];
    [parent release];
    [ident release];
    [[lines release];
    [super dealloc];
}

```

Implementing DirectoryI in Objective-C

The implementation of the Slice operations for directories is just as simple as for files:

Objective-C

```

-(NSString *) name:(ICECurrent *)current
{
    return myName;
}

-(NSArray *) list:(ICECurrent *)current
{
    return contents;
}

```

Because the `contents` instance variable stores the proxies for child nodes of the directory, the `list` operation simply returns that variable.

The convenience constructor looks much like the one for file servants:

Objective-C

```

+(id) directory:(NSString *)name parent:(DirectoryI *)parent
{
    DirectoryI *instance = [[[DirectoryI alloc] init] autorelease];
    if(instance == nil)
    {
        return nil;
    }
    instance.myName = name;
    instance.parent = parent;
    instance.ident = [ICEIdentity
        identity:(parent ? [ICEUtil generateUUID] : @"RootDir")
        category:nil];
    instance.contents = [[NSMutableArray alloc] init];
    return instance;
}

```

The only noteworthy differences are that, for the root directory (which has no parent), the code uses `"RootDir"` as the identity. (As we saw earlier, the client knows that this is the identity of the root directory and uses it to create its proxy.)

The `addChild` method connects our nodes into a hierarchy by updating the `contents` instance variable. That way, each directory knows which nodes are contained in it:

Objective-C

```

-(void) addChild:(id<FSNodePrx>)child
{
    [contents addObject:child];
}

```

Finally, the `activate` and `dealloc` methods are very much like the corresponding methods for files:

Objective-C

```
-(void) activate:(id<ICEObjectAdapter>)a
{
    id<FSNodePrx> thisNode = [FSNodePrx uncheckedCast:[a add:self
identity:ident]];
    [parent addChild:thisNode];
}

-(void) dealloc
{
    [myName release];
    [parent release];
    [ident release];
    [contents release];
    [super dealloc];
}
```

PHP Mapping

Ice currently provides a client-side mapping for PHP, but not a server-side mapping.

Topics

- [Client-Side Slice-to-PHP Mapping](#)

Client-Side Slice-to-PHP Mapping

The client-side Slice-to-PHP mapping defines how Slice data types are translated to PHP types, and how clients invoke operations, pass parameters, and handle errors. Much of the PHP mapping is intuitive. For example, Slice sequences map to PHP arrays, so there is essentially nothing new you have to learn in order to use Slice sequences in PHP.

Much of what appears in this chapter is reference material. We suggest that you skim the material on the initial reading and refer back to specific sections as needed. However, we recommend that you read at least the mappings for [exceptions](#), [interfaces](#), and [operations](#) in detail because these sections cover how to call operations from a client, pass parameters, and handle exceptions.

In order to use the PHP mapping, you should need no more than the Slice definition of your application and knowledge of the PHP mapping rules. In particular, looking through the generated code in order to discern how to use the PHP mapping is likely to be inefficient, due to the amount of detail. Of course, occasionally, you may want to refer to the generated code to confirm a detail of the mapping, but we recommend that you otherwise use the material presented here to see how to write your client-side code.

The Ice Module

All of the APIs for the Ice run time are nested in the `Ice` module, to avoid clashes with definitions for other libraries or applications. Some of the contents of the `Ice` module are generated from Slice definitions; other parts of the `Ice` module provide special-purpose definitions that do not have a corresponding Slice definition. We will incrementally cover the contents of the `Ice` module throughout the remainder of the manual.

A PHP application can load the Ice run time using the `require` statement:

```
require 'Ice.php';
```

If the statement executes without error, the Ice run time is loaded and available for use. You can determine the version of the Ice run time you have just loaded by calling the `stringVersion` function:

```
$icever = Ice_stringVersion();
```

Using the namespace mapping, you can refer to a global Ice function such as `stringVersion` either by its flattened name (as shown above) or by its namespace equivalent:

```
$icever = \Ice\stringVersion();
```

PHP Mapping for Identifiers

A Slice [identifier](#) maps to an identical PHP identifier. For example, the Slice identifier `clock` becomes the PHP identifier `clock`. There is one exception to this rule: if a Slice identifier is the same as a PHP keyword or is an identifier reserved by the Ice run time (such as `checkedCast`), the corresponding PHP identifier is prefixed with an underscore. For example, the Slice identifier `while` is mapped as `_while`.

You should try to [avoid such identifiers](#) as much as possible.

A single Slice identifier often results in several PHP identifiers. For example, for a Slice interface named `Foo`, the generated PHP code uses the identifiers `Foo` and `FooPrx` (among others). If the interface has the name `while`, the generated identifiers are `_while` and `whilePrx` (*not* `_whilePrx`), that is, the underscore prefix is applied only to those generated identifiers that actually require it.

PHP Mapping for Modules

By default, identifiers defined within a Slice `module` are mapped to a flattened symbol that uses underscores as module separators. Consider the following Slice definition:

Slice
<pre> module M { module N { enum Color { red, green, blue }; }; }; </pre>

The Slice identifier `Color` maps to `M_N_Color` by default because PHP releases prior to version 5.3 lacked language support for namespaces. If you prefer to use namespaces instead, you can enable an alternate mapping in which Slice modules map to PHP namespaces with the same name as the Slice module. This mapping preserves the nesting of the Slice definitions. Using the namespace mapping, the Slice identifier `Color` maps to `\M\N\Color`.

Be aware that using underscores in your Slice definitions can lead to name collisions in the flattened mapping. Consider the following example:

Slice
<pre> module M { module N { enum Color { red, green, blue }; }; }; module M_N { interface Color { }; }; </pre>

Although these definitions are syntactically correct, they both map to the flattened PHP symbol `M_N_Color`.

PHP Mapping for Built-In Types

On this page:

- [Mapping of Slice Built-In Types to PHP Types](#)
- [String Mapping in PHP](#)

Mapping of Slice Built-In Types to PHP Types

PHP has a limited set of primitive types: `boolean`, `integer`, `double`, and `string`. The Slice `built-in` types are mapped to PHP types as shown in the table below:

Slice	Ruby
<code>bool</code>	<code>true</code> or <code>false</code>
<code>byte</code>	<code>integer</code>
<code>short</code>	<code>integer</code>
<code>int</code>	<code>integer</code>
<code>long</code>	<code>integer</code>
<code>float</code>	<code>double</code>
<code>double</code>	<code>double</code>
<code>string</code>	<code>string</code>

PHP's `integer` type may not accommodate the range of values supported by Slice's `long` type, therefore `long` values that are outside this range are mapped as strings. Scripts must be prepared to receive an `integer` or `string` from any operation that returns a `long` value.

String Mapping in PHP

String values returned as the result of a Slice operation (including return values, out parameters, and data members) contain UTF-8 encoded strings unless the program has installed a `string converter`, in which case string values use the converter's native encoding instead.

As string input values for a remote Slice operation, Ice accepts `null` in addition to `string` objects; each occurrence of `null` is marshaled as an empty string. Ice assumes that all `string` objects contain valid UTF-8 encoded strings unless the program has installed a `string converter`, in which case Ice assumes that `string` objects use the native encoding expected by the converter.

PHP Mapping for Enumerations

PHP does not have an enumerated type, so a Slice [enumeration](#) is mapped to a PHP class: the name of the Slice enumeration becomes the name of the PHP class; for each enumerator, the class contains a constant with the same name as the enumerator. For example:

Slice
<pre>enum Fruit { Apple, Pear, Orange };</pre>

The generated PHP class looks as follows:

PHP
<pre>class Fruit { const Apple = 0; const Pear = 1; const Orange = 2; }</pre>

Suppose we modify the Slice definition to include a [custom enumerator value](#):

Slice
<pre>enum Fruit { Apple, Pear = 3, Orange };</pre>

The generated PHP class changes accordingly:

PHP
<pre>class Fruit { const Apple = 0; const Pear = 3; const Orange = 4; }</pre>

Since enumerated values are mapped to integer constants, application code is not required to use the generated constants. When an enumerated value enters the Ice run time, Ice validates that the given integer is a valid value for the enumeration. However, to minimize the potential for defects in your code, we recommend using the generated constants instead of literal integers.

PHP Mapping for Structures

A Slice [structure](#) maps to a PHP class containing a public variable for each member of the structure. For example, here is our `Employee` structure once more:

Slice
<pre>struct Employee { long number; string firstName; string lastName; };</pre>

The PHP mapping generates the following definition for this structure:

PHP
<pre>class Employee { public function __construct(\$number=0, \$firstName='', \$lastName=''); public function __toString(); public \$number; public \$firstName; public \$lastName; }</pre>

The class provides a constructor whose arguments correspond to the data members. This allows you to instantiate and initialize the class in a single statement (instead of having to first instantiate the class and then assign to its members). Each argument provides a default value appropriate for the member's type:

Data Member Type	Default Value
string	Empty string
enum	First enumerator in enumeration
struct	Default-constructed value
Numeric	Zero
bool	False
sequence	Null
dictionary	Null
class/interface	Null

You can also declare different [default values](#) for members of primitive and enumerated types.

The mapping also includes a definition for the `__toString` magic method, which returns a string representation of the structure.

PHP Mapping for Sequences

A Slice [sequence](#) maps to a native PHP indexed array. The first element of the Slice sequence is contained at index 0 (zero) of the PHP array, followed by the remaining elements in ascending index order.

Consider this example:

Slice
<pre>sequence<Fruit> FruitPlatter;</pre>

You can create an instance of `FruitPlatter` as shown below:

PHP
<pre>// Make a small platter with one Apple and one Orange // \$platter = array(Fruit::Apple, Fruit::Orange);</pre>

The Ice run time validates the elements of an array to ensure that they are compatible with the declared type and raises `InvalidArgumentException` if an incompatible type is encountered.

- [PHP Mapping for Constants](#)
- [PHP Mapping for Exceptions](#)

PHP Mapping for Dictionaries

A Slice [dictionary](#) maps to a native PHP associative array. The PHP mapping does not currently support all Slice dictionary types, however, because native PHP associative arrays support only integers and strings as keys.

A Slice dictionary whose key type is an enumeration or one of the primitive types `boolean`, `byte`, `short`, `int`, or `long` is mapped as an associative array with an integer key.

Boolean values are treated as integers, with `false` equivalent to 0 (zero) and `true` equivalent to 1 (one).

A Slice dictionary with a `string` key type is mapped as an associative array with a string key. All other key types cause a warning to be generated.

Here is the definition of our `EmployeeMap`:

Slice

```
dictionary<long, Employee> EmployeeMap;
```

You can create an instance of this dictionary as shown below:

PHP

```
$e1 = new Employee;
$e1->number = 42;
$e1->firstName = "Stan";
$e1->lastName = "Lipmann";

$e2 = new Employee;
$e2->number = 77;
$e2->firstName = "Herb";
$e2->lastName = "Sutter";

$em = array($e1->number => $e1, $e2->number => $e2);
```

The Ice run time validates the elements of a dictionary to ensure that they are compatible with the declared type; `InvalidArgumentException` exception is raised if an incompatible type is encountered.

- [PHP Mapping for Constants](#)
- [PHP Mapping for Exceptions](#)

PHP Mapping for Constants

A Slice constant maps to a PHP constant. Consider the following definitions:

Slice
<pre> module M { const bool AppendByDefault = true; const byte LowerNibble = 0x0f; const string Advice = "Don't Panic!"; const short TheAnswer = 42; const double PI = 3.1416; enum Fruit { Apple, Pear, Orange }; const Fruit FavoriteFruit = Pear; }; </pre>

The mapping for these constants is shown below:

PHP
<pre> define('M_AppendByDefault', true); define('M_LowerNibble', 15); define('M_Advice', "Don't Panic!"); define('M_TheAnswer', 42); define('M_PI', 3.1416); define('M_FavoriteFruit', M_Fruit::Pear); </pre>

Slice string literals that contain non-ASCII characters or universal character names are mapped to PHP string literals with these characters replaced by their UTF-8 encoding as octal escapes. For example:

Slice
<pre> module M { const string Egg = "æuf"; const string Heart = "c\u0153ur"; const string Banana = "\U0001F34C"; }; </pre>

is mapped to:

PHP
<pre> define('M_Egg', "\305\223uf"); define('M_Heart', "c\305\223ur"); define('M_Banana', "\360\237\215\214"); </pre>

An application refers to a constant using its flattened name:

```

PHP

```
$ans = M_TheAnswer;
```

```

Using the namespace mapping, Slice constants are mapped to PHP constants in the enclosing namespace:

```

PHP

```
$ans = \M\TheAnswer;
```

```

PHP Mapping for Exceptions

On this page:

- [Inheritance Hierarchy for Exceptions in PHP](#)
- [PHP Mapping for User Exceptions](#)
 - [Optional Data Members](#)
- [PHP Mapping for Run-Time Exceptions](#)

Inheritance Hierarchy for Exceptions in PHP

The mapping for exceptions is based on the inheritance hierarchy shown below:

Inheritance structure for Ice exceptions.

The ancestor of all exceptions is `Exception`, from which `Ice_Exception` is derived. `Ice_LocalException` and `Ice_UserException` are derived from `Ice_Exception` and form the base for all run-time and user exceptions.

PHP Mapping for User Exceptions

Here is a fragment of the [Slice definition](#) for our world time server once more:

```

Slice

```

exception GenericError {
 string reason;
};
exception BadTimeVal extends GenericError {};
exception BadZoneName extends GenericError {};

```

```

These exception definitions map to the abbreviated PHP class definitions shown below:

PHP
<pre> class GenericError extends Ice_UserException { public function __construct(\$reason=''); public function ice_name(); public function __toString(); public \$reason; } class BadTimeVal extends GenericError { public function __construct(\$reason=''); public function ice_name(); public function __toString(); } class BadZoneName extends GenericError { public function __construct(\$reason=''); public function ice_name(); public function __toString(); } </pre>

Each Slice exception is mapped to a PHP class with the same name. The inheritance structure of the Slice exceptions is preserved for the generated classes, so `BadTimeVal` and `BadZoneName` inherit from `GenericError`.

Each exception member corresponds to an instance variable of the instance, which the constructor initializes to a default value appropriate for its type:

Data Member Type	Default Value
string	Empty string
enum	First enumerator in enumeration
struct	Default-constructed value
Numeric	Zero
bool	False
sequence	Null
dictionary	Null
class/interface	Null

You can also declare different [default values](#) for members of primitive and enumerated types. For derived exceptions, the constructor has one parameter for each of the base exception's data members, plus one parameter for each of the derived exception's data members, in base-to-derived order. As an example, although `BadTimeVal` and `BadZoneName` do not declare data members, their constructors still accept a value for the inherited data member `reason` in order to pass it to the constructor of the base exception `GenericError`.

Each exception also defines the `ice_name` method to return the exception's type name, as well as the `__toString` magic method to return

a stringified representation of the exception and its members.

All user exceptions are derived from the base class `Ice_UserException`. This allows you to catch all user exceptions generically by installing a handler for `Ice_UserException`. Similarly, you can catch all Ice run-time exceptions with a handler for `Ice_LocalException`, and you can catch all Ice exceptions with a handler for `Ice_Exception`.

Optional Data Members

Optional data members use the same mapping as required data members, but an optional data member can also be set to the marker value `Ice_Unset` to indicate that the member is unset. A well-behaved program must compare an optional data member to `Ice_Unset` before using the member's value:

```

PHP

```

try {
 ...
} catch($ex) {
 if($ex->optionalMember == Ice_Unset)
 echo "optionalMember is unset\n";
 else
 echo "optionalMember = " . $ex->optionalMember . "\n";
}

```

```

The `Ice_Unset` marker value has different semantics than `null`. Since `null` is a legal value for certain Slice types, the Ice run time requires a separate marker value so that it can determine whether an optional value is set. An optional value set to `null` is considered to be set. If you need to distinguish between an unset value and a value set to `null`, you can do so as follows:

```

PHP

```

try {
 ...
} catch($ex) {
 if($ex->optionalMember == Ice_Unset)
 echo "optionalMember is unset\n";
 else if($ex->optionalMember == null)
 echo "optionalMember is None\n";
 else
 echo "optionalMember = " . $ex->optionalMember . "\n";
}

```

```

PHP Mapping for Run-Time Exceptions

The Ice run time throws [run-time exceptions](#) for a number of pre-defined error conditions. All run-time exceptions directly or indirectly derive from `Ice_LocalException` (which, in turn, derives from `Ice_Exception`).

By catching exceptions at the appropriate point in the inheritance hierarchy, you can handle exceptions according to the category of error they indicate:

- `Ice_LocalException`
This is the root of the inheritance tree for run-time exceptions.
- `Ice_UserException`

This is the root of the inheritance tree for user exceptions.

- `Ice_TimeoutException`
This is the base exception for both operation-invocation and connection-establishment timeouts.
- `Ice_ConnectTimeoutException`
This exception is raised when the initial attempt to establish a connection to a server times out.

For example, `Ice_ConnectTimeoutException` can be handled as `Ice_ConnectTimeoutException`, `Ice_TimeoutException`, `Ice_LocalException`, or `Ice_Exception`.

You will probably have little need to catch run-time exceptions as their most-derived type and instead catch them as `Ice_LocalException`; the fine-grained error handling offered by the remainder of the hierarchy is of interest mainly in the implementation of the Ice run time. Exceptions to this rule are the exceptions related to [facet](#) and [object](#) life cycles, which you may want to catch explicitly. These exceptions are `Ice_FacetNotExistException` and `Ice_ObjectNotExistException`, respectively.

PHP Mapping for Interfaces

The mapping of Slice [interfaces](#) revolves around the idea that, to invoke a remote operation, you call a member function on a local class instance that is a [proxy](#) for the remote object. This makes the mapping easy and intuitive to use because making a remote procedure call is no different from making a local procedure call (apart from error semantics).

On this page:

- [Proxy Objects in PHP](#)
- [Ice_ObjectPrx Class in PHP](#)
- [Proxy Helper Classes in PHP](#)
- [Casting Proxies in PHP](#)
 - [Proxy Backward Compatibility in PHP](#)
- [Using Proxy Methods in PHP](#)
- [Object Identity and Proxy Comparison in PHP](#)

Proxy Objects in PHP

Slice interfaces are implemented by instances of the `Ice_ObjectPrx` class. In the client's address space, an instance of `ObjectPrx` is the local ambassador for a remote instance of an interface in a server and is known as a *proxy instance*. All the details about the server-side object, such as its address, what protocol to use, and its object identity are encapsulated in that instance.

The PHP mapping for proxies differs from that of other Ice language mappings in that the `ObjectPrx` class is used to implement *all* Slice interfaces. The primary motivation for this design is minimizing the amount of code that is generated for each interface. As a result, a proxy object returned by the communicator operations `stringToProxy` and `propertyToProxy` is *untyped*, meaning it is not associated with a user-defined Slice interface. Once you narrow the proxy to a particular interface, you can use that proxy to invoke your Slice operations.

Proxy instances are always created on behalf of the client by the Ice run time, so client code never has any need to instantiate a proxy directly.

A value of `null` denotes the null proxy. The null proxy is a dedicated value that indicates that a proxy points "nowhere" (denotes no object).

For each operation in the interface, the proxy object supports a method of the same name. Each operation accepts an optional trailing parameter representing the operation context. This parameter is an associative string array for use by the Ice run time to store information about how to deliver a request. You normally do not need to use it. (We examine the context parameter in detail in [Request Contexts](#). The parameter is also used by [IceStorm](#).)

Ice_ObjectPrx Class in PHP

In the PHP language mapping, all proxies are instances of `Ice_ObjectPrx`. This class provides a number of methods:

PHP

```

class Ice_ObjectPrx
{
    function ice_getIdentity();
    function ice_isA($id);
    function ice_ids();
    function ice_id();
    function ice_ping();
    # ...
}

```

The methods behave as follows:

- **ice_getIdentity**
This method returns the identity of the object denoted by the proxy. The identity of an Ice object has the following Slice type:

Slice

```
module Ice {
    struct Identity {
        string name;
        string category;
    };
};
```

To see whether two proxies denote the same object, first obtain the identity for each object and then compare the identities:

PHP

```
$proxy1 = ...
$proxy2 = ...
$id1 = $proxy1->ice_getIdentity();
$id2 = $proxy2->ice_getIdentity();

if($id1 == $id2)
    // proxy1 and proxy2 denote the same object
else
    // proxy1 and proxy2 denote different objects
```

- **ice_isA**

The `ice_isA` method determines whether the object denoted by the proxy supports a specific interface. The argument to `ice_isA` is a [type ID](#). For example, to see whether a proxy of type `ObjectPrx` denotes a `Printer` object, we can write:

PHP

```
$proxy = ...
if($proxy != null && $proxy->ice_isA("::Printer"))
    // proxy denotes a Printer object
else
    // proxy denotes some other type of object
```

Note that we are testing whether the proxy is `null` before attempting to invoke the `ice_isA` method. This avoids getting a run-time error if the proxy is `null`.

- **ice_ids**

The `ice_ids` method returns an array of strings representing all of the [type IDs](#) that the object denoted by the proxy supports.

- **ice_id**

The `ice_id` method returns the [type ID](#) of the object denoted by the proxy. Note that the type returned is the type of the actual object, which may be more derived than the static type of the proxy. For example, if we have a proxy of type `BasePrx`, with a static type ID of `::Base`, the return value of `ice_id` might be `::Base`, or it might be something more derived, such as `::Derived`.

- **ice_ping**

The `ice_ping` method provides a basic reachability test for the object. If the object can physically be contacted (that is, the object

exists and its server is running and reachable), the call completes normally; otherwise, it throws an exception that indicates why the object could not be reached, such as `ObjectNotExistException` or `ConnectTimeoutException`.

The `ObjectPrx` class also defines an operator for comparing two proxies for equality. Note that all aspects of proxies are compared by this operation, such as the communication endpoints for the proxy. This means that, in general, if two proxies compare unequal, that does *not* imply that they denote different objects. For example, if two proxies denote the same Ice object via different transport endpoints, `==` returns `false` even though the proxies denote the same object.

The `ice_isA`, `ice_ids`, `ice_id`, and `ice_ping` methods are remote operations and therefore support an additional overloading that accepts a [request context](#). Also note that there are [other methods](#) in `ObjectPrx`, not shown here. These methods provide different ways to dispatch a call and also provide access to an object's [facets](#).

Proxy Helper Classes in PHP

The PHP mapping for a proxy generates a helper class with several static methods. For example, the following class is generated for the Slice interface named `Simple`:

```

PHP

```

class SimplePrxHelper
{
 public static function checkedCast($proxy, $facetOrCtx=null,
 $ctx=null);

 public static function uncheckedCast($proxy, $facet=null);

 public static function ice_staticId();
}

```

```

The `checkedCast` and `uncheckedCast` methods are described in the following section.

The `ice_staticId` method returns the [type ID](#) string corresponding to the interface. As an example, for the Slice interface `Simple` in module `M`, the string returned by `ice_staticId` is `"::M::Simple"`.

Casting Proxies in PHP

As shown above, the proxy's helper class includes two static methods that support down-casting:

```

PHP

```

class SimplePrxHelper
{
 public static function checkedCast($proxy, $facetOrCtx=null,
 $ctx=null);
 public static function uncheckedCast($proxy, $facet=null);

 // ...
}

```

```

The method names `checkedCast` and `uncheckedCast` are reserved for use in proxies. If a Slice interface defines an operation with either of those names, the mapping escapes the name in the generated proxy by prepending an underscore. For example, an interface that defines

an operation named `checkedCast` is mapped to a proxy with a method named `_checkedCast`.

For `checkedCast`, if the passed proxy is for an object of type `Simple`, or a proxy for an object with a type derived from `Simple`, the cast returns a proxy narrowed to that type; otherwise, if the passed proxy denotes an object of a different type (or if the passed proxy is `null`), the cast returns `null`.

The arguments are described below:

- `$proxy`
The proxy to be narrowed.
- `$facetOrCtx`
This optional argument can be either a string representing a desired `facet`, or an associative string array representing a `context`.
- `$ctx`
If `$facetOrCtx` contains a facet name, use this argument to supply an associative string array representing a `context`.
- `$facet`
Specifies the name of the desired `facet`.

Given a proxy of any type, you can use a `checkedCast` to determine whether the corresponding object supports a given type, for example:

```

PHP

$obj = ... // Get a proxy from somewhere...

$simple = SimplePrxHelper::checkedCast($obj);
if($simple != null)
    // Object supports the Simple interface...
else
    // Object is not of type Simple...
```

Note that a `checkedCast` contacts the server. This is necessary because only the server implementation has definite knowledge of the type of an object. As a result, a `checkedCast` may throw a `ConnectTimeoutException` or an `ObjectNotExistException`.

In contrast, an `uncheckedCast` does not contact the server and unconditionally returns a proxy of the requested type. However, if you do use an `uncheckedCast`, you must be certain that the proxy really does support the type you are casting to; otherwise, if you get it wrong, you will most likely get a run-time exception when you invoke an operation on the proxy. The most likely error for such a type mismatch is `OperationNotExistException`. However, other exceptions, such as a marshaling exception are possible as well. And, if the object happens to have an operation with the correct name, but different parameter types, no exception may be reported at all and you simply end up sending the invocation to an object of the wrong type; that object may do rather nonsensical things. To illustrate this, consider the following two interfaces:

```

Slice

interface Process {
    void launch(int stackSize, int dataSize);
};

// ...

interface Rocket {
    void launch(float xCoord, float yCoord);
};
```

Suppose you expect to receive a proxy for a `Process` object and use an `uncheckedCast` to down-cast the proxy:

```
PHP
```

```
$obj = ... // Get proxy...
$process = ProcessPrxHelper::uncheckedCast($obj); // No worries...
$process->launch(40, 60); // Oops...
```

If the proxy you received actually denotes a `Rocket` object, the error will go undetected by the Ice run time: because `int` and `float` have the same size and because the Ice protocol does not tag data with its type on the wire, the implementation of `Rocket::launch` will simply misinterpret the passed integers as floating-point numbers.

In fairness, this example is somewhat contrived. For such a mistake to go unnoticed at run time, both objects must have an operation with the same name and, in addition, the run-time arguments passed to the operation must have a total marshaled size that matches the number of bytes that are expected by the unmarshaling code on the server side. In practice, this is extremely rare and an incorrect `uncheckedCast` typically results in a run-time exception.

Proxy Backward Compatibility in PHP

Prior releases of the PHP language mapping provided two proxy methods for narrowing a proxy:

```
PHP
```

```
class Ice_ObjectPrx
{
    function ice_checkedCast($type, $facetOrCtx=null, $ctx=null);
    function ice_uncheckedCast($type, $facet=null);
    # ...
}
```

For example, a proxy can be narrowed as follows:

```
PHP
```

```
$proxy = $proxy->ice_checkedCast("::Demo::Hello");
```

Embedding such type ID strings in your application is a potential source of defects because the strings are not validated until run time. Although these methods are still supported for the sake of backward compatibility, we recommend using the static methods that are generated in the helper class corresponding to each interface, as shown below:

```
PHP
```

```
$proxy = Demo_HelloPrxHelper::checkedCast($proxy);
```

Not only are these static methods consistent with the APIs of other Ice language mappings, they also avoid the need to hard-code type ID strings in your application.

Using Proxy Methods in PHP

The base proxy class `ObjectPrx` supports a variety of [methods for customizing a proxy](#). Since proxies are immutable, each of these "factory methods" returns a copy of the original proxy that contains the desired modification. For example, you can obtain a proxy configured with a ten second timeout as shown below:

```

PHP

$proxy = $communicator->stringToProxy(...);
$proxy = $proxy->ice_timeout(10000);

```

A factory method returns a new proxy object if the requested modification differs from the current proxy, otherwise it returns the current proxy. With few exceptions, factory methods return a proxy of the same type as the current proxy, therefore it is generally not necessary to repeat a down-cast after using a factory method. The example below demonstrates these semantics:

```

PHP

$base = $communicator->stringToProxy(...);
$hello = Demo_HelloPrxHelper::checkedCast($base);
$hello = $hello->ice_timeout(10000); // Type is not discarded
$hello->sayHello();

```

The only exceptions are the factory methods `ice_facet` and `ice_identity`. Calls to either of these methods may produce a proxy for an object of an unrelated type, therefore they return an untyped proxy that you must subsequently down-cast to an appropriate type.

Object Identity and Proxy Comparison in PHP

Proxy objects support comparison using the comparison operators `==` and `!=`. Note that proxy comparison uses *all* of the information in a proxy for the comparison. This means that not only the object identity must match for a comparison to succeed, but other details inside the proxy, such as the protocol and endpoint information, must be the same. In other words, comparison tests for *proxy* identity, *not* object identity. A common mistake is to write code along the following lines:

```

PHP

$p1 = ...           // Get a proxy...
$p2 = ...           // Get another proxy...

if($p1 != $p2)
    // p1 and p2 denote different objects           // WRONG!
else
    // p1 and p2 denote the same object             // Correct

```

Even though `p1` and `p2` differ, they may denote the same Ice object. This can happen because, for example, both `p1` and `p2` embed the same object identity, but each uses a different protocol to contact the target object. Similarly, the protocols may be the same, but denote different endpoints (because a single Ice object can be contacted via several different transport endpoints). In other words, if two proxies compare equal, we know that the two proxies denote the same object (because they are identical in all respects); however, if two proxies compare unequal, we know absolutely nothing: the proxies may or may not denote the same object.

To compare the object identities of two proxies, you can use helper functions in the `Ice` module:

PHP

```
function Ice_proxyIdentityCompare($lhs, $rhs);
function Ice_proxyIdentityAndFacetCompare($lhs, $rhs);
```

`proxyIdentityCompare` allows you to correctly compare proxies for identity:

PHP

```
$p1 = ...           // Get a proxy...
$p2 = ...           // Get another proxy...

if(Ice_proxyIdentityCompare($p1, $p2) != 0)
    // p1 and p2 denote different objects           // Correct
else
    // p1 and p2 denote the same object             // Correct
```

The function returns 0 if the identities are equal, -1 if `p1` is less than `p2`, and 1 if `p1` is greater than `p2`. (The comparison uses `name` as the major sort key and `category` as the minor sort key.)

The `proxyIdentityAndFacetCompare` function behaves similarly, but compares both the identity and the [facet name](#).

 - [Optional Parameters in PHP](#)
- [Exception Handling in PHP](#)

Basic PHP Mapping for Operations

As we saw in the [PHP mapping for interfaces](#), for each operation on an interface, a proxy object narrowed to that type supports a corresponding method with the same name. To invoke an operation, you call it via the proxy. For example, here is part of the definitions for our file system:

Slice

```

module Filesystem {
    interface Node {
        idempotent string name();
    };
    // ...
};

```

The `name` operation returns a value of type `string`. Given a proxy to an object of type `Node`, the client can invoke the operation as follows:

PHP

```

$node = ...           // Initialize proxy
$name = $node->name(); // Get name via RPC

```

Normal and idempotent Operations in PHP

You can add an `idempotent` qualifier to a Slice operation. As far as the signature for the corresponding proxy method is concerned, `idempotent` has no effect.

Passing Parameters in PHP

In-Parameters in PHP

The PHP mapping for `in` parameters guarantees that the value of a parameter will not be changed by the invocation.

Here is an interface with operations that pass parameters of various types from client to server:

Slice

```

struct NumberAndString {
    int x;
    string str;
};

sequence<string> StringSeq;

dictionary<long, StringSeq> StringTable;

interface ClientToServer {
    void op1(int i, float f, bool b, string s);
    void op2(NumberAndString ns, StringSeq ss, StringTable st);
    void op3(ClientToServer* proxy);
};

```

A proxy object narrowed to the `ClientToServer` interface supports the following methods:

PHP

```

function op1($i, $f, $b, $s, $_ctx=null);
function op2($ns, $ss, $st, $_ctx=null);
function op3($proxy, $_ctx=null);

```

Given a proxy to a `ClientToServer` interface, the client code can pass parameters as in the following example:

PHP

```

$p = ... // Get proxy...

$p->op1(42, 3.14, true, "Hello world!"); // Pass simple literals

$i = 42;
$f = 3.14;
$b = true;
$s = "Hello world!";
$p->op1($i, $f, $b, $s); // Pass simple variables

$ns = new NumberAndString;
$ns->x = 42;
$ns->str = "The Answer";
$ss = array("Hello world!");
$st = array();
$st[0] = $ns;
$p->op2($ns, $ss, $st); // Pass complex variables

$p->op3($p); // Pass proxy

```

Out-Parameters in PHP

Out parameters are passed by reference. Here is the same Slice definition we saw earlier, but this time with all parameters being passed in the out direction:

Slice

```

struct NumberAndString {
    int x;
    string str;
};

sequence<string> StringSeq;

dictionary<long, StringSeq> StringTable;

interface ServerToClient {
    int op1(out float f, out bool b, out string s);
    void op2(out NumberAndString ns,
             out StringSeq ss,
             out StringTable st);
    void op3(out ServerToClient* proxy);
};

```

The PHP mapping looks the same as it did for the in-parameters version:

```
PHP
```

```
function op1($i, $f, $b, $s, $_ctx=null);
function op2($ns, $ss, $st, $_ctx=null);
function op3($proxy, $_ctx=null);
```

Given a proxy to a `ServerToClient` interface, the client code can receive the results as in the following example:

```
PHP
```

```
$p = ... // Get proxy...
$p->op1($i, $f, $b, $s);
$p->op2($ns, $ss, $st);
$p->op3($stcp);
```

Note that it is not necessary to use the reference operator (&) before each argument because the Ice run time forces each `out` parameter to have reference semantics.

Parameter Type Mismatches in PHP

The Ice run time performs validation on the arguments to a proxy invocation and reports any type mismatches as `InvalidArgumentException`.

Null Parameters in PHP

Some Slice types naturally have "empty" or "not there" semantics. Specifically, sequences, dictionaries, and strings all can be `null`, but the corresponding Slice types do not have the concept of a null value. To make life with these types easier, whenever you pass `null` as a parameter or return value of type sequence, dictionary, or string, the Ice run time automatically sends an empty sequence, dictionary, or string to the receiver.

This behavior is useful as a convenience feature: especially for deeply-nested data types, members that are sequences, dictionaries, or strings automatically arrive as an empty value at the receiving end. This saves you having to explicitly initialize, for example, every string element in a large sequence before sending the sequence in order to avoid a run-time error. Note that using null parameters in this way does *not* create null semantics for Slice sequences, dictionaries, or strings. As far as the object model is concerned, these do not exist (only *empty* sequences, dictionaries, and strings do). For example, it makes no difference to the receiver whether you send a string as `null` or as an empty string: either way, the receiver sees an empty string.

Optional Parameters in PHP

[Optional parameters](#) use the same mapping as required parameters. The only difference is that `Ice_Unset` can be passed as the value of an optional parameter or return value. Consider the following operation:

```
Slice
```

```
optional(1) int execute(optional(2) string params, out optional(3) float
value);
```

A client can invoke this operation as shown below:

PHP

```

$i = $proxy->execute("--file log.txt", $v);
$i = $proxy->execute(Ice_Unset, $v);

if($v != Ice_Unset)
    echo "value = " . $v . "\n";

```

A well-behaved program must always compare an optional parameter to `Ice_Unset` prior to using its value. Keep in mind that the `Ice_Unset` marker value has different semantics than `null`. Since `null` is a legal value for certain Slice types, the Ice run time requires a separate marker value so that it can determine whether an optional parameter is set. An optional parameter set to `null` is considered to be set. If you need to distinguish between an unset parameter and a parameter set to `null`, you can do so as follows:

PHP

```

if($optionalParam == Ice_Unset)
    echo "optionalParam is unset\n";
else if($optionalParam == null)
    echo "optionalParam is null\n";
else
    echo "optionalParam = " . $optionalParam . "\n";

```

Exception Handling in PHP

Any operation invocation may throw a [run-time exception](#) and, if the operation has an exception specification, may also throw [user exceptions](#). Suppose we have the following simple interface:

Slice

```

exception Tantrum {
    string reason;
};

interface Child {
    void askToCleanUp() throws Tantrum;
};

```

Slice exceptions are thrown as PHP exceptions, so you can simply enclose one or more operation invocations in a `try-catch` block:

PHP

```

$child = ...          // Get child proxy...

try
{
    $child->askToCleanUp();
}
catch(Tantrum $t)
{
    echo "The child says: " . $t->reason . "\n";
}

```

Typically, you will catch only a few exceptions of specific interest around an operation invocation; other exceptions, such as unexpected run-time errors, will usually be handled by exception handlers higher in the hierarchy. For example:

PHP

```

function run()
{
    $child = ...          // Get child proxy...
    try
    {
        $child->askToCleanUp();
    }
    catch(Tantrum $t)
    {
        echo "The child says: " . $t->reason . "\n";
        $child->scold(); // Recover from error...
    }
    $child->praise();     // Give positive feedback...
}

try
{
    // ...
    run();
    // ...
}
catch(Ice_Exception $ex)
{
    echo $ex->__toString() . "\n";
}

```

This code handles a specific exception of local interest at the point of call and deals with other exceptions generically. (This is also the strategy we used for our first simple application in [Hello World Application](#).)

PHP Mapping for Classes

On this page:

- [Basic PHP Mapping for Classes](#)
- [Inheritance from Object in PHP](#)
- [Class Data Members in PHP](#)
- [Class Constructors in PHP](#)
- [Class Operations in PHP](#)
- [Class Factories in PHP](#)

Basic PHP Mapping for Classes

A Slice `class` maps to a PHP class with the same name. For each Slice data member, the generated class contains a member variable, just as for structures and exceptions. Consider the following class definition:

```

Slice

```
class TimeOfDay {
 short hour; // 0 - 23
 short minute; // 0 - 59
 short second; // 0 - 59
 string format(); // Return time as hh:mm:ss
};
```

```

The PHP mapping generates the following code for this definition:

PHP

```

abstract class TimeOfDay extends Ice_ObjectImpl
{
    public function __construct($hour=0, $minute=0, $second=0)
    {
        $this->hour = $hour;
        $this->minute = $minute;
        $this->second = $second;
    }

    abstract public function format();

    public static function ice_staticId()
    {
        return '::TimeOfDay';
    }

    public function __toString()
    {
        // ...
    }

    public $hour;
    public $minute;
    public $second;
}

```

There are a number of things to note about the generated code:

1. The generated class `TimeOfDay` inherits from `Ice_ObjectImpl`. This reflects the semantics of Slice classes in that all classes implicitly inherit from `Object`, which is the ultimate ancestor of all classes. Note that `Object` is *not* the same as `Ice_ObjectPrx`. In other words, you *cannot* pass a class where a proxy is expected and vice versa.
2. The constructor initializes an instance variable for each Slice data member.
3. The class includes an abstract function declaration corresponding to the Slice operation `format`.
4. The class defines the class method `ice_staticId`.

There is quite a bit to discuss here, so we will look at each item in turn.

Inheritance from `Object` in PHP

Like interfaces, classes implicitly inherit from a common base class, `Ice_Object`. However, classes inherit from `Ice_Object` instead of `Ice_ObjectPrx`, therefore you cannot pass a class where a proxy is expected (and vice versa) because the base types for classes and proxies are not compatible.

`Ice_Object` contains a number of member functions:

PHP

```
interface Ice_Object
{
    public function ice_isA($id);

    public function ice_ping();

    public function ice_ids();

    public function ice_id();

    public function ice_preMarshal();

    public function ice_postUnmarshal();
}
```

The member functions of `Ice_Object` behave as follows:

- `ice_isA`
This method returns `true` if the object supports the given [type ID](#), and `false` otherwise.
- `ice_ping`
As for interfaces, `ice_ping` provides a basic reachability test for the object.
- `ice_ids`
This method returns a string sequence representing all of the [type IDs](#) supported by this object, including `::Ice::Object`.
- `ice_id`
This method returns the actual run-time [type ID](#) of the object. If you call `ice_id` through a reference to a base instance, the returned type ID is the actual (possibly more derived) type ID of the instance.
- `ice_preMarshal`
If the object supports this method, the Ice run time invokes it just prior to marshaling the object's state, providing the opportunity for the object to validate its declared data members.
- `ice_postUnmarshal`
If the object supports this method, the Ice run time invokes it after unmarshaling the object's state. An object typically defines this method when it needs to perform additional initialization using the values of its declared data members.

All Slice classes derive from `Ice_Object` via the `Ice_ObjectImpl` abstract base class, which provides default implementations of the `Ice_Object` methods.

Class Data Members in PHP

By default, data members of classes are mapped exactly as for structures and exceptions: for each data member in the Slice definition, the generated class contains a corresponding member variable.

[Optional data members](#) use the same mapping as required data members, but an optional data member can also be set to the marker value `Ice_Unset` to indicate that the member is unset. A well-behaved program must compare an optional data member to `Ice_Unset` before using the member's value:

PHP

```

$v = ...;
if($v->optionalMember == Ice_Unset)
    echo "optionalMember is unset\n";
else
    echo "optionalMember = " . $v->optionalMember . "\n";

```

The `Ice_Unset` marker value has different semantics than `null`. Since `null` is a legal value for certain Slice types, the Ice run time requires a separate marker value so that it can determine whether an optional value is set. An optional value set to `null` is considered to be set. If you need to distinguish between an unset value and a value set to `null`, you can do so as follows:

PHP

```

$v = ...;
if($v->optionalMember == Ice_Unset)
    echo "optionalMember is unset\n";
else if($v->optionalMember == null)
    echo "optionalMember is None\n";
else
    echo "optionalMember = " . $v->optionalMember . "\n";
}

```

If you wish to restrict access to a data member, you can modify its visibility using the `protected` metadata directive. The presence of this directive causes the Slice compiler to generate the data member with `protected` visibility. As a result, the member can be accessed only by the class itself or by one of its subclasses. For example, the `TimeOfDay` class shown below has the `protected` metadata directive applied to each of its data members:

Slice

```

class TimeOfDay {
    ["protected"] short hour;    // 0 - 23
    ["protected"] short minute; // 0 - 59
    ["protected"] short second; // 0 - 59
    string format();           // Return time as hh:mm:ss
};

```

The Slice compiler produces the following generated code for this definition:

PHP

```

abstract class TimeOfDay extends Ice_ObjectImpl
{
    public function __construct($hour=0, $minute=0, $second=0)
    {
        $this->hour = $hour;
        $this->minute = $minute;
        $this->second = $second;
    }

    abstract public function format();

    public static function ice_staticId()
    {
        return '::TimeOfDay';
    }

    public function __toString()
    {
        // ...
    }

    protected $hour;
    protected $minute;
    protected $second;
}

```

For a class in which all of the data members are protected, the metadata directive can be applied to the class itself rather than to each member individually. For example, we can rewrite the `TimeOfDay` class as follows:

Slice

```

["protected"] class TimeOfDay {
    short hour;          // 0 - 23
    short minute;       // 0 - 59
    short second;       // 0 - 59
    string format();    // Return time as hh:mm:ss
};

```

Class Constructors in PHP

Classes have a constructor that assigns to each data member a default value appropriate for its type:

Data Member Type	Default Value
string	Empty string
enum	First enumerator in enumeration

struct	Default-constructed value
Numeric	Zero
bool	False
sequence	Null
dictionary	Null
class/interface	Null

You can also declare different [default values](#) for data members of primitive and enumerated types.

For derived classes, the constructor has one parameter for each of the base class's data members, plus one parameter for each of the derived class's data members, in base-to-derived order.

Pass the marker value `Ice_Unset` as the value of any [optional data members](#) that you wish to be unset.

Class Operations in PHP

Operations of classes are mapped to abstract member functions in the generated class. This means that, if a class contains operations (such as the `format` operation of our `TimeOfDay` class), you must provide an implementation of the operation in a class that is derived from the generated class. For example:

```

PHP

class TimeOfDayI extends TimeOfDay
{
    public function format()
    {
        return strftime("%X");
    }
}
```

Class Factories in PHP

Having created a class such as `TimeOfDayI`, we have an implementation and we can instantiate the `TimeOfDayI` class, but we cannot receive it as the return value or as an out-parameter from an operation invocation. To see why, consider the following simple interface:

```

Slice

interface Time {
    TimeOfDay get();
};
```

When a client invokes the `get` operation, the Ice run time must instantiate and return an instance of the `TimeOfDay` class. However, `TimeOfDay` is an abstract class that cannot be instantiated. Unless we tell it, the Ice run time cannot magically know that we have created a `TimeOfDayI` class that implements the abstract `format` operation of the `TimeOfDay` abstract class. In other words, we must provide the Ice run time with a factory that knows that the `TimeOfDay` abstract class has a `TimeOfDayI` concrete implementation. The `Ice::CommunicatorI` interface provides us with the necessary operations:

Slice

```

module Ice {
    local interface ObjectFactory {
        Object create(string type);
        void destroy();
    };

    local interface Communicator {
        void addObjectFactory(ObjectFactory factory, string id);
        ObjectFactory findObjectFactory(string id);
        // ...
    };
};

```

To supply the Ice run time with a factory for our `TimeOfDayI` class, we must implement the `ObjectFactory` interface:

PHP

```

class ObjectFactory implements Ice_ObjectFactory {
    public function create($type) {
        if ($type == TimeOfDay::ice_staticId()) {
            return new TimeOfDayI;
        }
        assert(false);
        return null;
    }

    public function destroy() {
        // Nothing to do
    }
}

```

The object factory's `create` method is called by the Ice run time when it needs to instantiate a `TimeOfDay` class. The factory's `destroy` method is called by the Ice run time when its communicator is destroyed.

The `create` method is passed the **type ID** of the class to instantiate. For our `TimeOfDay` class, the type ID is `"::TimeOfDay"`. Our implementation of `create` checks the type ID: if it matches, the method instantiates and returns a `TimeOfDayI` object. For other type IDs, the method asserts because it does not know how to instantiate other types of objects.

Note that we used the `ice_staticId` method to obtain the type ID rather than embedding a literal string. Using a literal type ID string in your code is discouraged because it can lead to errors that are only detected at run time. For example, if a Slice class or one of its enclosing modules is renamed and the literal string is not changed accordingly, a receiver will fail to unmarshal the object and the Ice run time will raise `NoObjectFactoryException`. By using `ice_staticId` instead, we avoid any risk of a misspelled or obsolete type ID, and we can discover at compile time if a Slice class or module has been renamed.

Given a factory implementation, such as our `ObjectFactory`, we must inform the Ice run time of the existence of the factory:

PHP

```
$communicator = ...;
$communicator->addObjectFactory(new ObjectFactory,
TimeOfDay::ice_staticId());
```

Now, whenever the Ice run time needs to instantiate a class with the type ID `"::TimeOfDay"`, it calls the `create` method of the registered `ObjectFactory` instance.

The `destroy` operation of the object factory is invoked by the Ice run time when the communicator is destroyed. This gives you a chance to clean up any resources that may be used by your factory. Do not call `destroy` on the factory while it is registered with the communicator — if you do, the Ice run time has no idea that this has happened and, depending on what your `destroy` implementation is doing, may cause undefined behavior when the Ice run time tries to next use the factory.

The run time guarantees that `destroy` will be the last call made on the factory, that is, `create` will not be called concurrently with `destroy`, and `create` will not be called once `destroy` has been called.

Note that you cannot register a factory for the same type ID twice: if you call `addObjectFactory` with a type ID for which a factory is registered, the Ice run time throws an `AlreadyRegisteredException`.

Finally, keep in mind that if a class has only data members, but no operations, you need not create and register an object factory to transmit instances of such a class. Only if a class has operations do you have to define and register an object factory.

slice2php Command-Line Options

On this page:

- [slice2php Command-Line Options](#)
- [Compiler Output in PHP](#)
- [Include Files in PHP](#)

slice2php Command-Line Options

The Slice-to-PHP compiler, `slice2php`, offers the following command-line options in addition to the [standard options](#):

- `--all`
Generate code for all Slice definitions, including those included by the main Slice file.
- `-n, --namespace`
Generate code using PHP namespaces. Note that namespaces are only supported in PHP 5.3 or later. Also note that the Ice extension for PHP must be built with namespace support enabled.
- `--checksum`
Generate [checksums](#) for Slice definitions.

Compiler Output in PHP

For each Slice file `X.ice`, `slice2php` generates PHP code into a file named `X.php` in the output directory. The default output directory is the current working directory, but a different directory can be specified using the `--output-dir` option.

Include Files in PHP

It is important to understand how `slice2php` handles include files. In the absence of the `--all` option, the compiler does not generate PHP code for Slice definitions in included files. Rather, the compiler translates Slice `#include` statements into PHP `require` statements in the following manner:

1. Determine the full pathname of the included file.
2. Create the shortest possible relative pathname for the included file by iterating over each of the include directories (specified using the `-I` option) and removing the leading directory from the included file if possible.
For example, if the full pathname of an included file is `/opt/App/slice/OS/Process.ice`, and we specified the options `-I/opt/App` and `-I/opt/App/slice`, then the shortest relative pathname is `OS/Process.ice` after removing `/opt/App/slice`.
3. Replace the `.ice` extension with `.php`. Continuing our example from the previous step, the translated `require` statement becomes

```
require "OS/Process.php";
```

As a result, you can use `-I` options to tailor the `require` statements generated by the compiler in order to avoid absolute path names and match the organizational structure of your application's source files.

PHP Request Semantics

In PHP terminology, a *request* is the execution of a PHP script on behalf of a Web client. Each request essentially runs in its own instance of the PHP interpreter, isolated from any other requests that may be executing concurrently. Upon the completion of a request, the interpreter reclaims memory and other resources that were acquired during the request, including objects created by the Ice extension.

Using Communicators in PHP

A communicator represents an instance of the Ice run time. A PHP script that needs to invoke an operation on a remote Ice object must initialize a communicator, obtain and narrow a proxy, and make the invocation. For example, here is a minimal (but complete) Ice script:

PHP

```

<?php
require 'Ice.php';
require 'Hello.php';

$communicator = null;

try
{
    $data = new Ice_InitializationData;
    $data->properties = Ice_createProperties();
    $data->properties->load("props.cfg");
    $communicator = Ice_initialize($data);
    $proxy = $communicator->stringToProxy("...");
    $hello = Demo_HelloPrxHelper::checkedCast($proxy);
    $hello->sayHello();
}
catch(Ice_LocalException $ex)
{
    // Deal with exception...
}

if($communicator)
{
    try
    {
        $communicator->destroy();
    }
    catch(Ice_LocalException $ex)
    {
        // Ignore.
    }
}
?>

```

By default, the Ice extension automatically destroys any communicator that was created during a request. This means a script can usually omit the call to `destroy` unless there is an application-specific reason to destroy the communicator explicitly. Consequently, we can simplify our script to the following:

PHP

```

<?php
require 'Ice.php';
require 'Hello.php';

try
{
    $data = new Ice_InitializationData;
    $data->properties = Ice_createProperties();
    $data->properties->load("props.cfg");
    $communicator = Ice_initialize($data);
    $proxy = $communicator->stringToProxy("...");
    $hello = Demo_HelloPrxHelper::checkedCast($proxy);
    $hello->sayHello();
}
catch(Ice_LocalException $ex)
{
    // Deal with exception...
}
?>

```

Now we allow the Ice extension to destroy our communicator automatically. (The extension traps and ignores any exception raised by `destroy`.)

Although the automatic destruction of communicators is convenient, it is important to consider the performance characteristics of this script. Specifically, each execution of the script involves the following activities:

1. Create an Ice property set
2. Load and parse a property file
3. Initialize a communicator with the given configuration properties
4. Obtain a proxy for the remote Ice object
5. Establish a socket connection to the server
6. Send a request message and wait for the reply
7. Destroy the communicator, which closes the socket connection

Of primary concern are the activities that involve system calls, such as opening and reading files, creating and using sockets, and so on. The overhead incurred by these calls may not matter if the script is only executed infrequently, but for an application with high request rates it is necessary to minimize this overhead:

- A [pre-configured property set](#) eliminates the need to parse a property file in each request.
- [Timeouts](#) prevent a script from blocking indefinitely in case Ice encounters delays while performing socket operations.
- [Registering a communicator](#) avoids the need to create and destroy a communicator in every request.
- Be aware of the number of "round trips" (request-reply pairs) your script makes. For example, the script above uses `checkedCast` to verify that the remote Ice object supports the desired `Slice` interface. However, calling `checkedCast` causes the Ice run time to send a request to the server and await its reply, therefore this script is actually making two remote invocations. It is unnecessary to perform a checked cast if it is safe for the client to assume that the Ice object supports the correct interface, in which case using an `uncheckedCast` instead avoids the extra round trip.

Managing Property Sets in PHP

A PHP application can manually construct a [property set](#) for configuring its communicator. The Ice extension also provides a PHP-specific property set API that helps to minimize the overhead associated with initializing a communicator, allowing you to configure a default property

set along with an unlimited number of named property sets (or *profiles*). You can populate a property set using a configuration file, command-line options, or both. Property sets are initialized using the normal Ice semantics: command-line options override any settings from a configuration file.

The Ice extension creates these property sets during web server startup, which means any subsequent changes you might make to the configuration have no effect until the web server is restarted. Also keep in mind that specifying a relative path name for a configuration file usually means the path name is evaluated relative to the web server's working directory.

Default Property Set in PHP

The INI directives `ice.config` and `ice.options` specify the configuration file and the command-line options for the default property set, respectively. These directives must appear in PHP's configuration file, which is usually named `php.ini`:

```
; Snippet from php.ini on Linux
extension=IcePHP.so
ice.config=/opt/MyApp/default.cfg
ice.options="--Ice.Override.Timeout=2000"
```

Profiles in PHP

Profiles are useful when several unrelated applications execute in the same web server, or when a script needs to choose among multiple configurations. To configure your profiles, add an `ice.profiles` directive to PHP's configuration file. The value of this directive is a file containing profile definitions:

```
; Snippet from php.ini on Linux
ice.profiles=/opt/MyApp/profiles
```

The profile definition file uses INI syntax:

```
[Production]
config=/opt/MyApp/prod.cfg
options="..."

[Debug]
config=/opt/MyApp/debug.cfg
options="--Ice.Trace.Network=3 ..."
```

The name of each profile is enclosed in square brackets. The configuration file and command-line options for each profile are defined using the `config` and `options` entries, respectively.

Using Property Sets in PHP

The `Ice_getProperties` function allows a script to obtain a copy of a property set. When called without an argument, or with an empty string, the function returns the default property set. Otherwise, the function expects the name of a configured profile and returns the property set associated with that profile. The return value is an instance of `Ice_Properties`, or `null` if no matching profile was found.

Note that the Ice extension always creates the default property set, which is empty if the `ice.config` and `ice.options` directives are not defined. Also note that changes a script might make to a property set returned by this function have no effect on other requests because the script is modifying a *copy* of the original property set.

Now we can modify our script to use `Ice_getProperties` and avoid the need to load a configuration file in each request:

PHP

```

<?php
require 'Ice.php';
require 'Hello.php';

try
{
    $data = new Ice_InitializationData;
    $data->properties = Ice_getProperties();
    $communicator = Ice_initialize($data);
    $proxy = $communicator->stringToProxy("...");
    $hello = Demo_HelloPrxHelper::checkedCast($proxy);
    $hello->sayHello();
}
catch(Ice_LocalException $ex)
{
    // Deal with exception...
}
?>

```

Security Considerations for Property Sets in PHP

Ice configuration properties may contain sensitive information such as the path name of the private key for an X.509 certificate. If multiple untrusted PHP applications run in the same web server, avoid the use of the default property set and choose sufficiently unique names for your named profiles. The Ice extension does not provide a means for enumerating the names of the configured profiles, therefore a malicious script would have to guess the name of a profile in order to examine its configuration properties.

To prevent a script from using the value of `ice.profiles` to open the profile definition file directly, enable the `ice.hide_profiles` directive to cause the Ice extension to replace the `ice.profiles` setting after it has processed the file. The `ice.hide_profiles` directive is enabled by default.

Timeouts in PHP

All twoway remote invocations made by a PHP script have synchronous semantics: the script does not regain control until Ice receives a reply from the server. As a result, we recommend configuring a suitable `timeout` value for all of your proxies as a defensive measure against network delays.

Registered Communicators in PHP

You can register a communicator to prevent it from being destroyed at the completion of a script. For example, a session-based PHP application can create a communicator for each new session and register it for reuse in subsequent requests of the same session. Reusing a communicator in this way avoids the overhead associated with creating and destroying a communicator in each request. Furthermore, it allows socket connections established by the Ice run time to remain open and available for use in another request.

Limitations of Registered Communicators in PHP

A communicator object is local to the process that created it, which in the case of PHP is usually a web server process. The usefulness of a registered communicator is therefore limited to situations in which an application can ensure that subsequent page requests are handled by the same web server process as the one that originally created the registered communicator. For example, registered communicators would

not be appropriate in a typical CGI configuration because the CGI process terminates at the end of each request. A simple (but often impractical) solution is to configure your web server to use a single persistent process. The topic of configuring a web server to take advantage of registered communicators is outside the scope of this manual.

Using Registered Communicators in PHP

The API for registered communicators consists of three functions:

- `Ice_register($communicator, $name, $expires=0)`
Registers a communicator with the given name. On success, the function returns true. If another communicator is already registered with the same name, the function returns false. The `expires` argument specifies a timeout value in minutes; if `expires` is greater than zero, the Ice extension automatically destroys the communicator if it has not been retrieved (via `Ice_find`) for the specified number of minutes. The default value (zero) means the communicator never expires, in which case the Ice extension only destroys the communicator when the current process terminates. It is legal to register a communicator with more than one name. In that case, the most recent value of `expires` takes precedence.
- `Ice_unregister($name)`
Removes the registration for a communicator with the given name. Returns true if a match was found or false otherwise. Calling `Ice_unregister` does not cause the communicator to be destroyed; rather, the communicator is destroyed as soon as all pending requests that are currently using the communicator have completed. Destroying a registered communicator explicitly also removes its registration.
- `Ice_find($name)`
Retrieves the communicator associated with the given name. Returns `null` if no match is found.

An application typically uses registered communicators as follows:

PHP

```

<?php
require 'Ice.php';

$communicator = Ice_find('MyCommunicator');
$expires = ...;
if($communicator == null)
{
    $communicator = Ice_initialize(...);
    Ice_register($communicator, 'MyCommunicator', $expires);
}

...
?>

```

Note that communicators consume resources such as threads, sockets, and memory, therefore an application should be designed to minimize the number of communicators it registers. Using a suitable expiration timeout prevents registered communicators from accumulating indefinitely.

A simple application that demonstrates the use of registered communicators can be found in the `Glacier2/hello` subdirectory of the PHP sample programs.

Security Considerations for Registered Communicators in PHP

There are risks associated with allowing untrusted applications to gain access to a registered communicator. For example, if a malicious script obtains a registered communicator that is configured with SSL credentials, the script could potentially make secure invocations as if it were the trusted script.

Registering a communicator with a sufficiently unique name reduces the chance that a malicious script could guess the communicator's name. For applications that make use of PHP's session facility, the session ID is a reasonable choice for a communicator name. The sample application in `Glacier2/hello` demonstrates this solution.

Lifetime of Object Factories in PHP

PHP reclaims all memory at the end of each request, which means any object factories that a script might have installed in a registered communicator are destroyed when the request completes even if the communicator is not destroyed. As a result, a script must install its object factories in a registered communicator for *every* request, as shown in the example below:

```

PHP

```
<?php
require 'Ice.php';

$communicator = Ice_find('MyCommunicator');
$expires = ...;
if($communicator == null)
{
 $communicator = Ice_initialize(...);
 Ice_register($communicator, 'MyCommunicator', $expires);
}

$communicator->addObjectFactory(new MyFactory, MyClass::ice_staticId());
...
?>
```

```

The Ice extension invokes the `destroy` method of each factory prior to the completion of a request.

Using Slice Checksums in PHP

The Slice compilers can optionally generate [checksums](#) of Slice definitions. For `slice2php`, the `--checksum` option causes the compiler to generate code that adds checksums to the global array `Ice_sliceChecksums`. The checksums are installed automatically when the PHP code is first parsed; no action is required by the application.

In order to verify a server's checksums, a client could simply compare the two array objects using a comparison operator. However, this is not feasible if it is possible that the server might return a superset of the client's checksums. A more general solution is to iterate over the local checksums as demonstrated below:

PHP

```
global $Ice_sliceChecksums;
$serverChecksums = ...
foreach($Ice_sliceChecksums as $key => $value)
{
    if(!isset($serverChecksums[$key]))
        // No match found for type id!
    elseif($Ice_sliceChecksums[$key] != $serverChecksums[$key])
        // Checksum mismatch!
}
```

In this example, the client first verifies that the server's dictionary contains an entry for each Slice type ID, and then it proceeds to compare the checksums.

Example of a File System Client in PHP

This page presents a very simple client to access a server that implements the file system we developed in [Slice for a Simple File System](#). The PHP code shown here hardly differs from the code you would write for an ordinary PHP program. This is one of the biggest advantages of using Ice: accessing a remote object is as easy as accessing an ordinary, local PHP object. This allows you to put your effort where you should, namely, into developing your application logic instead of having to struggle with arcane networking APIs.

We now have seen enough of the client-side PHP mapping to develop a complete client to access our remote file system. For reference, here is the Slice definition once more:

```

Slice

module Filesystem {
    interface Node {
        idempotent string name();
    };

    exception GenericError {
        string reason;
    };

    sequence<string> Lines;

    interface File extends Node {
        idempotent Lines read();
        idempotent void write(Lines text) throws GenericError;
    };

    sequence<Node*> NodeSeq;

    interface Directory extends Node {
        idempotent NodeSeq list();
    };
};
```

To exercise the file system, the client does a recursive listing of the file system, starting at the root directory. For each node in the file system, the client shows the name of the node and whether that node is a file or directory. If the node is a file, the client retrieves the contents of the file and prints them.

The body of the client code looks as follows:

```

PHP

<?php
require 'Ice.php';
require 'Filesystem.php';

// Recursively print the contents of directory "dir"
// in tree fashion. For files, show the contents of
// each file. The "depth" parameter is the current
// nesting level (for indentation).
```

```

function listRecursive($dir, $depth = 0)
{
    $indent = str_repeat("\t", ++$depth);

    $contents = $dir->_list(); // list is a reserved word in PHP

    foreach ($contents as $i) {
        $dir = Filesystem_DirectoryPrxHelper::checkedCast($i);
        $file = Filesystem_FilePrxHelper::uncheckedCast($i);
        echo $indent . $i->name() .
($dir ? " (directory):" : " (file):") . "\n";
        if ($dir) {
            listRecursive($dir, $depth);
        } else {
            $text = $file->read();
            foreach ($text as $j)
                echo $indent . "\t" . $j . "\n";
        }
    }
}

$ic = null;
try
{
    // Create a communicator
    //
    $ic = Ice_initialize();

    // Create a proxy for the root directory
    //
    $obj = $ic->stringToProxy("RootDir:default -p 10000");

    // Down-cast the proxy to a Directory proxy
    //
    $rootDir = Filesystem_DirectoryPrxHelper::checkedCast($obj);

    // Recursively list the contents of the root directory
    //
    echo "Contents of root directory:\n";
    listRecursive($rootDir);
}
catch(Ice_LocalException $ex)
{
    print_r($ex);
}

if($ic)
{
    // Clean up

```

```
//  
try  
{  
    $ic->destroy();  
}  
catch(Exception $ex)  
{  
    print_r($ex);  
}
```

```
}
?>
```

The program first defines the `listRecursive` function, which is a helper function to print the contents of the file system, and the main program follows. Let us look at the main program first:

1. The client first creates a proxy to the root directory of the file system. For this example, we assume that the server runs on the local host and listens using the default protocol (TCP/IP) at port 10000. The object identity of the root directory is known to be `RootDir`.
2. The client down-casts the proxy to the `Directory` interface and passes that proxy to `listRecursive`, which prints the contents of the file system.

Most of the work happens in `listRecursive`. The function is passed a proxy to a directory to list, and an indent level. (The indent level increments with each recursive call and allows the code to print the name of each node at an indent level that corresponds to the depth of the tree at that node.) `listRecursive` calls the `list` operation on the directory and iterates over the returned sequence of nodes:

1. The code uses `checkedCast` to narrow the `Node` proxy to a `Directory` proxy, and uses `uncheckedCast` to narrow the `Node` proxy to a `File` proxy. Exactly one of those casts will succeed, so there is no need to call `checkedCast` twice: if the `Node` *is-a* `Directory`, the code uses the proxy returned by `checkedCast`; if `checkedCast` fails, we *know* that the `Node` *is-a* `File` and, therefore, `uncheckedCast` is sufficient to get a `File` proxy. In general, if you know that a down-cast to a specific type will succeed, it is preferable to use `uncheckedCast` instead of `checkedCast` because `uncheckedCast` does not incur any network traffic.
2. The code prints the name of the file or directory and then, depending on which cast succeeded, prints "`(directory)`" or "`(file)`" following the name.
3. The code checks the type of the node:
 - If it is a directory, the code recurses, incrementing the indent level.
 - If it is a file, the code calls the `read` operation on the file to retrieve the file contents and then iterates over the returned sequence of lines, printing each line.

Assume that we have a small file system consisting of a two files and a a directory as follows:

A small file system.

The output produced by the client for this file system is:

```
Contents of root directory:
```

```
  README (file):
```

```
    This file system contains a collection of poetry.
```

```
  Coleridge (directory):
```

```
    Kubla_Khan (file):
```

```
      In Xanadu did Kubla Khan
```

```
      A stately pleasure-dome decree:
```

```
      Where Alph, the sacred river, ran
```

```
      Through caverns measureless to man
```

```
      Down to a sunless sea.
```

Note that, so far, our client is not very sophisticated:

- The protocol and address information are hard-wired into the code.
- The client makes more remote procedure calls than strictly necessary; with minor redesign of the Slice definitions, many of these calls can be avoided.

We will see how to address these shortcomings in our discussions of [IceGrid](#) and [object life cycle](#).

- [Server-Side Slice-to-Python Mapping](#)

Client-Side Slice-to-Python Mapping

The client-side Slice-to-Python mapping defines how Slice data types are translated to Python types, and how clients invoke operations, pass parameters, and handle errors. Much of the Python mapping is intuitive. For example, Slice sequences map to Python lists, so there is essentially nothing new you have to learn in order to use Slice sequences in Python.

The Python API to the Ice run time is fully thread-safe. Obviously, you must still synchronize access to data from different threads. For example, if you have two threads sharing a sequence, you cannot safely have one thread insert into the sequence while another thread is iterating over the sequence. However, you only need to concern yourself with concurrent access to your own data — the Ice run time itself is fully thread safe, and none of the Ice API calls require you to acquire or release a lock before you safely can make the call.

Much of what appears in this chapter is reference material. We suggest that you skim the material on the initial reading and refer back to specific sections as needed. However, we recommend that you read at least the mappings for [exceptions](#), [interfaces](#), and [operations](#) in detail because these sections cover how to call operations from a client, pass parameters, and handle exceptions.

In order to use the Python mapping, you should need no more than the Slice definition of your application and knowledge of the Python mapping rules. In particular, looking through the generated code in order to discern how to use the Python mapping is likely to be inefficient, due to the amount of detail. Of course, occasionally, you may want to refer to the generated code to confirm a detail of the mapping, but we recommend that you otherwise use the material presented here to see how to write your client-side code.

The Ice Module

All of the APIs for the Ice run time are nested in the `Ice` module, to avoid clashes with definitions for other libraries or applications. Some of the contents of the `Ice` module are generated from Slice definitions; other parts of the `Ice` module provide special-purpose definitions that do not have a corresponding Slice definition. We will incrementally cover the contents of the `Ice` module throughout the remainder of the manual.

A Python application can load the Ice run time using the `import` statement:

```
import Ice
```

If the statement executes without error, the Ice run time is loaded and available for use. You can determine the version of the Ice run time you have just loaded by calling the `stringVersion` function:

```
icever = Ice.stringVersion()
```

Python Mapping for Identifiers

A Slice identifier maps to an identical Python identifier. For example, the Slice identifier `clock` becomes the Python identifier `clock`. There is one exception to this rule: if a Slice identifier is the same as a Python keyword or is an identifier reserved by the Ice run time (such as `checkedCast`), the corresponding Python identifier is prefixed with an underscore. For example, the Slice identifier `while` is mapped as `_while`.

You should try to [avoid such identifiers](#) as much as possible.

The mapping does not modify a Slice identifier that matches the name of a Python built-in function because it can always be accessed by its fully-qualified name. For example, the built-in function `hash` can also be accessed as `__builtin__.hash`.

Python Mapping for Modules

A Slice [module](#) maps to a Python module with the same name. The mapping preserves the nesting of the Slice definitions. Note that you can optionally use [packages](#) to gain further control over the generated code.

Python Mapping for Built-In Types

On this page:

- [Mapping of Slice Built-In Types to Python Types](#)
- [String Mapping in Python](#)

Mapping of Slice Built-In Types to Python Types

The Slice [built-in types](#) are mapped to Python types as shown in this table:

Slice	Python
bool	bool
short	int
int	int
long	long
float	double
double	double
string	string

Although Python supports arbitrary precision in its integer types, the Ice run time validates integer values to ensure they have valid ranges for their declared Slice types.

String Mapping in Python

String values returned as the result of a Slice operation (including return values, out parameters, and data members) are always represented as instances of Python's 8-bit `string` type. These string values contain UTF-8 encoded strings unless the program has installed a [string converter](#), in which case string values use the converter's native encoding instead.

Legal string input values for a remote Slice operation are shown below:

- None
Ice marshals an empty string whenever `None` is encountered.
- 8-bit string objects
Ice assumes that all 8-bit string objects contain valid UTF-8 encoded strings unless the program has installed a string converter, in which case Ice assumes that 8-bit string objects use the native encoding expected by the converter.
- Unicode objects
Ice converts a Unicode object into UTF-8 and marshals it directly. If a string converter is installed, it is not invoked for Unicode objects.

Python Mapping for Enumerations

Python does not have an enumerated type, so a Slice `enumeration` is emulated using a Python class: the name of the Slice enumeration becomes the name of the Python class; for each enumerator, the class contains an attribute with the same name as the enumerator. For example:

```
enum Fruit { Apple, Pear, Orange };
```

The generated Python class looks as follows:

```
class Fruit(Ice.EnumBase):
    def valueOf(self, n):
        # ...
    valueOf = classmethod(valueOf)

    # ...

Fruit.Apple = ...
Fruit.Pear = ...
Fruit.Orange = ...
```

Each instance of the class has a `value` attribute providing the Slice value of the enumerator, and a `name` attribute that returns its name. The `valueOf` class method translates a Slice value into its corresponding enumerator, or returns `None` if no match is found.

Given the above definitions, we can use enumerated values as follows:

Python

```
f1 = Fruit.Apple
f2 = Fruit.Orange

if f1 == Fruit.Apple:           # Compare with constant
    # ...

if f1 == f2:                    # Compare two enums
    # ...

if f2.value == Fruit.Apple.value: # Use Slice values
    # ...
elif f2.value == Fruit.Pear.value:
    # ...
elif f2.value == Fruit.Orange.value:
    # ...

Fruit.valueOf(1) # Pear
```

As you can see, the generated class enables natural use of enumerated values. The `Fruit` class attributes are preinitialized enumerators that you can use for initialization and comparison.

Note that the generated class also defines a number of Python special methods, such as `__str__` and rich comparison operators, which we have not shown. The rich comparison operators compare the Slice value of the enumerator, which is not necessarily the same as its ordinal value.

Suppose we modify the Slice definition to include a [custom enumerator value](#):

Slice

```
enum Fruit { Apple, Pear = 3, Orange };
```

We can use `valueOf` to examine the Slice values of the enumerators:

Python

```
Fruit.valueOf(0) # Apple
Fruit.valueOf(1) # None
Fruit.valueOf(3) # Pear
Fruit.valueOf(4) # Orange
```

See Also

- [Python Mapping for Built-In Types](#)

- [Python Mapping for Structures](#)
- [Python Mapping for Sequences](#)
- [Python Mapping for Dictionaries](#)
- [Python Mapping for Constants](#)
- [Python Mapping for Exceptions](#)

Python Mapping for Structures

A Slice [structure](#) maps to a Python class with the same name. For each Slice data member, the Python class contains a corresponding attribute. For example, here is our [Employee](#) structure once more:

Slice
<pre>struct Employee { long number; string firstName; string lastName; };</pre>

The Python mapping generates the following definition for this structure:

Python
<pre>class Employee(object): def __init__(self, number=0, firstName='', lastName=''): self.number = number self.firstName = firstName self.lastName = lastName def __eq__(self, other): # ... def __ne__(self, other): # ... def __str__(self): # ... def __hash__(self): # ... # ...</pre>

The constructor initializes each of the attributes to a default value appropriate for its type:

Data Member Type	Default Value
string	Empty string
enum	First enumerator in enumeration
struct	Default-constructed value
Numeric	Zero
bool	False

<code>sequence</code>	None
<code>dictionary</code>	None
<code>class/interface</code>	None

You can also declare different default values for members of primitive and enumerated types.

The `__eq__` method returns true if all members of two structures are (recursively) equal, and `__ne__` returns true if any member differs.

The `__str__` method returns a string representation of the structure.

For structures that are also [legal dictionary key types](#), the mapping also generates relational operators (`__lt__`, `__le__`, `__gt__`, `__ge__`) and a `__hash__` method. The `__hash__` method returns a hash value for the structure based on the value of all its data members.

- [Python Mapping for Constants](#)
- [Python Mapping for Exceptions](#)

Python Mapping for Sequences

On this page:

- [Default Sequence Mapping in Python](#)
- [Allowable Sequence Values in Python](#)
- [Customizing the Sequence Mapping in Python](#)

Default Sequence Mapping in Python

A Slice sequence maps by default to a Python list; the only exception is a sequence of bytes, which maps by default to a string in order to lower memory utilization and improve throughput. This use of native types means that the Python mapping does not generate a separate named type for a Slice sequence. It also means that you can take advantage of all the inherent functionality offered by Python's native types. For example, here is the definition of our `FruitPlatter` sequence once more:

```
Python
```

```
sequence<Fruit> FruitPlatter;
```

We can use the `FruitPlatter` sequence as shown below:

```
Python
```

```
platter = [ Fruit.Apple, Fruit.Pear ]
assert(len(platter) == 2)
platter.append(Fruit.Orange)
```

The Ice run time validates the elements of a tuple or list to ensure that they are compatible with the declared type; a `ValueError` exception is raised if an incompatible type is encountered.

Allowable Sequence Values in Python

Although each sequence type has a default mapping, the Ice run time allows a sender to use other types as well. Specifically, a tuple is also accepted for a sequence type that maps to a list, and in the case of a byte sequence, the sender is allowed to supply a tuple or list of integers as an alternative to a string.

Using a string for a byte sequence bypasses the validation step and avoids an extra copy, resulting in much greater throughput than a tuple or list. For larger byte sequences, the use of a string is strongly recommended.

Furthermore, the Ice run time accepts objects that implement Python's buffer protocol as legal values for sequences of all primitive types except strings. For example, you can use the `array` module to create a buffer that is transferred much more efficiently than a tuple or list. Consider the two sequence values in the sample code below:

```
Python
```

```
import array
...
seq1 = array.array("i", [1, 2, 3, 4, 5])
seq2 = [1, 2, 3, 4, 5]
```

The values have the same on-the-wire representation, but they differ greatly in marshaling overhead because the buffer can be traversed more quickly and requires no validation.

Note that the Ice run time has no way of knowing what type of elements a buffer contains, therefore it is the application's responsibility to ensure that a buffer is compatible with the declared sequence type.

Customizing the Sequence Mapping in Python

The previous section described the allowable types that an application may use when sending a sequence. That kind of flexibility is not possible when receiving a sequence, because in this case it is the Ice run time's responsibility to create the container that holds the sequence.

As stated earlier, the default mapping for most sequence types is a list, and for byte sequences the default mapping is a string. Unless otherwise indicated, an application always receives sequences as the container type specified by the default mapping. If it would be more convenient to receive a sequence as a different type, you can customize the mapping by annotating your Slice definitions with metadata. The following table describes the metadata directives supported by the Python mapping:

Directive	Description
<code>python:seq:default</code>	Use the default mapping.
<code>python:seq:list</code>	Map to a Python list.
<code>python:seq:tuple</code>	Map to a Python tuple.

A metadata directive may be specified when defining a sequence, or when a sequence is used as a parameter, return value or data member. If specified at the point of definition, the directive affects all occurrences of that sequence type unless overridden by another directive at a point of use. The following Slice definitions illustrate these points:

Slice

```

sequence<int> IntList; // Uses list by default
["python:seq:tuple"] sequence<int> IntTuple; // Defaults to tuple

sequence<byte> ByteString; // Uses string by default
["python:seq:list"] sequence<byte> ByteList; // Defaults to list

struct S {
    IntList i1; // list
    IntTuple i2; // tuple
    ["python:seq:tuple"] IntList i3; // tuple
    ["python:seq:list"] IntTuple i4; // list
    ["python:seq:default"] IntTuple i5; // list

    ByteString b1; // string
    ByteList b2; // list
    ["python:seq:list"] ByteString b3; // list
    ["python:seq:tuple"] ByteString b4; // tuple
    ["python:seq:default"] ByteList b5; // string
};

interface I {
    IntList op1(ByteString s1, out ByteList s2);

    ["python:seq:tuple"]
    IntList op2(["python:seq:list"] ByteString s1,
               ["python:seq:tuple"] out ByteList s2);
};

```

The operation `op2` and the data members of structure `S` demonstrate how to override the mapping for a sequence at the point of use.

It is important to remember that these metadata directives only affect the receiver of the sequence. For example, the data members of structure `S` are populated with the specified sequence types only when the Ice run time unmarshals an instance of `S`. In the case of an operation, custom metadata affects the client when specified for the operation's return type and output parameters, whereas metadata affects the server for input parameters.

Python Mapping for Dictionaries

Here is the definition of our `EmployeeMap` once more:

Slice
<pre>dictionary<long, Employee> EmployeeMap;</pre>

As for [sequences](#), the Python mapping does not create a separate named type for this definition. Instead, *all* dictionaries are simply instances of Python's dictionary type. For example:

Python
<pre>em = {} e = Employee() e.number = 31 e.firstName = "James" e.lastName = "Gosling" em[e.number] = e</pre>

The Ice run time validates the elements of a dictionary to ensure that they are compatible with the declared type; a `ValueError` exception is raised if an incompatible type is encountered.

- [Python Mapping for Exceptions](#)

Python Mapping for Constants

Here are the constant definitions once more:

```

Slice
const bool      AppendByDefault = true;
const byte      LowerNibble = 0x0f;
const string    Advice = "Don't Panic!";
const short     TheAnswer = 42;
const double    PI = 3.1416;

enum Fruit { Apple, Pear, Orange };
const Fruit     FavoriteFruit = Pear;

```

The generated definitions for these constants are shown below:

```

Python
AppendByDefault = True
LowerNibble = 15
Advice = "Don't Panic!"
TheAnswer = 42
PI = 3.1416
FavoriteFruit = Fruit.Pear

```

As you can see, each Slice constant is mapped to a Python attribute with the same name as the constant.

Slice string literals that contain non-ASCII characters or universal character names are mapped to Python string literals with these characters replaced by their UTF-8 encoding as octal escapes. For example:

```

Slice
const string Egg = "æuf";
const string Heart = "c\u0153ur";
const string Banana = "\U0001F34C";

```

is mapped to:

```

Python
Egg = "\305\223uf"
Heart = "c\305\223ur"
Banana = "\360\237\215\214"

```

- Python Mapping for Run-Time Exceptions

Inheritance Hierarchy for Exceptions in Python

The mapping for exceptions is based on the inheritance hierarchy shown below:

Inheritance structure for Ice exceptions.

The ancestor of all exceptions is `exceptions.Exception`, from which `Ice.Exception` is derived. `Ice.LocalException` and `Ice.UserException` are derived from `Ice.Exception` and form the base for all run-time and user exceptions.

Python Mapping for User Exceptions

Here is a fragment of the [Slice definition](#) for our world time server once more:

Slice

```

exception GenericError {
    string reason;
};
exception BadTimeVal extends GenericError {};
exception BadZoneName extends GenericError {};

```

These exception definitions map as follows:

Python
<pre> class GenericError(Ice.UserException): def __init__(self, reason=''): self.reason = reason def ice_name(self): # ... def __str__(self): # ... class BadTimeVal(GenericError): def __init__(self, reason=''): GenericError.__init__(self, reason) def ice_name(self): # ... def __str__(self): # ... class BadZoneName(GenericError): def __init__(self, reason=''): GenericError.__init__(self, reason) def ice_name(self): # ... def __str__(self): # ... </pre>

Each Slice exception is mapped to a Python class with the same name. The inheritance structure of the Slice exceptions is preserved for the generated classes, so `BadTimeVal` and `BadZoneName` inherit from `GenericError`.

Each exception member corresponds to an attribute of the instance, which the constructor initializes to a default value appropriate for its type:

Data Member Type	Default Value
string	Empty string
enum	First enumerator in enumeration
struct	Default-constructed value
Numeric	Zero
bool	False
sequence	None

dictionary	None
class/interface	None

You can also declare different [default values](#) for members of primitive and enumerated types. For derived exceptions, the constructor has one parameter for each of the base exception's data members, plus one parameter for each of the derived exception's data members, in base-to-derived order. As an example, although `BadTimeVal` and `BadZoneName` do not declare data members, their constructors still accept a value for the inherited data member `reason` in order to pass it to the constructor of the base exception `GenericError`.

Each exception also defines the `ice_name` method to return the name of the exception, and the special method `__str__` to return a stringified representation of the exception and its members.

All user exceptions are derived from the base class `Ice.UserException`. This allows you to catch all user exceptions generically by installing a handler for `Ice.UserException`. Similarly, you can catch all Ice run-time exceptions with a handler for `Ice.LocalException`, and you can catch all Ice exceptions with a handler for `Ice.Exception`.

Optional Data Members

[Optional data members](#) use the same mapping as required data members, but an optional data member can also be set to the marker value `Ice.Unset` to indicate that the member is unset. A well-behaved program must test an optional data member before using its value:

Python

```

try:
    ...
except ex:
    if ex.optionalMember:
        print("optionalMember = " + str(ex.optionalMember))
    else:
        print("optionalMember is unset")

```

The `Ice.Unset` marker value has different semantics than `None`. Since `None` is a legal value for certain Slice types, the Ice run time requires a separate marker value so that it can determine whether an optional value is set. An optional value set to `None` is considered to be set. If you need to distinguish between an unset value and a value set to `None`, you can do so as follows:

Python

```

try:
    ...
except ex:
    if ex.optionalMember is Ice.Unset:
        print("optionalMember is unset")
    elif ex.optionalMember is None:
        print("optionalMember is None")
    else:
        print("optionalMember = " + str(ex.optionalMember))

```

Python Mapping for Run-Time Exceptions

The Ice run time throws [run-time exceptions](#) for a number of pre-defined error conditions. All run-time exceptions directly or indirectly derive from `Ice.LocalException` (which, in turn, derives from `Ice.Exception`).

By catching exceptions at the appropriate point in the inheritance hierarchy, you can handle exceptions according to the category of error they indicate:

- `Ice.LocalException`
This is the root of the inheritance tree for run-time exceptions.
- `Ice.UserException`
This is the root of the inheritance tree for user exceptions.
- `Ice.TimeoutException`
This is the base exception for both operation-invocation and connection-establishment timeouts.
- `Ice.ConnectTimeoutException`
This exception is raised when the initial attempt to establish a connection to a server times out.

For example, a `ConnectTimeoutException` can be handled as `ConnectTimeoutException`, `TimeoutException`, `LocalException`, or `Exception`.

You will probably have little need to catch run-time exceptions as their most-derived type and instead catch them as `LocalException`; the fine-grained error handling offered by the remainder of the hierarchy is of interest mainly in the implementation of the Ice run time. Exceptions to this rule are the exceptions related to `facet` and `object` life cycles, which you may want to catch explicitly. These exceptions are `FacetNotExistException` and `ObjectNotExistException`, respectively.

Python Mapping for Interfaces

The mapping of Slice [interfaces](#) revolves around the idea that, to invoke a remote operation, you call a member function on a local class instance that is a [proxy](#) for the remote object. This makes the mapping easy and intuitive to use because making a remote procedure call is no different from making a local procedure call (apart from error semantics).

On this page:

- [Proxy Classes in Python](#)
- [Ice.ObjectPrx Class in Python](#)
- [Casting Proxies in Python](#)
- [Using Proxy Methods in Python](#)
- [Object Identity and Proxy Comparison in Python](#)

Proxy Classes in Python

On the client side, a Slice interface maps to a Python class with methods that correspond to the operations on that interface. Consider the following simple interface:

Slice
<pre>interface Simple { void op(); };</pre>

The Python mapping generates the following definition for use by the client:

Python
<pre>class SimplePrx(Ice.ObjectPrx): def op(self, _ctx=None): # ... def ice_staticId(): return '...' ice_staticId = staticmethod(ice_staticId) # ...</pre>

In the client's address space, an instance of `SimplePrx` is the local ambassador for a remote instance of the `Simple` interface in a server and is known as a *proxy instance*. All the details about the server-side object, such as its address, what protocol to use, and its object identity are encapsulated in that instance.

Note that `SimplePrx` inherits from `Ice.ObjectPrx`. This reflects the fact that all Ice interfaces implicitly inherit from `Ice::Object`.

For each operation in the interface, the proxy class has a method of the same name. In the preceding example, we find that the operation `op` has been mapped to the method `op`. Note that `op` accepts an optional trailing parameter `_ctx` representing the operation context. This parameter is a Python dictionary for use by the Ice run time to store information about how to deliver a request. You normally do not need to use it. (We examine the context parameter in detail in [Request Contexts](#). The parameter is also used by [IceStorm](#).)

Proxy instances are always created on behalf of the client by the Ice run time, so client code never has any need to instantiate a proxy directly.

A value of `None` denotes the null proxy. The null proxy is a dedicated value that indicates that a proxy points "nowhere" (denotes no object).

Another method defined by every proxy class is `ice_staticId`, which returns the [type ID](#) string corresponding to the interface. As an example, for the Slice interface `Simple` in module `M`, the string returned by `ice_staticId` is `"::M::Simple"`.

Ice.ObjectPrx Class in Python

All Ice objects have `Object` as the ultimate ancestor type, so all proxies inherit from `Ice.ObjectPrx`. `ObjectPrx` provides a number of methods:

Python
<pre>class ObjectPrx(object): def equals(self, other): def ice_getIdentity(self): def ice_isA(self, id): def ice_ids(self): def ice_id(self): def ice_ping(self): # ...</pre>

The methods behave as follows:

- equals**
 This method compares two proxies for equality. Note that all aspects of proxies are compared by this method, such as the communication endpoints for the proxy. This means that, in general, if two proxies compare unequal, that does *not* imply that they denote different objects. For example, if two proxies denote the same Ice object via different transport endpoints, `equals` returns `false` even though the proxies denote the same object.
- ice_getIdentity**
 This method returns the identity of the object denoted by the proxy. The identity of an Ice object has the following Slice type:

Slice
<pre>module Ice { struct Identity { string name; string category; }; };</pre>

To see whether two proxies denote the same object, first obtain the identity for each object and then compare the identities:

Python

```

proxy1 = ...
proxy2 = ...
id1 = proxy1.ice_getIdentity()
id2 = proxy2.ice_getIdentity()

if id1 == id2:
    # proxy1 and proxy2 denote the same object
else:
    # proxy1 and proxy2 denote different objects

```

- **ice_isA**

The `ice_isA` method determines whether the object denoted by the proxy supports a specific interface. The argument to `ice_isA` is a [type ID](#). For example, to see whether a proxy of type `ObjectPrx` denotes a `Printer` object, we can write:

Python

```

proxy = ...
if proxy != None and proxy.ice_isA("::Printer"):
    # proxy denotes a Printer object
else:
    # proxy denotes some other type of object

```

Note that we are testing whether the proxy is `None` before attempting to invoke the `ice_isA` method. This avoids getting a run-time error if the proxy is `None`.

- **ice_ids**

The `ice_ids` method returns an array of strings representing all of the [type IDs](#) that the object denoted by the proxy supports.

- **ice_id**

The `ice_id` method returns the [type ID](#) of the object denoted by the proxy. Note that the type returned is the type of the actual object, which may be more derived than the static type of the proxy. For example, if we have a proxy of type `BasePrx`, with a static type ID of `::Base`, the return value of `ice_id` might be `::Base`, or it might something more derived, such as `::Derived`.

- **ice_ping**

The `ice_ping` method provides a basic reachability test for the object. If the object can physically be contacted (that is, the object exists and its server is running and reachable), the call completes normally; otherwise, it throws an exception that indicates why the object could not be reached, such as `ObjectNotExistException` or `ConnectTimeoutException`.

The `ice_isA`, `ice_ids`, `ice_id`, and `ice_ping` methods are remote operations and therefore support an optional trailing parameter representing a [request context](#). Also note that there are [other methods](#) in `ObjectPrx`, not shown here. These methods provide different ways to dispatch a call and also provide access to an object's [facets](#).

Casting Proxies in Python

The Python mapping for a proxy also generates two static methods:

Python

```
class SimplePrx(Ice.ObjectPrx):
    # ...

    def checkedCast(proxy, facet=''):
        # ...
    checkedCast = staticmethod(checkedCast)

    def uncheckedCast(proxy, facet=''):
        # ...
    uncheckedCast = staticmethod(uncheckedCast)
```

The method names `checkedCast` and `uncheckedCast` are reserved for use in proxies. If a Slice interface defines an operation with either of those names, the mapping escapes the name in the generated proxy by prepending an underscore. For example, an interface that defines an operation named `checkedCast` is mapped to a proxy with a method named `_checkedCast`.

For `checkedCast`, if the passed proxy is for an object of type `Simple`, or a proxy for an object with a type derived from `Simple`, the cast returns a reference to a proxy of type `SimplePrx`; otherwise, if the passed proxy denotes an object of a different type (or if the passed proxy is `None`), the cast returns `None`.

Given a proxy of any type, you can use a `checkedCast` to determine whether the corresponding object supports a given type, for example:

Python

```
obj = ...          # Get a proxy from somewhere...

simple = SimplePrx.checkedCast(obj)
if simple != None:
    # Object supports the Simple interface...
else:
    # Object is not of type Simple...
```

Note that a `checkedCast` contacts the server. This is necessary because only the implementation of an object in the server has definite knowledge of the type of an object. As a result, a `checkedCast` may throw a `ConnectTimeoutException` or an `ObjectNotExistException`.

In contrast, an `uncheckedCast` does not contact the server and unconditionally returns a proxy of the requested type. However, if you do use an `uncheckedCast`, you must be certain that the proxy really does support the type you are casting to; otherwise, if you get it wrong, you will most likely get a run-time exception when you invoke an operation on the proxy. The most likely error for such a type mismatch is `OperationNotExistException`. However, other exceptions, such as a marshaling exception are possible as well. And, if the object happens to have an operation with the correct name, but different parameter types, no exception may be reported at all and you simply end up sending the invocation to an object of the wrong type; that object may do rather nonsensical things. To illustrate this, consider the following two interfaces:

Slice

```
interface Process {
    void launch(int stackSize, int dataSize);
};

// ...

interface Rocket {
    void launch(float xCoord, float yCoord);
};
```

Suppose you expect to receive a proxy for a `Process` object and use an `uncheckedCast` to down-cast the proxy:

Python

```
obj = ... # Get proxy...
process = ProcessPrx.uncheckedCast(obj) # No worries...
process.launch(40, 60) # Oops...
```

If the proxy you received actually denotes a `Rocket` object, the error will go undetected by the Ice run time: because `int` and `float` have the same size and because the Ice protocol does not tag data with its type on the wire, the implementation of `Rocket::launch` will simply misinterpret the passed integers as floating-point numbers.

In fairness, this example is somewhat contrived. For such a mistake to go unnoticed at run time, both objects must have an operation with the same name and, in addition, the run-time arguments passed to the operation must have a total marshaled size that matches the number of bytes that are expected by the unmarshaling code on the server side. In practice, this is extremely rare and an incorrect `uncheckedCast` typically results in a run-time exception.

Using Proxy Methods in Python

The base proxy class `ObjectPrx` supports a variety of [methods for customizing a proxy](#). Since proxies are immutable, each of these "factory methods" returns a copy of the original proxy that contains the desired modification. For example, you can obtain a proxy configured with a ten second timeout as shown below:

Python

```
proxy = communicator.stringToProxy(...)
proxy = proxy.ice_timeout(10000)
```

A factory method returns a new proxy object if the requested modification differs from the current proxy, otherwise it returns the current proxy. With few exceptions, factory methods return a proxy of the same type as the current proxy, therefore it is generally not necessary to repeat a down-cast after using a factory method. The example below demonstrates these semantics:

Python

```
base = communicator.stringToProxy(...)
hello = Demo.HelloPrx.checkedCast(base)
hello = hello.ice_timeout(10000) # Type is preserved
hello.sayHello()
```

The only exceptions are the factory methods `ice_facet` and `ice_identity`. Calls to either of these methods may produce a proxy for an object of an unrelated type, therefore they return a base proxy that you must subsequently down-cast to an appropriate type.

Object Identity and Proxy Comparison in Python

Proxy objects support comparison using the built-in relational operators as well as the `cmp` function. Note that proxy comparison uses *all* of the information in a proxy for the comparison. This means that not only the object identity must match for a comparison to succeed, but other details inside the proxy, such as the protocol and endpoint information, must be the same. In other words, comparison tests for *proxy* identity, *not* object identity. A common mistake is to write code along the following lines:

Python

```
p1 = ...          # Get a proxy...
p2 = ...          # Get another proxy...

if p1 != p2:
    # p1 and p2 denote different objects      # WRONG!
else:
    # p1 and p2 denote the same object        # Correct
```

Even though `p1` and `p2` differ, they may denote the same Ice object. This can happen because, for example, both `p1` and `p2` embed the same object identity, but each uses a different protocol to contact the target object. Similarly, the protocols may be the same, but denote different endpoints (because a single Ice object can be contacted via several different transport endpoints). In other words, if two proxies compare equal, we know that the two proxies denote the same object (because they are identical in all respects); however, if two proxies compare unequal, we know absolutely nothing: the proxies may or may not denote the same object.

To compare the object identities of two proxies, you can use helper functions in the `Ice` module:

Python

```
def proxyIdentityCompare(lhs, rhs)
def proxyIdentityAndFacetCompare(lhs, rhs)
```

`proxyIdentityCompare` allows you to correctly compare proxies for identity:

Python

```
p1 = ...          # Get a proxy...
p2 = ...          # Get another proxy...

if Ice.proxyIdentityCompare(p1, p2) != 0:
    # p1 and p2 denote different objects      # Correct
else:
    # p1 and p2 denote the same object       # Correct
```

The function returns 0 if the identities are equal, 1 if `p1` is less than `p2`, and -1 if `p1` is greater than `p2`. (The comparison uses `name` as the major sort key and `category` as the minor sort key.)

The `proxyIdentityAndFacetCompare` function behaves similarly, but compares both the identity and the facet name.

Python Mapping for Operations

On this page:

- [Basic Python Mapping for Operations](#)
- [Normal and idempotent Operations in Python](#)
- [Passing Parameters in Python](#)
 - [In-Parameters in Python](#)
 - [Out-Parameters in Python](#)
 - [Parameter Type Mismatches in Python](#)
 - [Null Parameters in Python](#)
 - [Optional Parameters in Python](#)
- [Exception Handling in Python](#)

Basic Python Mapping for Operations

As we saw in the [Python mapping for interfaces](#), for each operation on an interface, the proxy class contains a corresponding method with the same name. To invoke an operation, you call it via the proxy. For example, here is part of the definitions for our `file system`:

```

Slice

module Filesystem {
    interface Node {
        idempotent string name();
    };
    // ...
};
```

The `name` operation returns a value of type `string`. Given a proxy to an object of type `Node`, the client can invoke the operation as follows:

```

Python

node = ...           # Initialize proxy
name = node.name()  # Get name via RPC
```

Normal and idempotent Operations in Python

You can add an `idempotent` qualifier to a `Slice` operation. As far as the signature for the corresponding proxy method is concerned, `idempotent` has no effect. For example, consider the following interface:

```

Slice

interface Example {
    string op1();
    idempotent string op2();
};
```

The proxy class for this is:

Python

```
class ExamplePrx(Ice.ObjectPrx):
    def op1(self, _ctx=None):
        # ...

    def op2(self, _ctx=None):
        # ...
```

Because `idempotent` affects an aspect of call dispatch, not interface, it makes sense for the two methods to look the same.

Passing Parameters in Python

In-Parameters in Python

All parameters are passed by reference in the Python mapping; it is guaranteed that the value of a parameter will not be changed by the invocation.

Here is an interface with operations that pass parameters of various types from client to server:

Slice

```
struct NumberAndString {
    int x;
    string str;
};

sequence<string> StringSeq;

dictionary<long, StringSeq> StringTable;

interface ClientToServer {
    void op1(int i, float f, bool b, string s);
    void op2(NumberAndString ns, StringSeq ss, StringTable st);
    void op3(ClientToServer* proxy);
};
```

The Slice compiler generates the following proxy for this definition:

Python

```
class ClientToServerPrx(Ice.ObjectPrx):
    def op1(self, i, f, b, s, _ctx=None):
        # ...

    def op2(self, ns, ss, st, _ctx=None):
        # ...

    def op3(self, proxy, _ctx=None):
        # ...
```

Given a proxy to a `ClientToServer` interface, the client code can pass parameters as in the following example:

Python

```
p = ... # Get proxy...

p.op1(42, 3.14f, True, "Hello world!") # Pass simple literals

i = 42
f = 3.14f
b = True
s = "Hello world!"
p.op1(i, f, b, s) # Pass simple variables

ns = NumberAndString()
ns.x = 42
ns.str = "The Answer"
ss = [ "Hello world!" ]
st = {}
st[0] = ns
p.op2(ns, ss, st) # Pass complex variables

p.op3(p) # Pass proxy
```

Out-Parameters in Python

As in Java, Python functions do not support reference arguments. That is, it is not possible to pass an uninitialized variable to a Python function in order to have its value initialized by the function. The [Java mapping](#) overcomes this limitation with the use of *holder classes* that represent each `out` parameter. The Python mapping takes a different approach, one that is more natural for Python users.

The semantics of `out` parameters in the Python mapping depend on whether the operation returns one value or multiple values. An operation returns multiple values when it has declared multiple `out` parameters, or when it has declared a non-void return type and at least one `out` parameter.

If an operation returns multiple values, the client receives them in the form of a *result tuple*. A non-void return value, if any, is always the first element in the result tuple, followed by the `out` parameters in the order of declaration.

If an operation returns only one value, the client receives the value itself.

Here again are the same Slice definitions we saw earlier, but this time with all parameters being passed in the `out` direction:

Slice
<pre> struct NumberAndString { int x; string str; }; sequence<string> StringSeq; dictionary<long, StringSeq> StringTable; interface ServerToClient { int op1(out float f, out bool b, out string s); void op2(out NumberAndString ns, out StringSeq ss, out StringTable st); void op3(out ServerToClient* proxy); }; </pre>

The Python mapping generates the following code for this definition:

Python
<pre> class ServerToClientPrx(Ice.ObjectPrx): def op1(self, _ctx=None): # ... def op2(self, _ctx=None): # ... def op3(self, _ctx=None): # ... </pre>

Given a proxy to a `ServerToClient` interface, the client code can receive the results as in the following example:

Python
<pre> p = ... # Get proxy... i, f, b, s = p.op1() ns, ss, st = p.op2() stcp = p.op3() </pre>

The operations have no `in` parameters, therefore no arguments are passed to the proxy methods. Since `op1` and `op2` return multiple values, their result tuples are unpacked into separate values, whereas the return value of `op3` requires no unpacking.

Parameter Type Mismatches in Python

Although the Python compiler cannot check the types of arguments passed to a function, the Ice run time does perform validation on the arguments to a proxy invocation and reports any type mismatches as a `ValueError` exception.

Null Parameters in Python

Some Slice types naturally have "empty" or "not there" semantics. Specifically, sequences, dictionaries, and strings all can be `None`, but the corresponding Slice types do not have the concept of a null value. To make life with these types easier, whenever you pass `None` as a parameter or return value of type sequence, dictionary, or string, the Ice run time automatically sends an empty sequence, dictionary, or string to the receiver.

This behavior is useful as a convenience feature: especially for deeply-nested data types, members that are sequences, dictionaries, or strings automatically arrive as an empty value at the receiving end. This saves you having to explicitly initialize, for example, every string element in a large sequence before sending the sequence in order to avoid a run-time error. Note that using null parameters in this way does *not* create null semantics for Slice sequences, dictionaries, or strings. As far as the object model is concerned, these do not exist (only *empty* sequences, dictionaries, and strings do). For example, it makes no difference to the receiver whether you send a string as `None` or as an empty string: either way, the receiver sees an empty string.

Optional Parameters in Python

Optional parameters use the same mapping as required parameters. The only difference is that `Ice.Unset` can be passed as the value of an optional parameter or return value. Consider the following operation:

Slice
<pre>optional(1) int execute(optional(2) string params, out optional(3) float value);</pre>

A client can invoke this operation as shown below:

Python
<pre>i, v = proxy.execute("--file log.txt") i, v = proxy.execute(Ice.Unset) if v: print("value = " + str(v)) # v is set to a value</pre>

A well-behaved program must always test an optional parameter prior to using its value. Keep in mind that the `Ice.Unset` marker value has different semantics than `None`. Since `None` is a legal value for certain Slice types, the Ice run time requires a separate marker value so that it can determine whether an optional parameter is set. An optional parameter set to `None` is considered to be set. If you need to distinguish between an unset parameter and a parameter set to `None`, you can do so as follows:

Python

```

if optionalParam is Ice.Unset:
    print("optionalParam is unset")
elif optionalParam is None:
    print("optionalParam is None")
else:
    print("optionalParam = " + str(optionalParam))

```

Exception Handling in Python

Any operation invocation may throw a [run-time exception](#) and, if the operation has an exception specification, may also throw [user exceptions](#). Suppose we have the following simple interface:

Slice

```

exception Tantrum {
    string reason;
};

interface Child {
    void askToCleanUp() throws Tantrum;
};

```

Slice exceptions are thrown as Python exceptions, so you can simply enclose one or more operation invocations in a `try-except` block:

Python

```

child = ...          # Get child proxy...

try:
    child.askToCleanUp()
except Tantrum, t:
    print "The child says:", t.reason

```

Typically, you will catch only a few exceptions of specific interest around an operation invocation; other exceptions, such as unexpected run-time errors, will usually be handled by exception handlers higher in the hierarchy. For example:

Python

```
import traceback, Ice

def run():
    child = ... # Get child proxy...
    try:
        child.askToCleanUp()
    except Tantrum, t:
        print "The child says:", t.reason
        child.scold() # Recover from error...
        child.praise() # Give positive feedback...

try:
    # ...
    run()
    # ...
except Ice.Exception:
    traceback.print_exc()
```

This code handles a specific exception of local interest at the point of call and deals with other exceptions generically. (This is also the strategy we used for our first simple application in [Hello World Application](#).)

Python Mapping for Classes

On this page:

- [Basic Python Mapping for Classes](#)
- [Inheritance from Ice.Object in Python](#)
- [Class Data Members in Python](#)
- [Class Constructors in Python](#)
- [Class Operations in Python](#)
- [Class Factories in Python](#)

Basic Python Mapping for Classes

A Slice `class` maps to a Python class with the same name. The generated class contains an attribute for each Slice data member (just as for structures and exceptions). Consider the following class definition:

Slice
<pre>class TimeOfDay { short hour; // 0 - 23 short minute; // 0 - 59 short second; // 0 - 59 string format(); // Return time as hh:mm:ss };</pre>

The Python mapping generates the following code for this definition:

Python
<pre>class TimeOfDay(Ice.Object): def __init__(self, hour=0, minute=0, second=0): # ... self.hour = hour self.minute = minute self.second = second def ice_staticId(): return '::M::TimeOfDay' ice_staticId = staticmethod(ice_staticId) # ... # # Operation signatures. # # def format(self, current=None):</pre>

There are a number of things to note about the generated code:

1. The generated class `TimeOfDay` inherits from `Ice.Object`. This means that all classes implicitly inherit from `Ice.Object`, which

is the ultimate ancestor of all classes. Note that `Ice.Object` is *not* the same as `Ice.ObjectPrx`. In other words, you *cannot* pass a class where a proxy is expected and vice versa.

2. The constructor defines an attribute for each Slice data member.
3. The class defines the static method `ice_staticId`.
4. A comment summarizes the method signatures for each Slice operation.

There is quite a bit to discuss here, so we will look at each item in turn.

Inheritance from `Ice.Object` in Python

Like interfaces, classes implicitly inherit from a common base class, `Ice.Object`. However, as shown in the illustration below, classes inherit from `Ice.Object` instead of `Ice.ObjectPrx` (which is at the base of the inheritance hierarchy for proxies). As a result, you cannot pass a class where a proxy is expected (and vice versa) because the base types for classes and proxies are not compatible.

Inheritance from `Ice.ObjectPrx` and `Ice.Object`.

`Ice.Object` contains a number of methods:

Python

```

class Object(object):
    def ice_isA(self, id, current=None):
        # ...

    def ice_ping(self, current=None):
        # ...

    def ice_ids(self, current=None):
        # ...

    def ice_id(self, current=None):
        # ...

    def ice_staticId():
        # ...
    ice_staticId = staticmethod(ice_staticId)

    def ice_preMarshal(self):
        # ...

    def ice_postUnmarshal(self):
        # ...

```

The member functions of `Ice.Object` behave as follows:

- `ice_isA`
This method returns `true` if the object supports the given [type ID](#), and `false` otherwise.
- `ice_ping`
As for interfaces, `ice_ping` provides a basic reachability test for the object.
- `ice_ids`
This method returns a string sequence representing all of the [type IDs](#) supported by this object, including `::Ice::Object`.
- `ice_id`
This method returns the actual run-time [type ID](#) of the object. If you call `ice_id` through a reference to a base instance, the returned type ID is the actual (possibly more derived) type ID of the instance.
- `ice_staticId`
This method is generated in each class and returns the static [type ID](#) of the class.
- `ice_preMarshal`
The Ice run time invokes this method prior to marshaling the object's state, providing the opportunity for a subclass to validate its declared data members.
- `ice_postUnmarshal`
The Ice run time invokes this method after unmarshaling an object's state. A subclass typically overrides this function when it needs to perform additional initialization using the values of its declared data members.

Note that neither `Ice.Object` nor the generated class override `__hash__` and `__eq__`, so the default implementations apply.

Class Data Members in Python

By default, data members of classes are mapped exactly as for structures and exceptions: for each data member in the Slice definition, the generated class contains a corresponding attribute.

Optional data members use the same mapping as required data members, but an optional data member can also be set to the marker value `Ice.Unset` to indicate that the member is unset. A well-behaved program must test an optional data member before using its value:

Python

```
try:
    ...
except ex:
    if ex.optionalMember:
        print("optionalMember = " + str(ex.optionalMember))
    else:
        print("optionalMember is unset")
```

The `Ice.Unset` marker value has different semantics than `None`. Since `None` is a legal value for certain Slice types, the Ice run time requires a separate marker value so that it can determine whether an optional value is set. An optional value set to `None` is considered to be set. If you need to distinguish between an unset value and a value set to `None`, you can do so as follows:

Python

```
try:
    ...
except ex:
    if ex.optionalMember is Ice.Unset:
        print("optionalMember is unset")
    elif ex.optionalMember is None:
        print("optionalMember is None")
    else:
        print("optionalMember = " + str(ex.optionalMember))
```

Although Python provides no standard mechanism for restricting access to an object's attributes, by convention an attribute whose name begins with an underscore signals the author's intent that the attribute should only be accessed by the class itself or by one of its subclasses. You can employ this convention in your Slice classes using the `protected` metadata directive. The presence of this directive causes the Slice compiler to prepend an underscore to the mapped name of the data member. For example, the `TimeOfDay` class shown below has the `protected` metadata directive applied to each of its data members:

Slice

```
class TimeOfDay {
    ["protected"] short hour;    // 0 - 23
    ["protected"] short minute; // 0 - 59
    ["protected"] short second; // 0 - 59
    string format();           // Return time as hh:mm:ss
};
```

The Slice compiler produces the following generated code for this definition:

Python

```
class TimeOfDay(Ice.Object):
    def __init__(self, hour=0, minute=0, second=0):
        # ...
        self._hour = hour
        self._minute = minute
        self._second = second

    # ...

    #
    # Operation signatures.
    #
    # def format(self, current=None):
```

For a class in which all of the data members are protected, the metadata directive can be applied to the class itself rather than to each member individually. For example, we can rewrite the `TimeOfDay` class as follows:

Slice

```
["protected"] class TimeOfDay {
    short hour;           // 0 - 23
    short minute;        // 0 - 59
    short second;        // 0 - 59
    string format();     // Return time as hh:mm:ss
};
```

Class Constructors in Python

Classes have a constructor that assigns to each data member a default value appropriate for its type:

Data Member Type	Default Value
string	Empty string
enum	First enumerator in enumeration
struct	Default-constructed value
Numeric	Zero
bool	False
sequence	None
dictionary	None
class/interface	None

You can also declare different [default values](#) for data members of primitive and enumerated types.

For derived classes, the constructor has one parameter for each of the base class's data members, plus one parameter for each of the derived class's data members, in base-to-derived order.

You can invoke this constructor in one of two ways:

- Provide values for all members, including [optional members](#), in the order of declaration:

```

Python

t = TimeOfDay(12, 33, 45)
t2 = TimeOfDay(14, 7) # second defaults to 0
```

Pass `Ice.Unset` as the value of any optional member you want to be unset.

- Used named arguments to specify values for certain members and in any order:

```

Python

t = TimeOfDay(minute=33, hour=12)
```

Class Operations in Python

Operations of classes are mapped to methods in the generated class. This means that, if a class contains operations (such as the `format` operation of our `TimeOfDay` class), you must provide an implementation of the operation in a class that is derived from the generated class. For example:

```

Python

class TimeOfDayI(TimeOfDay):
    def __init__(self, hour=0, minute=0, second=0):
        TimeOfDay.__init__(self, hour, minute, second)

    def format(self, current=None):
        return "%02d:%02d:%02d" % (self.hour, self.minute, self.second)
```

A Slice class such as `TimeOfDay` that declares or inherits an operation is inherently abstract. Python does not support the notion of abstract classes or abstract methods, therefore the mapping merely summarizes the required method signatures in a comment for your convenience. Furthermore, the mapping generates code in the constructor of an abstract class to prevent it from being instantiated directly; any attempt to do so raises a `RuntimeError` exception.

You may notice that the mapping for an operation adds an optional trailing parameter named `current`. For now, you can ignore this parameter and pretend it does not exist.

Class Factories in Python

Having created a class such as `TimeOfDayI`, we have an implementation and we can instantiate the `TimeOfDayI` class, but we cannot receive it as the return value or as an out-parameter from an operation invocation. To see why, consider the following simple interface:

Slice

```
interface Time {
    TimeOfDay get();
};
```

When a client invokes the `get` operation, the Ice run time must instantiate and return an instance of the `TimeOfDay` class. However, `TimeOfDay` is an abstract class that cannot be instantiated. Unless we tell it, the Ice run time cannot magically know that we have created a `TimeOfDayI` class that implements the abstract `format` operation of the `TimeOfDay` abstract class. In other words, we must provide the Ice run time with a factory that knows that the `TimeOfDay` abstract class has a `TimeOfDayI` concrete implementation. The `Ice::Communicator` interface provides us with the necessary operations:

Slice

```
module Ice {
    local interface ObjectFactory {
        Object create(string type);
        void destroy();
    };

    local interface Communicator {
        void addObjectFactory(ObjectFactory factory, string id);
        ObjectFactory findObjectFactory(string id);
        // ...
    };
};
```

To supply the Ice run time with a factory for our `TimeOfDayI` class, we must implement the `ObjectFactory` interface:

Python

```
class ObjectFactory(Ice.ObjectFactory):
    def create(self, type):
        if type == M.TimeOfDay.ice_staticId():
            return TimeOfDayI()
        assert(False)
        return None

    def destroy(self):
        # Nothing to do
        pass
```

The object factory's `create` method is called by the Ice run time when it needs to instantiate a `TimeOfDay` class. The factory's `destroy` method is called by the Ice run time when its communicator is destroyed.

The `create` method is passed the `type ID` of the class to instantiate. For our `TimeOfDay` class, the type ID is `"::M::TimeOfDay"`. Our

implementation of `create` checks the type ID: if it matches, the method instantiates and returns a `TimeOfDayI` object. For other type IDs, the method asserts because it does not know how to instantiate other types of objects.

Note that we used the `ice_staticId` method to obtain the type ID rather than embedding a literal string. Using a literal type ID string in your code is discouraged because it can lead to errors that are only detected at run time. For example, if a Slice class or one of its enclosing modules is renamed and the literal string is not changed accordingly, a receiver will fail to unmarshal the object and the Ice run time will raise `NoObjectFactoryException`. By using `ice_staticId` instead, we avoid any risk of a misspelled or obsolete type ID, and we can discover earlier whether a Slice class or module has been renamed.

Given a factory implementation, such as our `ObjectFactory`, we must inform the Ice run time of the existence of the factory:

Python

```
ic = ... # Get Communicator...
ic.addObjectFactory(ObjectFactory(), M.TimeOfDay.ice_staticId())
```

Now, whenever the Ice run time needs to instantiate a class with the type ID `"::M::TimeOfDay"`, it calls the `create` method of the registered `ObjectFactory` instance.

The `destroy` operation of the object factory is invoked by the Ice run time when the communicator is destroyed. This gives you a chance to clean up any resources that may be used by your factory. Do not call `destroy` on the factory while it is registered with the communicator — if you do, the Ice run time has no idea that this has happened and, depending on what your `destroy` implementation is doing, may cause undefined behavior when the Ice run time tries to next use the factory.

The run time guarantees that `destroy` will be the last call made on the factory, that is, `create` will not be called concurrently with `destroy`, and `create` will not be called once `destroy` has been called. However, calls to `create` can be made concurrently.

Note that you cannot register a factory for the same type ID twice: if you call `addObjectFactory` with a type ID for which a factory is registered, the Ice run time throws an `AlreadyRegisteredException`.

Finally, keep in mind that if a class has only data members, but no operations, you need not create and register an object factory to transmit instances of such a class. Only if a class has operations do you have to define and register an object factory.

Asynchronous Method Invocation (AMI) in Python

Asynchronous Method Invocation (AMI) is the term used to describe the client-side support for the asynchronous programming model. AMI supports both oneway and twoway requests, but unlike their synchronous counterparts, AMI requests never block the calling thread. When a client issues an AMI request, the Ice run time hands the message off to the local transport buffer or, if the buffer is currently full, queues the request for later delivery. The application can then continue its activities and poll or wait for completion of the invocation, or receive a callback when the invocation completes.

AMI is transparent to the server: there is no way for the server to tell whether a client sent a request synchronously or asynchronously.

Basic Asynchronous API in Python

Consider the following simple Slice definition:

Slice
<pre> module Demo { interface Employees { string getName(int number); }; }; </pre>

Asynchronous Proxy Methods in Python

Besides the synchronous proxy methods, the Python mapping generates the following asynchronous proxy methods:

Python
<pre> def begin_getName(self, number, _response=None, _ex=None, _sent=None, _ctx=None) def end_getName(self, result) </pre>

As you can see, the single `getName` operation results in `begin_getName` and `end_getName` methods. The `begin_` method optionally accepts a [per-invocation context](#) and [callbacks](#).

- The `begin_getName` method sends (or queues) an invocation of `getName`. This method does not block the calling thread.
- The `end_getName` method collects the result of the asynchronous invocation. If, at the time the calling thread calls `end_getName`, the result is not yet available, the calling thread blocks until the invocation completes. Otherwise, if the invocation completed some time before the call to `end_getName`, the method returns immediately with the result.

A client could call these methods as follows:

Python

```
e = EmployeePrx.checkedCast(...)
r = e.begin_getName(99)

# Continue to do other things here...

name = e.end_getName(r)
```

Because `begin_getName` does not block, the calling thread can do other things while the operation is in progress.

Note that `begin_getName` returns a value of type `AsyncResult`. This value contains the state that the Ice run time requires to keep track of the asynchronous invocation. You must pass the `AsyncResult` that is returned by the `begin_` method to the corresponding `end_` method.

The `begin_` method has one parameter for each in-parameter of the corresponding Slice operation. The `end_` method accepts the `AsyncResult` object as its only argument and returns the out-parameters using the [same semantics](#) as for regular synchronous invocations. For example, consider the following operation:

Slice

```
double op(int inp1, string inp2, out bool outp1, out long outp2);
```

The `begin_op` and `end_op` methods have the following signature:

Python

```
def begin_op(self, inp1, inp2, ...)
def end_op(self, result)
```

The call to `end_op` returns the following tuple:

Python

```
doubleValue, outp1, outp2 = p.end_op(result)
```

Asynchronous Exception Semantics in Python

If an invocation raises an exception, the exception is thrown by the `end_` method, even if the actual error condition for the exception was encountered during the `begin_` method ("on the way out"). The advantage of this behavior is that all exception handling is located with the code that calls the `end_` method (instead of being present twice, once where the `begin_` method is called, and again where the `end_` method is called).

There is one exception to the above rule: if you destroy the communicator and then make an asynchronous invocation, the `begin_` method throws `CommunicatorDestroyedException`. This is necessary because, once the run time is finalized, it can no longer throw an exception from the `end_` method.

The only other exception that is thrown by the `begin_` and `end_` methods is `RuntimeError`. This exception indicates that you have used

the API incorrectly. For example, the `begin_` method throws this exception if you call an operation that has a return value or out-parameters on a oneway proxy. Similarly, the `end_` method throws this exception if you use a different proxy to call the `end_` method than the proxy you used to call the `begin_` method, or if the `AsyncResult` you pass to the `end_` method was obtained by calling the `begin_` method for a different operation.

AsyncResult Class in Python

The `AsyncResult` that is returned by the `begin_` method encapsulates the state of the asynchronous invocation:

Python
<pre> class AsyncResult: def cancel() def getCommunicator() def getConnection() def getProxy() def getOperation() def isCompleted() def waitForCompleted() def isSent() def waitForSent() def throwLocalException() def sentSynchronously() </pre>

The methods have the following semantics:

- `cancel()`
This method prevents a queued invocation from being sent or, if the invocation has already been sent, ignores a reply if the server sends one. `cancel` is a local operation and has no effect on the server. A canceled invocation is considered to be completed, meaning `isCompleted` returns true, and the result of the invocation is an `Ice.InvocationCanceledException`.
- `getCommunicator()`
This method returns the communicator that sent the invocation.
- `getConnection()`
This method returns the connection that was used for the invocation. Note that, for typical asynchronous proxy invocations, this method returns a nil value because the possibility of automatic retries means the connection that is currently in use could change unexpectedly. The `getConnection` method only returns a non-nil value when the `AsyncResult` object is obtained by calling `begin_flushBatchRequests` on a `Connection` object.
- `getProxy()`
This method returns the proxy that was used to call the `begin_` method, or nil if the `AsyncResult` object was not obtained via an asynchronous proxy invocation.
- `getOperation()`
This method returns the name of the operation.
- `isCompleted()`
This method returns true if, at the time it is called, the result of an invocation is available, indicating that a call to the `end_` method will not block the caller. Otherwise, if the result is not yet available, the method returns false.

- `waitForCompleted()`
This method blocks the caller until the result of an invocation becomes available.
- `isSent()`
When you call the `begin_` method, the Ice run time attempts to write the corresponding request to the client-side transport. If the transport cannot accept the request, the Ice run time queues the request for later transmission. `isSent` returns true if, at the time it is called, the request has been written to the local transport (whether it was initially queued or not). Otherwise, if the request is still queued or an exception occurred before the request could be sent, `isSent` returns false.
- `waitForSent()`
This method blocks the calling thread until a request has been written to the client-side transport, or an exception occurs. After `waitForSent` returns, `isSent` returns true if the request was successfully written to the client-side transport, or false if an exception occurred. In the case of a failure, you can call the corresponding `end_` method or `throwLocalException` to obtain the exception.
- `throwLocalException()`
This method throws the local exception that caused the invocation to fail. If no exception has occurred yet, `throwLocalException` does nothing.
- `sentSynchronously()`
This method returns true if a request was written to the client-side transport without first being queued. If the request was initially queued, `sentSynchronously` returns false (independent of whether the request is still in the queue or has since been written to the client-side transport).

Polling for Completion in Python

The `AsyncResult` methods allow you to poll for call completion. Polling is useful in a variety of cases. As an example, consider the following simple interface to transfer files from client to server:

Slice

```

interface FileTransfer
{
    void send(int offset, ByteSeq bytes);
};

```

The client repeatedly calls `send` to send a chunk of the file, indicating at which offset in the file the chunk belongs. A naïve way to transmit a file would be along the following lines:

Python

```

file = open(...)
ft = FileTransferPrx.checkedCast(...)
chunkSize = ...
offset = 0
while not file.eof():
    bytes = file.read(chunkSize) # Read a chunk
    ft.send(offset, bytes)      # Send the chunk
    offset += len(bytes.length)

```

This works, but not very well: because the client makes synchronous calls, it writes each chunk on the wire and then waits for the server to receive the data, process it, and return a reply before writing the next chunk. This means that both client and server spend much of their time doing nothing — the client does nothing while the server processes the data, and the server does nothing while it waits for the client to send the next chunk.

Using asynchronous calls, we can improve on this considerably:

Python

```

file = open(...)
ft = FileTransferPrx.checkedCast(...)
chunkSize = ...
offset = 0

results = []
numRequests = 5

while not file.eof():
    bytes = file.read(chunkSize) # Read a chunk

    # Send up to numRequests + 1 chunks asynchronously.
    r = ft.begin_send(offset, bytes)
    offset += len(bytes)

    # Wait until this request has been passed to the transport.
    r.waitForSent()
    results.append(r)

    # Once there are more than numRequests, wait for the least
    # recent one to complete.
    while len(results) > numRequests:
        r = results[0]
        del results[0]
        r.waitForCompleted()

    # Wait for any remaining requests to complete.
    while len(results) > 0:
        r = results[0]
        del results[0]
        r.waitForCompleted()

```

With this code, the client sends up to `numRequests + 1` chunks before it waits for the least recent one of these requests to complete. In other words, the client sends the next request without waiting for the preceding request to complete, up to the limit set by `numRequests`. In effect, this allows the client to "keep the pipe to the server full of data": the client keeps sending data, so both client and server continuously do work.

Obviously, the correct chunk size and value of `numRequests` depend on the bandwidth of the network as well as the amount of time taken by the server to process each request. However, with a little testing, you can quickly zoom in on the point where making the requests larger or queuing more requests no longer improves performance. With this technique, you can realize the full bandwidth of the link to within a percent or two of the theoretical bandwidth limit of a native socket connection.

Completion Callbacks in Python

The `begin_` method accepts three optional callback arguments that allow you to be notified asynchronously when a request completes. Here are the corresponding methods for the `getName` operation:

Python

```
def begin_getName(self, number, _response=None, _ex=None,
                 _sent=None, _ctx=None)
```

The value you pass for the response callback (`_response`), the exception callback (`_ex`), or the sent callback (`_sent`) argument must be a *callable object* such as a function or method. The response callback is invoked when the request completes successfully, and the exception callback is invoked when the operation raises an exception. (The sent callback is primarily used for [flow control](#).)

For example, consider the following callbacks for an invocation of the `getName` operation:

Python

```
def getNameCB(name):
    print "Name is: " + name

def failureCB(ex):
    print "Exception is: " + str(ex)
```

The response callback parameters depend on the operation signature. If the operation has a non-`void` return type, the first parameter of the response callback is the return value. The return value (if any) is followed by a parameter for each out-parameter of the corresponding Slice operation, in the order of declaration.

The exception callback is invoked if the invocation fails because of an Ice run time exception, or if the operation raises a user exception.

To inform the Ice run time that you want to receive callbacks for the completion of the asynchronous call, you pass the callbacks to the `begin_` method:

Python

```
e = EmployeesPrx.checkedCast(...)

e.begin_getName(99, getNameCB, failureCB)
```

Although the signature of an asynchronous proxy method implies that all of the callbacks are optional and therefore can be supplied in any combination, Ice enforces the following semantics at run time:

- If you omit all callbacks, you must call the `end_` method explicitly as described [earlier](#).
- If you supply either a response callback or a sent callback (or both), you must also supply an exception callback.
- You may omit the response callback for an operation that returns no data (that is, an operation with a `void` return type and no out-parameters).

Sharing State Between `begin_` and `end_` Methods in Python

It is common for the `end_` method to require access to some state that is established by the code that calls the `begin_` method. As an example, consider an application that asynchronously starts a number of operations and, as each operation completes, needs to update different user interface elements with the results. In this case, the `begin_` method knows which user interface element should receive the update, and the `end_` method needs access to that element.

Assuming that we have a `Widget` class that designates a particular user interface element, you could pass different widgets by storing the widget to be used as a member of a callback class:

Python

```
class MyCallback(object):
    def __init__(self, w):
        self._w = w

    def getNameCB(self, name):
        self._w.writeString(name)

    def failureCB(self, ex):
        print "Exception is: " + str(ex)
```

For this example, we assume that widgets have a `writeString` method that updates the relevant UI element.

When you call the `begin_` method, you pass the appropriate callback instance to inform the `end_` method how to update the display:

Python

```
e = EmployeesPrx.checkedCast(...)
widget1 = ...
widget2 = ...

# Invoke the getName operation with different widget callbacks.
cb1 = MyCallback(widget1)
e.begin_getName(99, cb1.getNameCB, cb1.failureCB)
cb2 = MyCallback(widget2)
e.begin_getName(24, cb2.getNameCB, cb2.failureCB)
```

The callback class provides a simple and effective way for you to pass state between the point where an operation is invoked and the point where its results are processed. Moreover, if you have a number of operations that share common state, you can pass the same callback instance to multiple invocations. (If you do this, your callback methods may need to use synchronization.)

For those situations in which a stateless callback is preferred, you can use a lambda function to pass state to a callback. Consider the following example:

Python

```
def getNameCB(name, w):
    w.writeString(name)

def failureCB(ex):
    print "Exception is: " + str(ex)

e = EmployeesPrx.checkedCast(...)
widget1 = ...
widget2 = ...

# Use lambda functions to pass state.
e.begin_getName(99, lambda name: getNameCB(name, widget1), failureCB)
e.begin_getName(24, lambda name: getNameCB(name, widget2), failureCB)
```

This strategy eliminates the need to encapsulate shared state in a callback class. Since lambda functions can refer to variables in the enclosing scope, they provide a convenient way to pass state directly to your callback.

Asynchronous Oneway Invocations in Python

You can invoke operations via oneway proxies asynchronously, provided the operation has `void` return type, does not have any out-parameters, and does not raise user exceptions. If you call the `begin_` method on a oneway proxy for an operation that returns values or raises a user exception, the `begin_` method throws a `RuntimeError`.

The callback signatures look exactly as for a twoway invocation, but the response method is never called and may be omitted.

Flow Control in Python

Asynchronous method invocations never block the thread that calls the `begin_` method: the Ice run time checks to see whether it can write the request to the local transport. If it can, it does so immediately in the caller's thread. (In that case, `AsyncResult.sentSynchronously` returns true.) Alternatively, if the local transport does not have sufficient buffer space to accept the request, the Ice run time queues the request internally for later transmission in the background. (In that case, `AsyncResult.sentSynchronously` returns false.)

This creates a potential problem: if a client sends many asynchronous requests at the time the server is too busy to keep up with them, the requests pile up in the client-side run time until, eventually, the client runs out of memory.

The API provides a way for you to implement flow control by counting the number of requests that are queued so, if that number exceeds some threshold, the client stops invoking more operations until some of the queued operations have drained out of the local transport.

You can supply a sent callback to be notified when the request was successfully sent:

Python

```
def response(name):
    # ...

def exception(ex):
    # ...

def sent(sentSynchronously):
    # ...
```

You inform the Ice run time that you want to be informed when a call has been passed to the local transport as usual:

Python

```
e.begin_getName(99, response, exception, sent)
```

If the Ice run time can immediately pass the request to the local transport, it does so and invokes the `sent` callback from the thread that calls the `begin_` method. On the other hand, if the run time has to queue the request, it calls the `sent` callback from a different thread once it has written the request to the local transport. The boolean `sentSynchronously` parameter indicates whether the request was sent synchronously or was queued.

The `sent` callback allows you to limit the number of queued requests by counting the number of requests that are queued and decrementing the count when the Ice run time passes a request to the local transport.

Asynchronous Batch Requests in Python

Applications that send [batched requests](#) can either flush a batch explicitly or allow the Ice run time to flush automatically. The proxy method `ice_flushBatchRequests` performs an immediate flush using the synchronous invocation model and may block the calling thread until the entire message can be sent. Ice also provides asynchronous versions of this method so you can flush batch requests asynchronously.

`begin_ice_flushBatchRequests` and `end_ice_flushBatchRequests` are proxy methods that flush any batch requests queued by that proxy.

In addition, similar methods are available on the communicator and the `Connection` object that is returned by `AsyncResult.getConnection`. These methods flush batch requests sent via the same communicator and via the same connection, respectively.

Concurrency Semantics for AMI in Python

The Ice run time always invokes your callback methods from a separate thread, with one exception: it calls the `sent` callback from the thread calling the `begin_` method if the request could be sent synchronously. In the `sent` callback, you know which thread is calling the callback by looking at the `sentSynchronously` parameter.

Code Generation in Python

The Python mapping supports two forms of code generation: dynamic and static.

On this page:

- [Dynamic Code Generation in Python](#)
 - [Ice.loadSlice Options in Python](#)
 - [Locating Slice Files in Python](#)
 - [Loading Multiple Slice Files in Python](#)
- [Static Code Generation in Python](#)
 - [Compiler Output in Python](#)
 - [Include Files in Python](#)
- [Static Versus Dynamic Code Generation in Python](#)
 - [Application Considerations for Code Generation in Python](#)
 - [Mixing Static and Dynamic Code Generation in Python](#)
- [slice2py Command-Line Options](#)
- [Generating Packages in Python](#)

Dynamic Code Generation in Python

Using dynamic code generation, Slice files are "loaded" at run time and dynamically translated into Python code, which is immediately compiled and available for use by the application. This is accomplished using the `Ice.loadSlice` function, as shown in the following example:

Python
<pre>Ice.loadSlice("Color.ice") import M print "My favorite color is", M.Color.blue</pre>

For this example, we assume that `Color.ice` contains the following definitions:

Slice
<pre>module M { enum Color { red, green, blue }; };</pre>

The code imports module `M` after the Slice file is loaded because module `M` is not defined until the Slice definitions have been translated into Python.

Ice.loadSlice Options in Python

The `Ice.loadSlice` function behaves like a Slice compiler in that it accepts command-line arguments for specifying preprocessor options and controlling code generation. The arguments must include at least one Slice file.

The function has the following Python definition:

Python

```
def Ice.loadSlice(cmd, args=[])
```

The command-line arguments can be specified entirely in the first argument, `cmd`, which must be a string. The optional second argument can be used to pass additional command-line arguments as a list; this is useful when the caller already has the arguments in list form. The function always returns `None`.

For example, the following calls to `Ice.loadSlice` are functionally equivalent:

Python

```
Ice.loadSlice("-I/opt/IcePy/slice Color.ice")
Ice.loadSlice("-I/opt/IcePy/slice", ["Color.ice"])
Ice.loadSlice("", ["-I/opt/IcePy/slice", "Color.ice"])
```

In addition to the [standard compiler options](#), `Ice.loadSlice` also supports the following command-line options:

- `--all`
Generate code for all Slice definitions, including those from included files.
- `--checksum`
Generate [checksums](#) for Slice definitions.

Locating Slice Files in Python

If your Slice files depend on Ice types, you can avoid hard-coding the path name of your Ice installation directory by calling the `Ice.getSliceDir` function:

Python

```
Ice.loadSlice("-I" + Ice.getSliceDir() + " Color.ice")
```

This function attempts to locate the `slice` subdirectory of your Ice installation using an algorithm that succeeds for the following scenarios:

- Installation of a binary Ice archive
- Installation of an Ice source distribution using `make install`
- Installation via a Windows installer
- RPM installation on Linux
- Execution inside a compiled Ice source distribution

If the `slice` subdirectory can be found, `getSliceDir` returns its absolute path name, otherwise the function returns `None`.

Loading Multiple Slice Files in Python

You can specify as many Slice files as necessary in a single invocation of `Ice.loadSlice`, as shown below:

Python

```
Ice.loadSlice("Syscall.ice Process.ice")
```

Alternatively, you can call `Ice.loadSlice` several times:

Python

```
Ice.loadSlice("Syscall.ice")
Ice.loadSlice("Process.ice")
```

If a Slice file includes another file, the default behavior of `Ice.loadSlice` generates Python code only for the named file. For example, suppose `Syscall.ice` includes `Process.ice` as follows:

Slice

```
// Syscall.ice
#include <Process.ice>
...
```

If you call `Ice.loadSlice("-I. Syscall.ice")`, Python code is not generated for the Slice definitions in `Process.ice` or for any definitions that may be included by `Process.ice`. If you also need code to be generated for included files, one solution is to load them individually in subsequent calls to `Ice.loadSlice`. However, it is much simpler, not to mention more efficient, to use the `--all` option instead:

Python

```
Ice.loadSlice("--all -I. Syscall.ice")
```

When you specify `--all`, `Ice.loadSlice` generates Python code for all Slice definitions included directly or indirectly from the named Slice files.

There is no harm in loading a Slice file multiple times, aside from the additional overhead associated with code generation. For example, this situation could arise when you need to load multiple top-level Slice files that happen to include a common subset of nested files. Suppose that we need to load both `Syscall.ice` and `Kernel.ice`, both of which include `Process.ice`. The simplest way to load both files is with a single call to `Ice.loadSlice`:

Python

```
Ice.loadSlice("--all -I. Syscall.ice Kernel.ice")
```

Although this invocation causes the Ice extension to generate code twice for `Process.ice`, the generated code is structured so that the interpreter ignores duplicate definitions. We could have avoided generating unnecessary code with the following sequence of steps:

Python

```
Ice.loadSlice("--all -I. Syscall.ice")
Ice.loadSlice("-I. Kernel.ice")
```

In more complex cases, however, it can be difficult or impossible to completely avoid this situation, and the overhead of code generation is usually not significant enough to justify such an effort.

Static Code Generation in Python

You should be familiar with static code generation if you have used other Slice language mappings, such as C++ or Java. Using static code generation, the Slice compiler `slice2py` generates Python code from your Slice definitions.

Compiler Output in Python

For each Slice file `X.ice`, `slice2py` generates Python code into a file named `X_ice.py` in the output directory.

Using the file name `X.py` would create problems if `X.ice` defined a module named `X`, therefore the suffix `_ice` is appended to the name of the generated file.

The default output directory is the current working directory, but a different directory can be specified using the `--output-dir` option.

In addition to the generated file, `slice2py` creates a Python package for each Slice module it encounters. A Python package is nothing more than a subdirectory that contains a file with a special name (`__init__.py`). This file is executed automatically by Python when a program first imports the package. It is created by `slice2py` and must not be edited manually. Inside the file is Python code to import the generated files that contain definitions in the Slice module of interest.

For example, the Slice files `Process.ice` and `Syscall.ice` both define types in the Slice module `OS`. First we present `Process.ice`:

Slice

```
module OS {
    interface Process {
        void kill();
    };
};
```

And here is `Syscall.ice`:

Slice

```
#include <Process.ice>
module OS {
    interface Syscall {
        Process getProcess(int pid);
    };
};
```

Next, we translate these files using the Slice compiler:

```
> slice2py -I. Process.ice Syscall.ice
```

If we list the contents of the output directory, we see the following entries:

Python

```
OS/
Process_ice.py
Syscall_ice.py
```

The subdirectory `OS` is the Python package that `slice2py` created for the Slice module `OS`. Inside this directory is the special file `__init__.py` that contains the following statements:

Python

```
import Process_ice
import Syscall_ice
```

Now when a Python program executes `import OS`, the two files `Process_ice.py` and `Syscall_ice.py` are implicitly imported.

Subsequent invocations of `slice2py` for Slice files that also contain definitions in the `OS` module result in additional `import` statements being added to `OS/__init__.py`. Be aware, however, that `import` statements may persist in `__init__.py` files after a Slice file is renamed or becomes obsolete. This situation may manifest itself as a run-time error if the interpreter can no longer locate the generated file while attempting to import the package. It may also cause more subtle problems, if an obsolete generated file is still present and being loaded unintentionally. In general, it is advisable to remove the package directory and regenerate it whenever the set of Slice files changes.

A Python program may also import a generated file explicitly, using a statement such as `import Process_ice`. Typically, however, it is more convenient to import the Python module once, rather than importing potentially several individual files that comprise the module, especially when you consider that the program must still import the module explicitly in order to make its definitions available. For example, it is much simpler to state

Python

```
import OS
```

rather than the following alternative:

Python

```
import Process_ice
import Syscall_ice
import OS
```

Include Files in Python

It is important to understand how `slice2py` handles include files. In the absence of the `--all` option, the compiler does not generate Python code for Slice definitions in included files. Rather, the compiler translates Slice `#include` statements into Python `import` statements in the following manner:

1. Determine the full pathname of the include file.
2. Create the shortest possible relative pathname for the include file by iterating over each of the include directories (specified using the `-I` option) and removing the leading directory from the include file if possible.
For example, if the full pathname of an include file is `/opt/App/slice/OS/Process.ice`, and we specified the options `-I/opt/App` and `-I/opt/App/slice`, then the shortest relative pathname is `OS/Process.ice` after removing `/opt/App/slice`.
3. Replace any slashes with underscores, remove the `.ice` extension, and append `_ice`. Continuing our example from the previous step, the translated import statement becomes
`import OS_Process_ice`

There is a potential problem here that must be addressed. The generated `import` statement shown above expects to find the file `OS_Process_ice.py` somewhere in Python's search path. However, `slice2py` uses a different default name, `Process_ice.py`, when it compiles `Process.ice`. To resolve this issue, we must use the `--prefix` option when compiling `Process.ice`:

```
> slice2py --prefix OS_ Process.ice
```

The `--prefix` option causes the compiler to prepend the specified prefix to the name of each generated file. When executed, the above command creates the desired file name: `OS_Process_ice.py`.

It should be apparent by now that generating Python code for a complex Ice application requires a bit of planning. In particular, it is imperative that you be consistent in your use of `#include` statements, include directories, and `--prefix` options to ensure that the correct file names are used at all times.

Of course, these precautionary steps are only necessary when you are compiling Slice files individually. An alternative is to use the `--all` option and generate Python code for all of your Slice definitions into one Python source file. If you do not have a suitable Slice file that includes all necessary Slice definitions, you could write a "master" Slice file specifically for this purpose.

Static Versus Dynamic Code Generation in Python

There are several issues to consider when evaluating your requirements for code generation.

Application Considerations for Code Generation in Python

The requirements of your application generally dictate whether you should use dynamic or static code generation. Dynamic code generation is convenient for a number of reasons:

- it avoids the intermediate compilation step required by static code generation
- it makes the application more compact because the application requires only the Slice files, not the assortment of files and directories produced by static code generation
- it reduces complexity, which is especially helpful during testing, or when writing short or transient programs.

Static code generation, on the other hand, is appropriate in many situations:

- when an application uses a large number of Slice definitions and the startup delay must be minimized
- when it is not feasible to deploy Slice files with the application
- when a number of applications share the same Slice files
- when Python code is required in order to utilize third-party Python tools.

Mixing Static and Dynamic Code Generation in Python

Using a combination of static and dynamic translation in an application can produce unexpected results. For example, consider a situation where a dynamically-translated Slice file includes another Slice file that was statically translated:

Slice

```
// Slice
#include <Glacier2/Session.ice>

module App {
    interface SessionFactory {
        Glacier2::Session* createSession();
    };
};
```

The Slice file `Session.ice` is statically translated, as are all of the Slice files included with the Ice run time.

Assuming the above definitions are saved in `App.ice`, let's execute a simple Python script:

Python

```
# Python
import Ice
Ice.loadSlice("-I/opt/Ice/slice App.ice")

import Glacier2
class MyVerifier(Glacier2.PermissionsVerifier): # Error
    def checkPermissions(self, userId, password):
        return (True, "")
```

The code looks reasonable, but running it produces the following error:

```
'module' object has no attribute 'PermissionsVerifier'
```

Normally, importing the `Glacier2` module as we have done here would load all of the Python code generated for the `Glacier2` Slice files. However, since `App.ice` has already included a subset of the `Glacier2` definitions, the Python interpreter ignores any subsequent requests to import the entire module, and therefore the `PermissionsVerifier` type is not present.

One way to address this problem is to import the statically-translated modules first, prior to loading Slice files dynamically:

Python

```
# Python
import Ice, Glacier2 # Import Glacier2 before App.ice is loaded
Ice.loadSlice("-I/opt/Ice/slice App.ice")

class MyVerifier(Glacier2.PermissionsVerifier): # OK
    def checkPermissions(self, userId, password):
        return (True, "")
```

The disadvantage of this approach in a non-trivial application is that it breaks encapsulation, forcing one Python module to know what other modules are doing. For example, suppose we place our `PermissionsVerifier` implementation in a module named `verifier.py`:

Python

```
# Python
import Glacier2
class MyVerifier(Glacier2.PermissionsVerifier):
    def checkPermissions(self, userId, password):
        return (True, "")
```

Now that the use of `Glacier2` definitions is encapsulated in `verifier.py`, we would like to remove references to `Glacier2` from the main script:

Python

```
# Python
import Ice
Ice.loadSlice("-I/opt/Ice/slice App.ice")
...
import verifier # Error
v = verifier.MyVerifier()
```

Unfortunately, executing this script produces the same error as before. To fix it, we have to break the `verifier` module's encapsulation and import the `Glacier2` module in the main script because we know that the `verifier` module requires it:

Python

```
# Python
import Ice, Glacier2
Ice.loadSlice("-I/opt/Ice/slice App.ice")
...
import verifier # OK
v = verifier.MyVerifier()
```

Although breaking encapsulation in this way might offend our sense of good design, it is a relatively minor issue.

Another solution is to import the necessary submodules explicitly. We can safely remove the Glacier2 reference from our main script after rewriting `verifier.py` as shown below:

Python

```
# Python
import Glacier2_PermissionsVerifier_ice
import Glacier2
class MyVerifier(Glacier2.PermissionsVerifier):
    def checkPermissions(self, userId, password):
        return (True, "")
```

Using the rules defined for [static code generation](#), we can derive the name of the module containing the code generated for `PermissionsVerifier.ice` and import it directly. We need a second `import` statement to make the Glacier2 definitions accessible in this module.

slice2py Command-Line Options

The Slice-to-Python compiler, `slice2py`, offers the following command-line options in addition to the [standard options](#):

- `--all`
Generate code for all Slice definitions, including those from included files.
- `--checksum`
Generate [checksums](#) for Slice definitions.
- `--prefix PREFIX`
Use `PREFIX` as the prefix for [generated](#) file names.

Generating Packages in Python

By default, the scope of a Slice definition determines the [module](#) of its mapped Python construct. There are times, however, when applications require greater control over the packaging of generated Python code. For example, consider the following Slice definitions:

Slice

```

module sys {
    interface Process {
        // ...
    };
};

```

Other language mappings can use these Slice definitions as shown, but they present a problem for the Python mapping: the top-level Slice module `sys` conflicts with Python's predefined module `sys`. A Python application executing the statement `import sys` would import whichever module the interpreter happens to locate first in its search path.

A workaround for this problem is to modify the Slice definitions so that the top-level module no longer conflicts with a predefined Python module, but that may not be feasible in certain situations. For example, the application may already be deployed using other language mappings, in which case the impact of modifying the Slice definitions could represent an unacceptable expense.

The Python mapping could have addressed this issue by considering the names of predefined modules to be reserved, in which case the Slice module `sys` would be mapped to the Python module `_sys`. However, the likelihood of a name conflict is relatively low to justify such a solution, therefore the mapping supports a different approach: global `metadata` can be used to enclose generated code in a Python package. Our modified Slice definitions demonstrate this feature:

Slice

```

[["python:package:zeroc"]]
module sys {
    interface Process {
        // ...
    };
};

```

The global metadata directive `python:package:zeroc` causes the mapping to generate all of the code resulting from definitions in this Slice file into the Python package `zeroc`. The net effect is the same as if we had enclosed our Slice definitions in the module `zeroc`: the Slice module `sys` is mapped to the Python module `zeroc.sys`. However, by using metadata we have not affected the semantics of the Slice definitions, nor have we affected other language mappings.

- [Using the Slice Compilers](#)
- [Python Mapping for Modules](#)
- [Using Slice Checksums in Python](#)
- [Metadata](#)

Using Slice Checksums in Python

The Slice compilers can optionally generate [checksums](#) of Slice definitions. For `slice2py`, the `--checksum` option causes the compiler to generate code that adds checksums to the dictionary `Ice.sliceChecksums`. The checksums are installed automatically when the Python code is first imported; no action is required by the application.

In order to verify a server's checksums, a client could simply compare the dictionaries using the comparison operator. However, this is not feasible if it is possible that the server might return a superset of the client's checksums. A more general solution is to iterate over the local checksums as demonstrated below:

Python

```
serverChecksums = ...
for i in Ice.sliceChecksums:
    if not serverChecksums.has_key(i):
        # No match found for type id!
    elif Ice.sliceChecksums[i] != serverChecksums[i]:
        # Checksum mismatch!
```

In this example, the client first verifies that the server's dictionary contains an entry for each Slice type ID, and then it proceeds to compare the checksums.

- [Slice Checksums](#)

Example of a File System Client in Python

This page presents a very simple client to access a server that implements the file system we developed in [Slice for a Simple File System](#). The Python code shown here hardly differs from the code you would write for an ordinary Python program. This is one of the biggest advantages of using Ice: accessing a remote object is as easy as accessing an ordinary, local Python object. This allows you to put your effort where you should, namely, into developing your application logic instead of having to struggle with arcane networking APIs. This is true for the [server side](#) as well, meaning that you can develop distributed applications easily and efficiently.

We now have seen enough of the client-side Python mapping to develop a complete client to access our remote file system. For reference, here is the Slice definition once more:

```

Slice

module Filesystem {
    interface Node {
        idempotent string name();
    };

    exception GenericError {
        string reason;
    };

    sequence<string> Lines;

    interface File extends Node {
        idempotent Lines read();
        idempotent void write(Lines text) throws GenericError;
    };

    sequence<Node*> NodeSeq;

    interface Directory extends Node {
        idempotent NodeSeq list();
    };
};
```

To exercise the file system, the client does a recursive listing of the file system, starting at the root directory. For each node in the file system, the client shows the name of the node and whether that node is a file or directory. If the node is a file, the client retrieves the contents of the file and prints them.

The body of the client code looks as follows:

```

Python

import sys, traceback, Ice, Filesystem

# Recursively print the contents of directory "dir"
# in tree fashion. For files, show the contents of
# each file. The "depth" parameter is the current
# nesting level (for indentation).
```

```

def listRecursive(dir, depth):
    indent = ''
    depth = depth + 1
    for i in range(depth):
        indent = indent + '\t'

    contents = dir.list()

    for node in contents:
        subdir = Filesystem.DirectoryPrx.checkedCast(node)
        file = Filesystem.FilePrx.uncheckedCast(node)
        print indent + node.name(),
        if subdir:
            print "(directory):"
            listRecursive(subdir, depth)
        else:
            print "(file):"
            text = file.read()
            for line in text:
                print indent + "\t" + line

status = 0
ic = None
try:
    # Create a communicator
    #
    ic = Ice.initialize(sys.argv)

    # Create a proxy for the root directory
    #
    obj = ic.stringToProxy("RootDir:default -p 10000")

    # Down-cast the proxy to a Directory proxy
    #
    rootDir = Filesystem.DirectoryPrx.checkedCast(obj)

    # Recursively list the contents of the root directory
    #
    print "Contents of root directory:"
    listRecursive(rootDir, 0)
except:
    traceback.print_exc()
    status = 1

if ic:
    # Clean up
    #
    try:
        ic.destroy()
    except:

```

```
traceback.print_exc()  
status = 1
```

```
sys.exit(status)
```

The program first defines the `listRecursive` function, which is a helper function to print the contents of the file system, and the main program follows. Let us look at the main program first:

1. The structure of the code follows what we saw in [Hello World Application](#). After initializing the run time, the client creates a proxy to the root directory of the file system. For this example, we assume that the server runs on the local host and listens using the default protocol (TCP/IP) at port 10000. The object identity of the root directory is known to be `RootDir`.
2. The client down-casts the proxy to `DirectoryPrx` and passes that proxy to `listRecursive`, which prints the contents of the file system.

Most of the work happens in `listRecursive`. The function is passed a proxy to a directory to list, and an indent level. (The indent level increments with each recursive call and allows the code to print the name of each node at an indent level that corresponds to the depth of the tree at that node.) `listRecursive` calls the `list` operation on the directory and iterates over the returned sequence of nodes:

1. The code does a `checkedCast` to narrow the `Node` proxy to a `Directory` proxy, as well as an `uncheckedCast` to narrow the `Node` proxy to a `File` proxy. Exactly one of those casts will succeed, so there is no need to call `checkedCast` twice: if the `Node` is-a `Directory`, the code uses the `DirectoryPrx` returned by the `checkedCast`; if the `checkedCast` fails, we *know* that the `Node` is-a `File` and, therefore, an `uncheckedCast` is sufficient to get a `FilePrx`.
In general, if you know that a down-cast to a specific type will succeed, it is preferable to use an `uncheckedCast` instead of a `checkedCast` because an `uncheckedCast` does not incur any network traffic.
2. The code prints the name of the file or directory and then, depending on which cast succeeded, prints "(directory)" or "(file)" following the name.
3. The code checks the type of the node:
 - If it is a directory, the code recurses, incrementing the indent level.
 - If it is a file, the code calls the `read` operation on the file to retrieve the file contents and then iterates over the returned sequence of lines, printing each line.

Assume that we have a small file system consisting of a two files and a directory as follows:

A small file system.

The output produced by the client for this file system is:

```
Contents of root directory:
```

```
  README (file):
```

```
    This file system contains a collection of poetry.
```

```
  Coleridge (directory):
```

```
    Kubla_Khan (file):
```

```
      In Xanadu did Kubla Khan
```

```
      A stately pleasure-dome decree:
```

```
      Where Alph, the sacred river, ran
```

```
      Through caverns measureless to man
```

```
      Down to a sunless sea.
```

Note that, so far, our client (and server) are not very sophisticated:

- The protocol and address information are hard-wired into the code.
- The client makes more remote procedure calls than strictly necessary; with minor redesign of the Slice definitions, many of these calls can be avoided.

We will see how to address these shortcomings in our discussions of [IceGrid](#) and [object life cycle](#).

Server-Side Slice-to-Python Mapping

The mapping for Slice data types to Python is identical on the client side and server side. This means that everything in the [Client-Side Slice-to-Python Mapping](#) section also applies to the server side. However, for the server side, there are a few additional things you need to know — specifically, how to:

- Initialize and finalize the server-side run time
- Implement servants
- Pass parameters and throw exceptions
- Create servants and register them with the Ice run time.

Although the examples in this chapter are simple, they accurately reflect the basics of writing an Ice server. Of course, for more sophisticated servers, you will be using [additional APIs](#), for example, to improve performance or scalability. However, these APIs are all described in [Slice](#), so, to use these APIs, you need not learn any Python mapping rules beyond those described here.

The Python interpreter's Global Interpreter Lock (GIL) can impact an Ice server's ability to utilize multiple processing cores. Refer to our [FAQ](#) for more information.

The Server-Side main Program in Python

This section discussed how to initialize and finalize the server-side run time.

On this page:

- [Initializing and Finalizing the Server-Side Run Time in Python](#)
- [The Ice.Application Class in Python](#)
 - [Using Ice.Application on the Client Side in Python](#)
 - [Catching Signals in Python](#)
 - [Ice.Application and Properties in Python](#)
 - [Limitations of Ice.Application in Python](#)

Initializing and Finalizing the Server-Side Run Time in Python

The main entry point to the Ice run time is represented by the local interface `Ice::Communicator`. As for the client side, you must initialize the Ice run time by calling `Ice.initialize` before you can do anything else in your server. `Ice.initialize` returns a reference to an instance of `Ice.Communicator`:

Python

```
import sys, traceback, Ice

status = 0
ic = None
try:
    ic = Ice.initialize(sys.argv)
    # ...
except:
    traceback.print_exc()
    status = 1

# ...
```

`Ice.initialize` accepts the argument list that is passed to the program by the operating system. The function scans the argument list for any command-line options that are relevant to the Ice run time; any such options are removed from the argument list so, when `Ice.initialize` returns, the only options and arguments remaining are those that concern your application. If anything goes wrong during initialization, `initialize` throws an exception.

You can pass a second argument of type `InitializationData` to `Ice.initialize`. `InitializationData` is defined as follows:

Python

```
class InitializationData(object):
    def __init__(self):
        self.properties = None
        self.logger = None
        self.threadHook = None
```

You can pass in an instance of this class to set `properties` for the communicator, establish a `logger`, and to establish a `thread notification hook`.

Before leaving your program, you *must* call `Communicator.destroy`. The `destroy` operation is responsible for finalizing the Ice run time.

In particular, `destroy` waits for any operation implementations that are still executing in the server to complete. In addition, `destroy` ensures that any outstanding threads are joined with and reclaims a number of operating system resources, such as file descriptors and memory. Never allow your program to terminate without calling `destroy` first; doing so has undefined behavior.

The general shape of our server-side program is therefore as follows:

Python

```

import sys, traceback, Ice

status = 0
ic = None
try:
    ic = Ice.initialize(sys.argv)
    # ...
except:
    traceback.print_exc()
    status = 1

if ic:
    try:
        ic.destroy()
    except:
        traceback.print_exc()
        status = 1

sys.exit(status)

```

Note that the code places the call to `Ice.initialize` into a `try` block and takes care to return the correct exit status to the operating system. Also note that an attempt to destroy the communicator is made only if the initialization succeeded.

The `Ice.Application` Class in Python

The preceding program structure is so common that Ice offers a class, `Ice.Application`, that encapsulates all the correct initialization and finalization activities. The synopsis of the class is as follows (with some detail omitted for now):

Python

```
class Application(object):

    def __init__(self, signalPolicy=0):

    def main(self, args, configFile=None, initData=None):

    def run(self, args):

    def appName():
        # ...
    appName = staticmethod(appName)

    def communicator():
        # ...
    communicator = staticmethod(communicator)
```

The intent of this class is that you specialize `Ice.Application` and implement the abstract `run` method in your derived class. Whatever code you would normally place in your main program goes into `run` instead. Using `Ice.Application`, our program looks as follows:

Python

```
import sys, Ice

class Server(Ice.Application):
    def run(self, args):
        # Server code here...
        return 0

app = Server()
status = app.main(sys.argv)
sys.exit(status)
```

You also can call `main` with an optional file name or an `InitializationData` structure. If you pass a `configuration file name` to `main`, the property settings in this file are overridden by settings in a file identified by the `ICE_CONFIG` environment variable (if defined). Property settings supplied on the `command line` take precedence over all other settings.

The `Application.main` function does the following:

1. It installs an exception handler. If your code fails to handle an exception, `Application.main` prints the exception information before returning with a non-zero return value.
2. It initializes (by calling `Ice.initialize`) and finalizes (by calling `Communicator.destroy`) a communicator. You can get access to the communicator for your server by calling the static `communicator` accessor.
3. It scans the argument list for options that are relevant to the Ice run time and removes any such options. The argument list that is passed to your `run` method therefore is free of Ice-related options and only contains options and arguments that are specific to your application.
4. It provides the name of your application via the static `appName` member function. The return value from this call is the first element of the argument vector passed to `Application.main`, so you can get at this name from anywhere in your code by calling `Ice.Application.appName` (which is often necessary for error messages).

5. It installs a signal handler that properly shuts down the communicator.
6. It installs a [per-process logger](#) if the application has not already configured one. The per-process logger uses the value of the `Ice.ProgramName` property as a prefix for its messages and sends its output to the standard error channel. An application can also specify an [alternate logger](#).

Using `Ice.Application` ensures that your program properly finalizes the Ice run time, whether your server terminates normally or in response to an exception or signal. We recommend that all your programs use this class; doing so makes your life easier. In addition, `Ice.Application` also provides features for signal handling and configuration that you do not have to implement yourself when you use this class.

Using `Ice.Application` on the Client Side in Python

You can use `Ice.Application` for your clients as well: simply implement a class that derives from `Ice.Application` and place the client code into its `run` method. The advantage of this approach is the same as for the server side: `Ice.Application` ensures that the communicator is destroyed correctly even in the presence of exceptions or signals.

Catching Signals in Python

The simple server we developed in [Hello World Application](#) had no way to shut down cleanly: we simply interrupted the server from the command line to force it to exit. Terminating a server in this fashion is unacceptable for many real-life server applications: typically, the server has to perform some cleanup work before terminating, such as flushing database buffers or closing network connections. This is particularly important on receipt of a signal or keyboard interrupt to prevent possible corruption of database files or other persistent data.

To make it easier to deal with signals, `Ice.Application` encapsulates Python's signal handling capabilities, allowing you to cleanly shut down on receipt of a signal:

Python

```

class Application(object):
    # ...
    def destroyOnInterrupt():
        # ...
    destroyOnInterrupt = classmethod(destroyOnInterrupt)

    def shutdownOnInterrupt():
        # ...
    shutdownOnInterrupt = classmethod(shutdownOnInterrupt)

    def ignoreInterrupt():
        # ...
    ignoreInterrupt = classmethod(ignoreInterrupt)

    def callbackOnInterrupt():
        # ...
    callbackOnInterrupt = classmethod(callbackOnInterrupt)

    def holdInterrupt():
        # ...
    holdInterrupt = classmethod(holdInterrupt)

    def releaseInterrupt():
        # ...
    releaseInterrupt = classmethod(releaseInterrupt)

    def interrupted():
        # ...
    interrupted = classmethod(interrupted)

    def interruptCallback(self, sig):
        # Default implementation does nothing.
        pass

```

The methods behave as follows:

- `destroyOnInterrupt`
This method installs a signal handler that destroys the communicator if it is interrupted. This is the default behavior.
- `shutdownOnInterrupt`
This method installs a signal handler that shuts down the communicator if it is interrupted.
- `ignoreInterrupt`
This method causes signals to be ignored.
- `callbackOnInterrupt`
This method configures `Ice.Application` to invoke `interruptCallback` when a signal occurs, thereby giving the subclass responsibility for handling the signal.
- `holdInterrupt`

This method temporarily blocks signal delivery.

- `releaseInterrupt`
This method restores signal delivery to the previous disposition. Any signal that arrives after `holdInterrupt` was called is delivered when you call `releaseInterrupt`.
- `interrupted`
This method returns `True` if a signal caused the communicator to shut down, `False` otherwise. This allows us to distinguish intentional shutdown from a forced shutdown that was caused by a signal. This is useful, for example, for logging purposes.
- `interruptCallback`
A subclass overrides this method to respond to signals. The function may be called concurrently with any other thread and must not raise exceptions.

By default, `Ice.Application` behaves as if `destroyOnInterrupt` was invoked, therefore our server program requires no change to ensure that the program terminates cleanly on receipt of a signal. (You can disable the signal-handling functionality of `Ice.Application` by passing `1` to the constructor. In that case, signals retain their default behavior, that is, terminate the process.) However, we add a diagnostic to report the occurrence of a signal, so our program now looks like:

Python

```
import sys, Ice

class MyApplication(Ice.Application):
    def run(self, args):

        # Server code here...

        if self.interrupted():
            print self.appName() + ": terminating"

        return 0

app = MyApplication()
status = app.main(sys.argv)
sys.exit(status)
```

Note that, if your server is interrupted by a signal, the Ice run time waits for all currently executing operations to finish. This means that an operation that updates persistent state cannot be interrupted in the middle of what it was doing and cause partial update problems.

Ice.Application and Properties in Python

Apart from the functionality shown in this section, `Ice.Application` also takes care of initializing the Ice run time with property values. `Properties` allow you to configure the run time in various ways. For example, you can use properties to control things such as the thread pool size or port number for a server. The `main` method of `Ice.Application` accepts an optional second parameter allowing you to specify the name of a [configuration file](#) that will be processed during initialization.

Limitations of Ice.Application in Python

`Ice.Application` is a singleton class that creates a single communicator. If you are using multiple communicators, you cannot use `Ice.Application`. Instead, you must structure your code as we saw in [Hello World Application](#) (taking care to always destroy the communicator). See Also

- [Hello World Application](#)

- [Communicator Initialization](#)
- [Logger Facility](#)
- [Thread Safety](#)

Server-Side Python Mapping for Interfaces

The server-side mapping for interfaces provides an up-call API for the Ice run time: by implementing methods in a servant class, you provide the hook that gets the thread of control from the Ice server-side run time into your application code.

On this page:

- [Skeleton Classes in Python](#)
- [Servant Classes in Python](#)
 - [Server-Side Normal and idempotent Operations in Python](#)

Skeleton Classes in Python

On the client side, interfaces map to proxy classes. On the server side, interfaces map to *skeleton classes*. A skeleton is an abstract base class from which you derive your servant class and define a method for each operation on the corresponding interface. For example, consider our [Slice definition](#) for the `Node` interface:

Slice

```

module Filesystem {
    interface Node {
        idempotent string name();
    };
    // ...
};

```

The Python mapping generates the following definition for this interface:

Python

```

class Node(Ice.Object):
    def __init__(self):
        # ...

    #
    # Operation signatures.
    #
    # def name(self, current=None):

```

The important points to note here are:

- As for the client side, Slice modules are mapped to Python modules with the same name, so the skeleton class definitions are part of the `Filesystem` module.
- The name of the skeleton class is the same as the name of the Slice interface (`Node`).
- The skeleton class contains a comment summarizing the method signature of each operation in the Slice interface.
- The skeleton class is an abstract base class because its constructor prevents direct instantiation of the class.
- The skeleton class inherits from `Ice.Object` (which forms the root of the Ice object hierarchy).

Servant Classes in Python

In order to provide an implementation for an Ice object, you must create a servant class that inherits from the corresponding skeleton class. For example, to create a servant for the `Node` interface, you could write:

Python

```
import Filesystem

class NodeI(Filesystem.Node):
    def __init__(self, name):
        self._name = name

    def name(self, current=None):
        return self._name
```

By convention, servant classes have the name of their interface with an `I`-suffix, so the servant class for the `Node` interface is called `NodeI`. (This is a convention only: as far as the Ice run time is concerned, you can choose any name you prefer for your servant classes.) Note that `NodeI` extends `Filesystem.Node`, that is, it derives from its skeleton class.

As far as Ice is concerned, the `NodeI` class must implement only a single method: the `name` method that is defined in the `Node` interface. This makes the servant class a concrete class that can be instantiated. You can add other member functions and data members as you see fit to support your implementation. For example, in the preceding definition, we added a `_name` member and a constructor. (Obviously, the constructor initializes the `_name` member and the `name` function returns its value.)

Server-Side Normal and idempotent Operations in Python

Whether an operation is an ordinary operation or an `idempotent` operation has no influence on the way the operation is mapped. To illustrate this, consider the following interface:

Slice

```
interface Example {
    void normalOp();
    idempotent void idempotentOp();
};
```

The mapping for this interface is shown below:

Python

```
class Example(Ice.Object):
    # ...

    #
    # Operation signatures.
    #
    # def normalOp(self, current=None):
    # def idempotentOp(self, current=None):
```

Note that the signatures of the methods are unaffected by the `idempotent` qualifier.

See Also

- [Slice for a Simple File System](#)
- [Python Mapping for Interfaces](#)
- [Parameter Passing in Python](#)
- [Raising Exceptions in Python](#)

Parameter Passing in Python

For each `in` parameter of a Slice operation, the Python mapping generates a corresponding parameter for the method in the skeleton. In addition, every operation has a trailing parameter of type `Ice.Current`. For example, the `name` operation of the `Node` interface has no parameters, but the `name` method in a Python servant has a `current` parameter. We will ignore this parameter for now.

Parameter passing on the server side follows the rules for the [client side](#). An operation returning multiple values returns them in a tuple consisting of a non-void return value, if any, followed by the `out` parameters in the order of declaration. An operation returning only one value simply returns the value itself.

An operation returns multiple values when it declares multiple `out` parameters, or when it declares a non-void return type and at least one `out` parameter.

To illustrate these rules, consider the following interface that passes string parameters in all possible directions:

Slice

```
interface Example {
    string op1(string sin);
    void op2(string sin, out string sout);
    string op3(string sin, out string sout);
};
```

The generated skeleton class for this interface looks as follows:

Python

```
class Example(Ice.Object):
    def __init__(self):
        # ...

    #
    # Operation signatures.
    #
    # def op1(self, sin, current=None):
    # def op2(self, sin, current=None):
    # def op3(self, sin, current=None):
```

The signatures of the Python methods are identical because they all accept a single `in` parameter, but their implementations differ in the way they return values. For example, we could implement the operations as follows:

Python

```
class ExampleI(Example):
    def op1(self, sin, current=None):
        print sin          # In params are initialized
        return "Done"     # Return value

    def op2(self, sin, current=None):
        print sin          # In params are initialized
        return "Hello World!" # Out parameter

    def op3(self, sin, current=None):
        print sin          # In params are initialized
        return ("Done", "Hello World!")
```

Notice that `op1` and `op2` return their string values directly, whereas `op3` returns a tuple consisting of the return value followed by the out parameter.

This code is in no way different from what you would normally write if you were to pass strings to and from a function; the fact that remote procedure calls are involved does not impact your code in any way. The same is true for parameters of other types, such as proxies, classes, or dictionaries: the parameter passing conventions follow normal Python rules and do not require special-purpose API calls.

See Also

- [Server-Side Python Mapping for Interfaces](#)
- [Python Mapping for Operations](#)
- [Raising Exceptions in Python](#)
- [The Current Object](#)

Raising Exceptions in Python

To throw an exception from an operation implementation, you simply instantiate the exception, initialize it, and throw it. For example:

```

Python

class FileI(Filesystem.File):
    # ...

    def write(self, text, current=None):
        # Try to write the file contents here...
        # Assume we are out of space...
        if error:
            e = Filesystem.GenericError()
            e.reason = "file too large"
            raise e
```

The [mapping for exceptions](#) generates a constructor that accepts values for data members, so we can simplify this example by changing our `raise` statement to the following:

```

Python

class FileI(Filesystem.File):
    # ...

    def write(self, text, current=None):
        # Try to write the file contents here...
        # Assume we are out of space...
        if error:
            raise Filesystem.GenericError("file too large")
```

If you throw an arbitrary Python run-time exception, the Ice run time catches the exception and then returns an `UnknownException` to the client. Similarly, if you throw an "impossible" user exception (a user exception that is not listed in the exception specification of the operation), the client receives an `UnknownUserException`.

If you throw a run-time exception, such as `MemoryLimitException`, the client receives an `UnknownLocalException`. For that reason, you should never throw system exceptions from operation implementations. If you do, all the client will see is an `UnknownLocalException`, which does not tell the client anything useful.

Three run-time exceptions are [treated specially](#) and not changed to `UnknownLocalException` when returned to the client: `ObjectNotExistException`, `OperationNotExistException`, and `FacetNotExistException`.

Object Incarnation in Python

Having created a servant class such as the rudimentary `NodeI` class, you can instantiate the class to create a concrete servant that can receive invocations from a client. However, merely instantiating a servant class is insufficient to incarnate an object. Specifically, to provide an implementation of an Ice object, you must take the following steps:

1. Instantiate a servant class.
2. Create an identity for the Ice object incarnated by the servant.
3. Inform the Ice run time of the existence of the servant.
4. Pass a proxy for the object to a client so the client can reach it.

On this page:

- [Instantiating a Python Servant](#)
- [Creating an Identity in Python](#)
- [Activating a Python Servant](#)
- [UUIDs as Identities in Python](#)
- [Creating Proxies in Python](#)
 - [Proxies and Servant Activation in Python](#)
 - [Direct Proxy Creation in Python](#)

Instantiating a Python Servant

Instantiating a servant means to allocate an instance:

Python

```
servant = NodeI("Fred")
```

This statement creates a new `NodeI` instance and assigns its reference to the variable `servant`.

Creating an Identity in Python

Each Ice object requires an identity. That identity must be unique for all servants using the same object adapter.

The Ice object model assumes that all objects (regardless of their adapter) have a [globally unique identity](#).

An Ice object identity is a structure with the following Slice definition:

Slice

```
module Ice {
    struct Identity {
        string name;
        string category;
    };
    // ...
};
```

The full identity of an object is the combination of both the `name` and `category` fields of the `Identity` structure. For now, we will leave the `category` field as the empty string and simply use the `name` field. (The `category` field is most often used in conjunction with [servant locators](#).)

To create an identity, we simply assign a key that identifies the servant to the `name` field of the `Identity` structure:

Python

```
id = Ice.Identity()
id.name = "Fred" # Not unique, but good enough for now
```

Note that the [mapping for structures](#) allows us to write the following equivalent code:

Python

```
id = Ice.Identity("Fred") # Not unique, but good enough for now
```

Activating a Python Servant

Merely creating a servant instance does nothing: the Ice run time becomes aware of the existence of a servant only once you explicitly tell the object adapter about the servant. To activate a servant, you invoke the `add` operation on the object adapter. Assuming that we have access to the object adapter in the `adapter` variable, we can write:

Python

```
adapter.add(servant, id)
```

Note the two arguments to `add`: the servant and the object identity. Calling `add` on the object adapter adds the servant and the servant's identity to the adapter's servant map and links the proxy for an Ice object to the correct servant instance in the server's memory as follows:

1. The proxy for an Ice object, apart from addressing information, contains the identity of the Ice object. When a client invokes an operation, the object identity is sent with the request to the server.
2. The object adapter receives the request, retrieves the identity, and uses the identity as an index into the servant map.
3. If a servant with that identity is active, the object adapter retrieves the servant from the servant map and dispatches the incoming request into the correct member function on the servant.

Assuming that the object adapter is in the [active state](#), client requests are dispatched to the servant as soon as you call `add`.

UUIDs as Identities in Python

The Ice object model assumes that object identities are globally unique. One way of ensuring that uniqueness is to use UUIDs (Universally Unique Identifiers) as identities. The `Ice.generateUUID` function creates such identities:

Python

```
import Ice
print Ice.generateUUID()
```

When executed, this program prints a unique string such as `5029a22c-e333-4f87-86b1-cd5e0fcce509`. Each call to `generateUUID` creates a string that differs from all previous ones.

You can use a UUID such as this to create object identities. For convenience, the object adapter has an operation `addWithUUID` that generates a UUID and adds a servant to the servant map in a single step. Using this operation, we can create an identity and register a servant with that identity in a single step as follows:

Python

```
adapter.addWithUUID(NodeI("Fred"))
```

Creating Proxies in Python

Once we have activated a servant for an Ice object, the server can process incoming client requests for that object. However, clients can only access the object once they hold a proxy for the object. If a client knows the server's address details and the object identity, it can create a proxy from a string, as we saw in our first example in [Hello World Application](#). However, creation of proxies by the client in this manner is usually only done to allow the client access to initial objects for bootstrapping. Once the client has an initial proxy, it typically obtains further proxies by invoking operations.

The object adapter contains all the details that make up the information in a proxy: the addressing and protocol information, and the object identity. The Ice run time offers a number of ways to create proxies. Once created, you can pass a proxy to the client as the return value or as an out-parameter of an operation invocation.

Proxies and Servant Activation in Python

The `add` and `addWithUUID` servant activation operations on the object adapter return a proxy for the corresponding Ice object. This means we can write:

Python

```
proxy = adapter.addWithUUID(NodeI("Fred"))
nodeProxy = Filesystem.NodePrx.uncheckedCast(proxy)

# Pass nodeProxy to client...
```

Here, `addWithUUID` both activates the servant and returns a proxy for the Ice object incarnated by that servant in a single step.

Note that we need to use an `uncheckedCast` here because `addWithUUID` returns a proxy of type `Ice.ObjectPrx`.

Direct Proxy Creation in Python

The object adapter offers an operation to create a proxy for a given identity:

Slice

```
module Ice {
    local interface ObjectAdapter {
        Object* createProxy(Identity id);
        // ...
    };
};
```

Note that `createProxy` creates a proxy for a given identity whether a servant is activated with that identity or not. In other words, proxies

have a life cycle that is quite independent from the life cycle of servants:

Python

```
id = Ice.Identity()  
id.name = Ice.generateUUID()  
proxy = adapter.createProxy(id)
```

This creates a proxy for an Ice object with the identity returned by `generateUUID`. Obviously, no servant yet exists for that object so, if we return the proxy to a client and the client invokes an operation on the proxy, the client will receive an `ObjectNotExistException`. (We examine these life cycle issues in more detail in [Object Life Cycle](#).)

Asynchronous Method Dispatch (AMD) in Python

The number of simultaneous synchronous requests a server is capable of supporting is determined by the number of threads in the server's [thread pool](#). If all of the threads are busy dispatching long-running operations, then no threads are available to process new requests and therefore clients may experience an unacceptable lack of responsiveness.

Asynchronous Method Dispatch (AMD), the server-side equivalent of [AMI](#), addresses this scalability issue. Using AMD, a server can receive a request but then suspend its processing in order to release the dispatch thread as soon as possible. When processing resumes and the results are available, the server sends a response explicitly using a callback object provided by the Ice run time.

AMD is transparent to the client, that is, there is no way for a client to distinguish a request that, in the server, is processed synchronously from a request that is processed asynchronously.

In practical terms, an AMD operation typically queues the request data (i.e., the callback object and operation arguments) for later processing by an application thread (or thread pool). In this way, the server minimizes the use of dispatch threads and becomes capable of efficiently supporting thousands of simultaneous clients.

An alternate use case for AMD is an operation that requires further processing after completing the client's request. In order to minimize the client's delay, the operation returns the results while still in the dispatch thread, and then continues using the dispatch thread for additional work.

On this page:

- [Enabling AMD with Metadata in Python](#)
- [AMD Mapping in Python](#)
- [AMD Exceptions in Python](#)
- [AMD Example in Python](#)

Enabling AMD with Metadata in Python

To enable asynchronous dispatch, you must add an ["amd"] metadata directive to your Slice definitions. The directive applies at the interface and the operation level. If you specify ["amd"] at the interface level, all operations in that interface use asynchronous dispatch; if you specify ["amd"] for an individual operation, only that operation uses asynchronous dispatch. In either case, the metadata directive *replaces* synchronous dispatch, that is, a particular operation implementation must use synchronous or asynchronous dispatch and cannot use both.

Consider the following Slice definitions:

Slice

```
["amd"] interface I {
    bool isValid();
    float computeRate();
};

interface J {
    ["amd"] void startProcess();
    int endProcess();
};
```

In this example, both operations of interface `I` use asynchronous dispatch, whereas, for interface `J`, `startProcess` uses asynchronous dispatch and `endProcess` uses synchronous dispatch.

Specifying metadata at the operation level (rather than at the interface or class level) minimizes the amount of generated code and, more importantly, minimizes complexity: although the asynchronous model is more flexible, it is also more complicated to use. It is therefore in your best interest to limit the use of the asynchronous model to those operations that need it, while using the simpler synchronous model for the rest.

AMD Mapping in Python

For each AMD operation, the Python mapping emits a dispatch method with the same name as the operation and the suffix `_async`. This method returns `None`. The first parameter is a reference to a callback object, as described below. The remaining parameters comprise the `i` `n` parameters of the operation, in the order of declaration.

The callback object defines two methods:

- `def ice_response(self, <params>)`
The `ice_response` method allows the server to report the successful completion of the operation. If the operation has a non-void return type, the first parameter to `ice_response` is the return value. Parameters corresponding to the operation's `out` parameters follow the return value, in the order of declaration.
- `def ice_exception(self, ex)`
The `ice_exception` method allows the server to report an exception.

Neither `ice_response` nor `ice_exception` throw any exceptions to the caller.

Suppose we have defined the following operation:

```

Slice

interface I {
    ["amd"] int foo(short s, out long l);
};
```

The callback interface generated for operation `foo` is shown below:

```

Python

class ...
    #
    # Operation signatures.
    #
    # def ice_response(self, _result, l)
    # def ice_exception(self, ex)
```

The dispatch method for asynchronous invocation of operation `foo` is generated as follows:

```

Python

def foo_async(self, __cb, s)
```

AMD Exceptions in Python

There are two processing contexts in which the logical implementation of an AMD operation may need to report an exception: the dispatch thread (the thread that receives the invocation), and the response thread (the thread that sends the response).

These are not necessarily two different threads: it is legal to send the response from the dispatch thread.

Although we recommend that the callback object be used to report all exceptions to the client, it is legal for the implementation to raise an exception instead, but only from the dispatch thread.

As you would expect, an exception raised from a response thread cannot be caught by the Ice run time; the application's run time environment determines how such an exception is handled. Therefore, a response thread must ensure that it traps all exceptions and sends the appropriate response using the callback object. Otherwise, if a response thread is terminated by an uncaught exception, the request may never be completed and the client might wait indefinitely for a response.

Whether raised in a dispatch thread or reported via the callback object, user exceptions are [validated](#) and local exceptions may undergo [translation](#).

AMD Example in Python

To demonstrate the use of AMD in Ice, let us define the Slice interface for a simple computational engine:

Slice

```

module Demo {
    sequence<float> Row;
    sequence<Row> Grid;

    exception RangeError {};

    interface Model {
        ["amd"] Grid interpolate(Grid data, float factor)
            throws RangeError;
    };
};

```

Given a two-dimensional grid of floating point values and a factor, the `interpolate` operation returns a new grid of the same size with the values interpolated in some interesting (but unspecified) way.

Our servant class derives from `Demo.Model` and supplies a definition for the `interpolate_async` method that creates a `Job` to hold the callback object and arguments, and adds the `Job` to a queue. The method uses a lock to guard access to the queue:

Python

```

class ModelI(Demo.Model):
    def __init__(self):
        self._mutex = threading.Lock()
        self._jobs = []

    def interpolate_async(self, cb, data, factor, current=None):
        self._mutex.acquire()
        try:
            self._jobs.append(Job(cb, data, factor))
        finally:
            self._mutex.release()

```

After queuing the information, the operation returns control to the Ice run time, making the dispatch thread available to process another request. An application thread removes the next `Job` from the queue and invokes `execute`, which uses `interpolateGrid` (not shown) to perform the computational work:

Python

```
class Job(object):
    def __init__(self, cb, grid, factor):
        self._cb = cb
        self._grid = grid
        self._factor = factor

    def execute(self):
        if not self.interpolateGrid():
            self._cb.ice_exception(Demo.RangeError())
            return
        self._cb.ice_response(self._grid)

    def interpolateGrid(self):
        # ...
```

If `interpolateGrid` returns `False`, then `ice_exception` is invoked to indicate that a range error has occurred. The `return` statement following the call to `ice_exception` is necessary because `ice_exception` does not throw an exception; it only marshals the exception argument and sends it to the client.

If interpolation was successful, `ice_response` is called to send the modified grid back to the client.

Example of a File System Server in Python

This page presents the source code for a Python server that implements our [file system](#) and communicates with the [client](#) we wrote earlier.

The server is remarkably free of code that relates to distribution: most of the server code is simply application logic that would be present just the same as a non-distributed version. Again, this is one of the major advantages of Ice: distribution concerns are kept away from application code so that you can concentrate on developing application logic instead of networking infrastructure.

On this page:

- [Thread Safety in Python](#)

Implementing a File System Server in Python

We have now seen enough of the server-side Python mapping to implement a server for our [file system](#). (You may find it useful to review these Slice definitions before studying the source code.)

Our server is implemented in a single source file, `Server.py`, containing our server's main program as well as the definitions of our `Directory` and `File` servant subclasses.

Server Main Program in Python

Our server main program uses the `Ice.Application` class. The `run` method installs a signal handler, creates an object adapter, instantiates a few servants for the directories and files in the file system, and then activates the adapter. This leads to a main program as follows:

```

Python

import sys, threading, Ice, Filesystem

# DirectoryI servant class ...
# FileI servant class ...

class Server(Ice.Application):
    def run(self, args):
        # Terminate cleanly on receipt of a signal
        #
        self.shutdownOnInterrupt()

        # Create an object adapter (stored in the _adapter
        # static members)
        #
        adapter = self.communicator().createObjectAdapterWithEndpoints(
            "SimpleFilesystem", "default -p 10000")
        DirectoryI._adapter = adapter
        FileI._adapter = adapter

        # Create the root directory (with name "/" and no parent)
        #
```

```
root = DirectoryI("/", None)

# Create a file called "README" in the root directory
#
file = FileI("README", root)
text = [ "This file system contains a collection of poetry." ]
try:
    file.write(text)
except Filesystem.GenericError, e:
    print e.reason

# Create a directory called "Coleridge"
# in the root directory
#
coleridge = DirectoryI("Coleridge", root)

# Create a file called "Kubla_Khan"
# in the Coleridge directory
#
file = FileI("Kubla_Khan", coleridge)
text = [ "In Xanadu did Kubla Khan",
        "A stately pleasure-dome decree:",
        "Where Alph, the sacred river, ran",
        "Through caverns measureless to man",
        "Down to a sunless sea." ]
try:
    file.write(text)
except Filesystem.GenericError, e:
    print e.reason

# All objects are created, allow client requests now
#
adapter.activate()

# Wait until we are done
#
self.communicator().waitForShutdown()

if self.interrupted():
    print self.appName() + ": terminating"

return 0
```

```
app = Server()
sys.exit(app.main(sys.argv))
```

The code defines the `Server` class, which derives from `Ice.Application` and contains the main application logic in its `run` method. Much of this code is boiler plate that we saw previously: we create an object adapter, and, towards the end, activate the object adapter and call `waitForShutdown`.

The interesting part of the code follows the adapter creation: here, the server instantiates a few nodes for our file system to create the structure shown below:

A small file system.

As we will see shortly, the servants for our directories and files are of type `DirectoryI` and `FileI`, respectively. The constructor for either type of servant accepts two parameters, the name of the directory or file to be created and a reference to the servant for the parent directory. (For the root directory, which has no parent, we pass `None`.) Thus, the statement

Python

```
root = DirectoryI("/", None)
```

creates the root directory, with the name `" / "` and no parent directory.

Here is the code that establishes the structure in the above illustration:

Python

```

# Create the root directory (with name "/" and no parent)
#
root = DirectoryI("/", None)

# Create a file called "README" in the root directory
#
file = FileI("README", root)
text = [ "This file system contains a collection of poetry." ]
try:
    file.write(text)
except Filesystem.GenericError, e:
    print e.reason

# Create a directory called "Coleridge"
# in the root directory
#
coleridge = DirectoryI("Coleridge", root)

# Create a file called "Kubla_Khan"
# in the Coleridge directory
#
file = FileI("Kubla_Khan", coleridge)
text = [ "In Xanadu did Kubla Khan",
        "A stately pleasure-dome decree:",
        "Where Alph, the sacred river, ran",
        "Through caverns measureless to man",
        "Down to a sunless sea." ]
try:
    file.write(text)
except Filesystem.GenericError, e:
    print e.reason

```

We first create the root directory and a file `README` within the root directory. (Note that we pass a reference to the root directory as the parent when we create the new node of type `FileI`.)

The next step is to fill the file with text:

Python

```

text = [ "This file system contains a collection of poetry." ]
try:
    file.write(text)
except Filesystem.GenericError, e:
    print e.reason

```

Recall that [Slice sequences](#) map to Python lists. The Slice type `Lines` is simply a list of strings; we add a line of text to our `README` file by initializing the `text` list to contain one element.

Finally, we call the Slice `write` operation on our `FileI` servant by simply writing:

```

Python

```
file.write(text)
```

```

This statement is interesting: the server code invokes an operation on one of its own servants. Because the call happens via a reference to the servant (of type `FileI`) and not via a proxy (of type `FilePrx`), the Ice run time does not know that this call is even taking place — such a direct call into a servant is not mediated by the Ice run time in any way and is dispatched as an ordinary Python method call.

In similar fashion, the remainder of the code creates a subdirectory called `Coleridge` and, within that directory, a file called `Kubla_Khan` to complete the structure in the above illustration.

FileI Servant Class in Python

Our `FileI` servant class has the following basic structure:

```

Python

```
class FileI(Filesystem.File):
 # Constructor and operations here...

 _adapter = None
```

```

The class has a number of data members:

- `_adapter`
This class member stores a reference to the single object adapter we use in our server.
- `_name`
This instance member stores the name of the file incarnated by the servant.
- `_parent`
This instance member stores the reference to the servant for the file's parent directory.
- `_lines`
This instance member holds the contents of the file.

The `_name`, `_parent`, and `_lines` data members are initialized by the constructor:

Python

```

def __init__(self, name, parent):
    self._name = name
    self._parent = parent
    self._lines = []

    assert(self._parent != None)

    # Create an identity
    #
    myID = Ice.Identity()
    myID.name = Ice.generateUUID()

    # Add ourself to the object adapter
    #
    self._adapter.add(self, myID)

    # Create a proxy for the new node and
    # add it as a child to the parent
    #
    thisNode = Filesystem.NodePrx.uncheckedCast(self._adapter.createProxy(myID))
    self._parent.addChild(thisNode)

```

After initializing the instance members, the code verifies that the reference to the parent is not `None` because every file must have a parent directory. The constructor then generates an identity for the file by calling `Ice.generateUUID` and adds itself to the servant map by calling `ObjectAdapter.add`. Finally, the constructor creates a proxy for this file and calls the `addChild` method on its parent directory. `addChild` is a helper function that a child directory or file calls to add itself to the list of descendant nodes of its parent directory. We will see the implementation of this function in [DirectoryI Methods](#).

The remaining methods of the `FileI` class implement the Slice operations we defined in the `Node` and `File` Slice interfaces:

Python

```
# Slice Node::name() operation

def name(self, current=None):
    return self._name

# Slice File::read() operation

def read(self, current=None):
    return self._lines

# Slice File::write() operation

def write(self, text, current=None):
    self._lines = text
```

The `name` method is inherited from the generated `Node` class. It simply returns the value of the `_name` instance member.

The `read` and `write` methods are inherited from the generated `File` class and simply return and set the `_lines` instance member.

DirectoryI Servant Class in Python

The `DirectoryI` class has the following basic structure:

Python

```
class DirectoryI(Filesystem.Directory):
    # Constructor and operations here...

    _adapter = None
```

DirectoryI Data Members in Python

As for the `FileI` class, we have data members to store the object adapter, the name, and the parent directory. (For the root directory, the `_parent` member holds `None`.) In addition, we have a `_contents` data member that stores the list of child directories. These data members are initialized by the constructor:

Python

```

def __init__(self, name, parent):
    self._name = name
    self._parent = parent
    self._contents = []

    # Create an identity. The
    # parent has the fixed identity "RootDir"
    #
    myID = Ice.Identity()
    if(self._parent):
        myID.name = Ice.generateUUID()
    else:
        myID.name = "RootDir"

    # Add ourself to the object adapter
    #
    self._adapter.add(self, myID)

    # Create a proxy for the new node and
    # add it as a child to the parent
    #
    thisNode = Filesystem.NodePrx.uncheckedCast(self._adapter.createProxy(myID))
    if self._parent:
        self._parent.addChild(thisNode)

```

DirectoryI Constructor in Python

The constructor creates an identity for the new directory by calling `Ice.generateUUID`. (For the root directory, we use the fixed identity "RootDir".) The servant adds itself to the servant map by calling `ObjectAdapter.add` and then creates a proxy to itself and passes it to the `addChild` helper function.

DirectoryI Methods in Python

`addChild` simply adds the passed reference to the `_contents` list:

Python

```

def addChild(self, child):
    self._contents.append(child)

```

The remainder of the operations, `name` and `list`, are trivial:

Python

```
def name(self, current=None):
    return self._name

def list(self, current=None):
    return self._contents
```

Thread Safety in Python

The server code we have written so far is not quite correct as it stands: if two clients access the same file in parallel, each via a different thread, one thread may read the `_lines` data member while another thread updates it. Obviously, if that happens, we may write or return garbage or, worse, crash the server. However, we can make the `read` and `write` operations thread-safe with a few trivial changes to the `FileI` class:

Python

```
def __init__(self, name, parent):
    self._name = name
    self._parent = parent
    self._lines = []
    self._mutex = threading.Lock()

    # ...

def name(self, current=None):
    return self._name

def read(self, current=None):
    self._mutex.acquire()
    lines = self._lines[:] # Copy the list
    self._mutex.release()
    return lines

def write(self, text, current=None):
    self._mutex.acquire()
    self._lines = text
    self._mutex.release()
```

We modified the constructor to add the instance member `_mutex`, and then enclosed our `read` and `write` implementations in a critical section. (The `name` method does not require a critical section because the file's name is immutable.)

No changes for thread safety are necessary in the `DirectoryI` class because the `Directory` interface, in its current form, defines no operations that modify the object.

Ruby Mapping

Ice currently provides a client-side mapping for Ruby, but not a server-side mapping.

Topics

- [Client-Side Slice-to-Ruby Mapping](#)

Client-Side Slice-to-Ruby Mapping

The client-side Slice-to-Ruby mapping defines how Slice data types are translated to Ruby types, and how clients invoke operations, pass parameters, and handle errors. Much of the Ruby mapping is intuitive. For example, Slice sequences map to Ruby arrays, so there is essentially nothing new you have to learn in order to use Slice sequences in Ruby.

The Ruby API to the Ice run time is fully thread-safe. Obviously, you must still synchronize access to data from different threads. For example, if you have two threads sharing a sequence, you cannot safely have one thread insert into the sequence while another thread is iterating over the sequence. However, you only need to concern yourself with concurrent access to your own data — the Ice run time itself is fully thread safe, and none of the Ice API calls require you to acquire or release a lock before you safely can make the call.

Much of what appears in this chapter is reference material. We suggest that you skim the material on the initial reading and refer back to specific sections as needed. However, we recommend that you read at least the mappings for [exceptions](#), [interfaces](#), and [operations](#) in detail because these sections cover how to call operations from a client, pass parameters, and handle exceptions.

In order to use the Ruby mapping, you should need no more than the Slice definition of your application and knowledge of the Ruby mapping rules. In particular, looking through the generated code in order to discern how to use the Ruby mapping is likely to be inefficient, due to the amount of detail. Of course, occasionally, you may want to refer to the generated code to confirm a detail of the mapping, but we recommend that you otherwise use the material presented here to see how to write your client-side code.

The Ice Module

All of the APIs for the Ice run time are nested in the `Ice` module, to avoid clashes with definitions for other libraries or applications. Some of the contents of the `Ice` module are generated from Slice definitions; other parts of the `Ice` module provide special-purpose definitions that do not have a corresponding Slice definition. We will incrementally cover the contents of the `Ice` module throughout the remainder of the manual.

A Ruby application can load the Ice run time using the `require` statement:

```
require 'Ice'
```

If the statement executes without error, the Ice run time is loaded and available for use. You can determine the version of the Ice run time you have just loaded by calling the `stringVersion` function:

```
icever = Ice::stringVersion()
```

Ruby Mapping for Identifiers

A Slice identifier maps to an identical Ruby identifier. For example, the Slice identifier `clock` becomes the Ruby identifier `clock`. There are two exceptions to this rule:

1. Ruby requires the names of classes, modules, and constants to begin with an upper case letter. If a Slice identifier maps to the name of a Ruby class, module, or constant, and the Slice identifier does not begin with an upper case letter, the mapping replaces the leading character with its upper case equivalent. For example, the Slice identifier `bankAccount` is mapped as `BankAccount`.
2. If a Slice identifier is the same as a Ruby keyword, the corresponding Ruby identifier is prefixed with an underscore. For example, the Slice identifier `while` is mapped as `_while`.

You should try to [avoid such identifiers](#) as much as possible.

Ruby Mapping for Built-In Types

On this page:

- [Mapping of Slice Built-In Types to Ruby Types](#)
- [String Mapping in Ruby](#)

Mapping of Slice Built-In Types to Ruby Types

The Slice [built-in types](#) are mapped to Ruby types as shown in this table:

Slice	Ruby
bool	true or false
byte	Fixnum
short	Fixnum
int	Fixnum or Bignum
long	Fixnum or Bignum
float	Float
double	Float
string	String

Although Ruby supports arbitrary precision in its integer types, the Ice run time validates integer values to ensure they have valid ranges for their declared Slice types.

String Mapping in Ruby

String values returned as the result of a Slice operation (including return values, out parameters, and data members) contain UTF-8 encoded strings unless the program has installed a [string converter](#), in which case string values use the converter's native encoding instead.

As string input values for a remote Slice operation, Ice accepts `nil` in addition to `String` objects; each occurrence of `nil` is marshaled as an empty string. Ice assumes that all `String` objects contain valid UTF-8 encoded strings unless the program has installed a string converter, in which case Ice assumes that `String` objects use the native encoding expected by the converter.

Ruby Mapping for Enumerations

Ruby does not have an enumerated type, so a Slice enumeration is emulated using a Ruby class: the name of the Slice enumeration becomes the name of the Ruby class; for each enumerator, the class contains a constant with the **same name** as the enumerator. For example:

```

Slice

enum Fruit { Apple, Pear, Orange };

```

The generated Ruby class looks as follows:

```

Ruby

class Fruit
  include Comparable

  Apple = # ...
  Pear = # ...
  Orange = # ...

  def Fruit.from_int(val)

  def to_i

  def to_s

  def <=>(other)

  def hash

  # ...
end

```

The compiler generates a class constant for each enumerator that holds a corresponding instance of `Fruit`. The `from_int` class method returns an instance given its Slice value, while `to_i` returns the Slice value of an enumerator and `to_s` returns its Slice identifier.

Given the above definitions, we can use enumerated values as follows:

Ruby

```
f1 = Fruit::Apple
f2 = Fruit::Orange

if f1 == Fruit::Apple # Compare for equality
  # ...

if f1 < f2           # Compare two enums
  # ...

case f2
when Fruit::Orange
  puts "found Orange"
else
  puts "found #{f2.to_s}"
end
end
```

Comparison operators are available as a result of including `Comparable`, which means a program can compare enumerators according to their `Slice` values. Note that, when using `custom enumerator values`, the order of enumerators by their `Slice` values may not match their order of declaration.

Suppose we modify the `Slice` definition to include a custom enumerator value:

Slice

```
enum Fruit { Apple, Pear = 3, Orange };
```

We can use `from_int` to examine the `Slice` values of the enumerators:

Ruby

```
Fruit::from_int(0) # Apple
Fruit::from_int(1) # nil
Fruit::from_int(3) # Pear
Fruit::from_int(4) # Orange
```

Ruby Mapping for Structures

A Slice [structure](#) maps to a Ruby class with the [same name](#). For each Slice data member, the Ruby class contains a corresponding instance variable as well as accessors to read and write its value. For example, here is our [Employee](#) structure once more:

Slice
<pre>struct Employee { long number; string firstName; string lastName; };</pre>

The Ruby mapping generates the following definition for this structure:

Ruby
<pre>class Employee def initialize(number=0, firstName='', lastName='') @number = number @firstName = firstName @lastName = lastName end def hash # ... end def == # ... end def inspect # ... end attr_accessor :number, :firstName, :lastName end</pre>

The constructor initializes each of the instance variables to a default value appropriate for its type:

Data Member Type	Default Value
string	Empty string
enum	First enumerator in enumeration
struct	Default-constructed value
Numeric	Zero

<code>bool</code>	False
<code>sequence</code>	Null
<code>dictionary</code>	Null
<code>class/interface</code>	Null

You can also declare different [default values](#) for members of primitive and enumerated types.

The compiler generates a definition for the `hash` method, which allows instances to be used as keys in a hash collection. The `hash` method returns a hash value for the structure based on the value of its data members.

The `==` method returns true if all members of two structures are (recursively) equal.

The `inspect` method returns a string representation of the structure.

Ruby Mapping for Sequences

On this page:

- [Mapping Slice Sequences to Ruby Arrays](#)
- [Mapping for Byte Sequences in Ruby](#)

Mapping Slice Sequences to Ruby Arrays

A Slice [sequence](#) maps to a Ruby array; the only exception is a sequence of bytes, which [maps to a string](#). The use of a Ruby array means that the mapping does not generate a separate named type for a Slice sequence. It also means that you can take advantage of all the array functionality provided by Ruby. For example:

Slice
<pre>sequence<Fruit> FruitPlatter;</pre>

We can use the `FruitPlatter` sequence as shown below:

Ruby
<pre>platter = [Fruit::Apple, Fruit::Pear] platter.push(Fruit::Orange)</pre>

The Ice run time validates the elements of a sequence to ensure that they are compatible with the declared type; a `TypeError` exception is raised if an incompatible type is encountered.

Mapping for Byte Sequences in Ruby

A Ruby string can contain arbitrary 8-bit binary data, therefore it is a more efficient representation of a byte sequence than a Ruby array in both memory utilization and throughput performance.

When receiving a byte sequence (as the result of an operation, as an out parameter, or as a member of a data structure), the value is always represented as a string. When sending a byte sequence as an operation parameter or data member, the Ice run time accepts both a string and an array of integers as legal values. For example, consider the following Slice definitions:

Slice
<pre>// Slice sequence<byte> Data; interface I { void sendData(Data d); Data getData(); };</pre>

The interpreter session below uses these Slice definitions to demonstrate the mapping for a sequence of bytes:

Ruby

```
> proxy = ...
> proxy.sendData("\0\1\2\3") # Send as a string
> proxy.sendData([0, 1, 2, 3]) # Send as an array
> d = proxy.getData()
> d.class
=> String
> d
=> "\000\001\002\003"
```

The two invocations of `sendData` are equivalent; however, the second invocation incurs additional overhead as the Ice run time must validate the type and range of each array element.

- [Ruby Mapping for Interfaces](#)
- [Ruby Mapping for Operations](#)

Ruby Mapping for Dictionaries

Here is the definition of our `EmployeeMap` once more:

Slice
<pre>dictionary<long, Employee> EmployeeMap;</pre>

As for [sequences](#), the Ruby mapping does not create a separate named type for this definition. Instead, *all* dictionaries are simply instances of Ruby's hash collection type. For example:

Ruby
<pre>em = {} e = Employee.new e.number = 31 e.firstName = "James" e.lastName = "Gosling" em[e.number] = e</pre>

The Ice run time validates the elements of a dictionary to ensure that they are compatible with the declared type; a `TypeError` exception is raised if an incompatible type is encountered.

- [Ruby Mapping for Exceptions](#)
- [Ruby Mapping for Interfaces](#)
- [Ruby Mapping for Operations](#)

Ruby Mapping for Constants

Here are the constant definitions once more:

```

Slice
const bool      AppendByDefault = true;
const byte      LowerNibble = 0x0f;
const string    Advice = "Don't Panic!";
const short     TheAnswer = 42;
const double    PI = 3.1416;

enum Fruit { Apple, Pear, Orange };
const Fruit     FavoriteFruit = Pear;

```

The generated definitions for these constants are shown below:

```

Ruby
AppendByDefault = true
LowerNibble = 15
Advice = "Don't Panic!"
TheAnswer = 42
PI = 3.1416
FavoriteFruit = Fruit::Pear

```

As you can see, each Slice constant is mapped to a Ruby constant with the same name.

Slice string literals that contain non-ASCII characters or universal character names are mapped to Ruby string literals with these characters replaced by their UTF-8 encoding as octal escapes. For example:

```

Slice
const string Egg = "æuf";
const string Heart = "c\u0153ur";
const string Banana = "\U0001F34C";

```

is mapped to:

```

Ruby
Egg = "\305\223uf"
Heart = "c\305\223ur"
Banana = "\360\237\215\214"

```

Ruby Mapping for Exceptions

On this page:

- [Inheritance Hierarchy for Exceptions in Ruby](#)
- [Ruby Mapping for User Exceptions](#)
 - [Optional Data Members](#)
- [Ruby Mapping for Run-Time Exceptions](#)

Inheritance Hierarchy for Exceptions in Ruby

The mapping for exceptions is based on the inheritance hierarchy shown below:

Inheritance structure for Ice exceptions.

The ancestor of all exceptions is `StandardError`, from which `Ice::Exception` is derived. `Ice::LocalException` and `Ice::UserException` are derived from `Ice::Exception` and form the base for all run-time and user exceptions.

Ruby Mapping for User Exceptions

Here is a fragment of the `Slice` definition for our world time server once more:

```

Slice

exception GenericError {
  string reason;
};
exception BadTimeVal extends GenericError {};
exception BadZoneName extends GenericError {};
  
```

These exception definitions map to the abbreviated Ruby class definitions shown below:

Ruby

```

class GenericError < Ice::UserException
  def initialize(reason='')

  def to_s

  def inspect

  attr_accessor :reason
end

class BadTimeVal < GenericError
  def initialize(reason='')

  def to_s

  def inspect
end

class BadZoneName < GenericError
  def initialize(reason='')

  def to_s

  def inspect
end

```

Each Slice exception is mapped to a Ruby class with the same name. The inheritance structure of the Slice exceptions is preserved for the generated classes, so `BadTimeVal` and `BadZoneName` inherit from `GenericError`.

Each exception member corresponds to an instance variable of the instance, which the constructor initializes to a default value appropriate for its type:

Data Member Type	Default Value
string	Empty string
enum	First enumerator in enumeration
struct	Default-constructed value
Numeric	Zero
bool	False
sequence	Null
dictionary	Null
class/interface	Null

You can also declare different [default values](#) for members of primitive and enumerated types. For derived exceptions, the constructor has one parameter for each of the base exception's data members, plus one parameter for each of the derived exception's data members, in

base-to-derived order. As an example, although `BadTimeVal` and `BadZoneName` do not declare data members, their constructors still accept a value for the inherited data member `reason` in order to pass it to the constructor of the base exception `GenericError`. The generated class defines an accessor for each data member to read and write its value.

Each exception also defines the standard methods `to_s` and `inspect` to return the name of the exception and a stringified representation of the exception and its members, respectively.

All user exceptions are derived from the base class `Ice::UserException`. This allows you to catch all user exceptions generically by installing a handler for `Ice::UserException`. Similarly, you can catch all Ice run-time exceptions with a handler for `Ice::LocalException`, and you can catch all Ice exceptions with a handler for `Ice::Exception`.

Optional Data Members

Optional data members use the same mapping as required data members, but an optional data member can also be set to the marker value `Ice::Unset` to indicate that the member is unset. A well-behaved program must compare an optional data member to `Ice::Unset` before using the member's value:

```

Ruby

begin
  ...
rescue => ex
  if ex.optionalMember == Ice::Unset
    puts "optionalMember is unset"
  else
    puts "optionalMember = " + ex.optionalMember
  end
end
end
```

The `Ice::Unset` marker value has different semantics than `nil`. Since `nil` is a legal value for certain Slice types, the Ice run time requires a separate marker value so that it can determine whether an optional value is set. An optional value set to `nil` is considered to be set. If you need to distinguish between an unset value and a value set to `nil`, you can do so as follows:

```

Ruby

begin
  ...
rescue => ex
  if ex.optionalMember == Ice::Unset
    puts "optionalMember is unset"
  elsif ex.optionalMember == nil
    puts "optionalMember is nil"
  else
    puts "optionalMember = " + ex.optionalMember
  end
end
end
```

Ruby Mapping for Run-Time Exceptions

The Ice run time throws [run-time exceptions](#) for a number of pre-defined error conditions. All run-time exceptions directly or indirectly derive from `Ice::LocalException` (which, in turn, derives from `Ice::Exception`).

By catching exceptions at the appropriate point in the inheritance hierarchy, you can handle exceptions according to the category of error they indicate:

- `Ice::LocalException`
This is the root of the inheritance tree for run-time exceptions.
- `Ice::UserException`
This is the root of the inheritance tree for user exceptions.
- `Ice::TimeoutException`
This is the base exception for both operation-invocation and connection-establishment timeouts.
- `Ice::ConnectTimeoutException`
This exception is raised when the initial attempt to establish a connection to a server times out.

For example, a `ConnectTimeoutException` can be handled as `ConnectTimeoutException`, `TimeoutException`, `LocalException`, or `Exception`.

You will probably have little need to catch run-time exceptions as their most-derived type and instead catch them as `LocalException`; the fine-grained error handling offered by the remainder of the hierarchy is of interest mainly in the implementation of the Ice run time. Exceptions to this rule are the exceptions related to `facet` and `object` life cycles, which you may want to catch explicitly. These exceptions are `FacetNotExistException` and `ObjectNotExistException`, respectively.

Ruby Mapping for Interfaces

The mapping of Slice [interfaces](#) revolves around the idea that, to invoke a remote operation, you call a member function on a local class instance that is a [proxy](#) for the remote object. This makes the mapping easy and intuitive to use because making a remote procedure call is no different from making a local procedure call (apart from error semantics).

On this page:

- [Proxy Classes in Ruby](#)
- [Ice::ObjectPrx Class in Ruby](#)
- [Casting Proxies in Ruby](#)
- [Using Proxy Methods in Ruby](#)
- [Object Identity and Proxy Comparison in Ruby](#)

Proxy Classes in Ruby

On the client side, a Slice interface maps to a Ruby class with methods that correspond to the operations on those interfaces. Consider the following simple interface:

Slice
<pre>interface Simple { void op(); };</pre>

The Ruby mapping generates the following definition for use by the client:

Ruby
<pre>class SimplePrx < Ice::ObjectPrx def op(_ctx=nil) # ... end def SimplePrx.ice_staticId() # ... end # ... end</pre>

In the client's address space, an instance of `SimplePrx` is the local ambassador for a remote instance of the `Simple` interface in a server and is known as a *proxy instance*. All the details about the server-side object, such as its address, what protocol to use, and its object identity are encapsulated in that instance.

Note that `SimplePrx` inherits from `Ice::ObjectPrx`. This reflects the fact that all Ice interfaces implicitly inherit from `Ice::Object`.

For each operation in the interface, the proxy class has a method of the same name. In the preceding example, we find that the operation `op` has been mapped to the method `op`. Note that `op` accepts an optional trailing parameter `_ctx` representing the operation context. This parameter is a Ruby hash value for use by the Ice run time to store information about how to deliver a request. You normally do not need to use it. (We examine the context parameter in detail in [Request Contexts](#). The parameter is also used by [IceStorm](#).)

Proxy instances are always created on behalf of the client by the Ice run time, so client code never has any need to instantiate a proxy directly.

A value of `nil` denotes the null proxy. The null proxy is a dedicated value that indicates that a proxy points "nowhere" (denotes no object).

Another method defined by every proxy class is `ice_staticId`, which returns the [type ID](#) string corresponding to the interface. As an example, for the Slice interface `Simple` in module `M`, the string returned by `ice_staticId` is `":M::Simple"`.

Ice::ObjectPrx Class in Ruby

All Ice objects have `Object` as the ultimate ancestor type, so all proxies inherit from `Ice::ObjectPrx`. `ObjectPrx` provides a number of methods:

Ruby
<pre>class ObjectPrx def eql?(proxy) def ice_getIdentity def ice_isA(id) def ice_ids def ice_id def ice_ping # ... end</pre>

The methods behave as follows:

- **eql?**
The implementation of this standard Ruby method compares two proxies for equality. Note that all aspects of proxies are compared by this operation, such as the communication endpoints for the proxy. This means that, in general, if two proxies compare unequal, that does *not* imply that they denote different objects. For example, if two proxies denote the same Ice object via different transport endpoints, `eql?` returns `false` even though the proxies denote the same object.
- **ice_getIdentity**
This method returns the identity of the object denoted by the proxy. The identity of an Ice object has the following Slice type:

Slice
<pre>module Ice { struct Identity { string name; string category; }; };</pre>

To see whether two proxies denote the same object, first obtain the identity for each object and then compare the identities:

Ruby

```

proxy1 = ...
proxy2 = ...
id1 = proxy1.ice_getIdentity
id2 = proxy2.ice_getIdentity

if id1 == id2
  # proxy1 and proxy2 denote the same object
else
  # proxy1 and proxy2 denote different objects
end

```

- **ice_isA**

The `ice_isA` method determines whether the object denoted by the proxy supports a specific interface. The argument to `ice_isA` is a [type ID](#). For example, to see whether a proxy of type `ObjectPrx` denotes a `Printer` object, we can write:

Ruby

```

proxy = ...
if proxy && proxy.ice_isA("::Printer")
  # proxy denotes a Printer object
else
  # proxy denotes some other type of object
end

```

Note that we are testing whether the proxy is `nil` before attempting to invoke the `ice_isA` method. This avoids getting a run-time error if the proxy is `nil`.

- **ice_ids**

The `ice_ids` method returns an array of strings representing all of the [type IDs](#) that the object denoted by the proxy supports.

- **ice_id**

The `ice_id` method returns the [type ID](#) of the object denoted by the proxy. Note that the type returned is the type of the actual object, which may be more derived than the static type of the proxy. For example, if we have a proxy of type `BasePrx`, with a static type ID of `::Base`, the return value of `ice_id` might be `::Base`, or it might be something more derived, such as `::Derived`.

- **ice_ping**

The `ice_ping` method provides a basic reachability test for the object. If the object can physically be contacted (that is, the object exists and its server is running and reachable), the call completes normally; otherwise, it throws an exception that indicates why the object could not be reached, such as `ObjectNotExistException` or `ConnectTimeoutException`.

The `ice_isA`, `ice_ids`, `ice_id`, and `ice_ping` methods are remote operations and therefore support an additional overloading that accepts a [request context](#). Also note that there are [other methods](#) in `ObjectPrx`, not shown here. These methods provide different ways to dispatch a call and also provide access to an object's [facets](#).

Casting Proxies in Ruby

The Ruby mapping for a proxy also generates two class methods:

Ruby

```
class SimplePrx < Ice::ObjectPrx
  # ...

  def SimplePrx.checkedCast(proxy, facet='', ctx={})

  def SimplePrx.uncheckedCast(proxy, facet='')
end
```

The method names `checkedCast` and `uncheckedCast` are reserved for use in proxies. If a Slice interface defines an operation with either of those names, the mapping escapes the name in the generated proxy by prepending an underscore. For example, an interface that defines an operation named `checkedCast` is mapped to a proxy with a method named `_checkedCast`.

For `checkedCast`, if the passed proxy is for an object of type `Simple`, or a proxy for an object with a type derived from `Simple`, the cast returns a reference to a proxy of type `SimplePrx`; otherwise, if the passed proxy denotes an object of a different type (or if the passed proxy is `nil`), the cast returns `nil`.

Given a proxy of any type, you can use a `checkedCast` to determine whether the corresponding object supports a given type, for example:

Ruby

```
obj = ...          # Get a proxy from somewhere...

simple = SimplePrx::checkedCast(obj)
if simple
  # Object supports the Simple interface...
else
  # Object is not of type Simple...
end
```

Note that a `checkedCast` contacts the server. This is necessary because only the server implementation has definite knowledge of the type of an object. As a result, a `checkedCast` may throw a `ConnectTimeoutException` or an `ObjectNotExistException`.

In contrast, an `uncheckedCast` does not contact the server and unconditionally returns a proxy of the requested type. However, if you do use an `uncheckedCast`, you must be certain that the proxy really does support the type you are casting to; otherwise, if you get it wrong, you will most likely get a run-time exception when you invoke an operation on the proxy. The most likely error for such a type mismatch is `OperationNotExistException`. However, other exceptions, such as a marshaling exception are possible as well. And, if the object happens to have an operation with the correct name, but different parameter types, no exception may be reported at all and you simply end up sending the invocation to an object of the wrong type; that object may do rather nonsensical things. To illustrate this, consider the following two interfaces:

Slice

```
interface Process {
    void launch(int stackSize, int dataSize);
};

// ...

interface Rocket {
    void launch(float xCoord, float yCoord);
};
```

Suppose you expect to receive a proxy for a `Process` object and use an `uncheckedCast` to down-cast the proxy:

Ruby

```
obj = ... # Get proxy...
process = ProcessPrx::uncheckedCast(obj) # No worries...
process.launch(40, 60) # Oops...
```

If the proxy you received actually denotes a `Rocket` object, the error will go undetected by the Ice run time: because `int` and `float` have the same size and because the Ice protocol does not tag data with its type on the wire, the implementation of `Rocket::launch` will simply misinterpret the passed integers as floating-point numbers.

In fairness, this example is somewhat contrived. For such a mistake to go unnoticed at run time, both objects must have an operation with the same name and, in addition, the run-time arguments passed to the operation must have a total marshaled size that matches the number of bytes that are expected by the unmarshaling code on the server side. In practice, this is extremely rare and an incorrect `uncheckedCast` typically results in a run-time exception.

Using Proxy Methods in Ruby

The base proxy class `ObjectPrx` supports a variety of [methods for customizing a proxy](#). Since proxies are immutable, each of these "factory methods" returns a copy of the original proxy that contains the desired modification. For example, you can obtain a proxy configured with a ten second timeout as shown below:

Ruby

```
proxy = communicator.stringToProxy(...)
proxy = proxy.ice_timeout(10000)
```

A factory method returns a new proxy object if the requested modification differs from the current proxy, otherwise it returns the current proxy. With few exceptions, factory methods return a proxy of the same type as the current proxy, therefore it is generally not necessary to repeat a down-cast after using a factory method. The example below demonstrates these semantics:

Ruby

```
base = communicator.stringToProxy(...)
hello = Demo::HelloPrx::checkedCast(base)
hello = hello.ice_timeout(10000) # Type is not discarded
hello.sayHello()
```

The only exceptions are the factory methods `ice_facet` and `ice_identity`. Calls to either of these methods may produce a proxy for an object of an unrelated type, therefore they return a base proxy that you must subsequently down-cast to an appropriate type.

Object Identity and Proxy Comparison in Ruby

Proxy objects support comparison using the comparison operators `==`, `!=`, and `<=>`, as well as the `eq1?` method. Note that proxy comparison uses *all* of the information in a proxy for the comparison. This means that not only the object identity must match for a comparison to succeed, but other details inside the proxy, such as the protocol and endpoint information, must be the same. In other words, comparison tests for *proxy* identity, *not* object identity. A common mistake is to write code along the following lines:

Ruby

```
p1 = ...           # Get a proxy...
p2 = ...           # Get another proxy...

if p1 != p2
  # p1 and p2 denote different objects      # WRONG!
else
  # p1 and p2 denote the same object       # Correct
end
```

Even though `p1` and `p2` differ, they may denote the same Ice object. This can happen because, for example, both `p1` and `p2` embed the same object identity, but each uses a different protocol to contact the target object. Similarly, the protocols may be the same, but denote different endpoints (because a single Ice object can be contacted via several different transport endpoints). In other words, if two proxies compare equal, we know that the two proxies denote the same object (because they are identical in all respects); however, if two proxies compare unequal, we know absolutely nothing: the proxies may or may not denote the same object.

To compare the object identities of two proxies, you can use helper functions in the `Ice` module:

Ruby

```
def proxyIdentityCompare(lhs, rhs)
def proxyIdentityAndFacetCompare(lhs, rhs)
```

`proxyIdentityCompare` allows you to correctly compare proxies for identity:

Ruby

```
p1 = ...      # Get a proxy...
p2 = ...      # Get another proxy...

if Ice.proxyIdentityCompare(p1, p2) != 0
  # p1 and p2 denote different objects      # Correct
else
  # p1 and p2 denote the same object      # Correct
end
```

The function returns 0 if the identities are equal, -1 if `p1` is less than `p2`, and 1 if `p1` is greater than `p2`. (The comparison uses `name` as the major sort key and `category` as the minor sort key.)

The `proxyIdentityAndFacetCompare` function behaves similarly, but compares both the identity and the `facet name`.

 - [Optional Parameters in Ruby](#)
- [Exception Handling in Ruby](#)

Basic Ruby Mapping for Operations

As we saw in the [Ruby mapping for interfaces](#), for each operation on an interface, the proxy class contains a corresponding method with the same name. To invoke an operation, you call it via the proxy. For example, here is part of the definitions for our [file system](#):

```

Slice

```

module Filesystem {
 interface Node {
 idempotent string name();
 };
 // ...
};

```

```

The `name` operation returns a value of type `string`. Given a proxy to an object of type `Node`, the client can invoke the operation as follows:

```

Ruby

```

node = ... # Initialize proxy
name = node.name() # Get name via RPC

```

```

Normal and idempotent Operations in Ruby

You can add an `idempotent` qualifier to a `Slice` operation. As far as the signature for the corresponding proxy method is concerned, `idempotent` has no effect. For example, consider the following interface:

```

Slice

```

interface Example {
 string op1();
 idempotent string op2();
};

```

```

The proxy class for this is:

Ruby

```
class ExamplePrx < Ice::ObjectPrx
  def op1(_ctx=nil)

  def op2(_ctx=nil)
end
```

Because `idempotent` affects an aspect of call dispatch, not interface, it makes sense for the two methods to look the same.

Passing Parameters in Ruby

In-Parameters in Ruby

All parameters are passed by reference in the Ruby mapping; it is guaranteed that the value of a parameter will not be changed by the invocation.

Here is an interface with operations that pass parameters of various types from client to server:

Slice

```
struct NumberAndString {
  int x;
  string str;
};

sequence<string> StringSeq;

dictionary<long, StringSeq> StringTable;

interface ClientToServer {
  void op1(int i, float f, bool b, string s);
  void op2(NumberAndString ns, StringSeq ss, StringTable st);
  void op3(ClientToServer* proxy);
};
```

The Slice compiler generates the following proxy for this definition:

Ruby

```
class ClientToServerPrx < Ice::ObjectPrx
  def op1(i, f, b, s, _ctx=nil)

  def op2(ns, ss, st, _ctx=nil)

  def op3(proxy, _ctx=nil)
end
```

Given a proxy to a `ClientToServer` interface, the client code can pass parameters as in the following example:

Ruby

```
p = ... # Get proxy...

p.op1(42, 3.14, true, "Hello world!") # Pass simple literals

i = 42
f = 3.14
b = true
s = "Hello world!"
p.op1(i, f, b, s) # Pass simple variables

ns = NumberAndString.new()
ns.x = 42
ns.str = "The Answer"
ss = [ "Hello world!" ]
st = {}
st[0] = ns
p.op2(ns, ss, st) # Pass complex variables

p.op3(p) # Pass proxy
```

Out-Parameters in Ruby

As in Java, Ruby functions do not support reference arguments. That is, it is not possible to pass an uninitialized variable to a Ruby function in order to have its value initialized by the function. The [Java mapping](#) overcomes this limitation with the use of *holder classes* that represent each *out* parameter. The Ruby mapping takes a different approach, one that is more natural for Ruby users.

The semantics of *out* parameters in the Ruby mapping depend on whether the operation returns one value or multiple values. An operation returns multiple values when it has declared multiple *out* parameters, or when it has declared a non-void return type and at least one *out* parameter.

If an operation returns multiple values, the client receives them in the form of a *result array*. A non-void return value, if any, is always the first element in the result array, followed by the *out* parameters in the order of declaration.

If an operation returns only one value, the client receives the value itself.

Here again are the same Slice definitions we saw earlier, but this time with all parameters being passed in the `out` direction:

```

Slice

struct NumberAndString {
    int x;
    string str;
};

sequence<string> StringSeq;

dictionary<long, StringSeq> StringTable;

interface ServerToClient {
    int op1(out float f, out bool b, out string s);
    void op2(out NumberAndString ns,
             out StringSeq ss,
             out StringTable st);
    void op3(out ServerToClient* proxy);
};

```

The Ruby mapping generates the following code for this definition:

```

Ruby

class ClientToServerPrx < Ice::ObjectPrx
    def op1(_ctx=nil)

    def op2(_ctx=nil)

    def op3(_ctx=nil)
end

```

Given a proxy to a `ServerToClient` interface, the client code can receive the results as in the following example:

```

Ruby

p = ...           # Get proxy...
i, f, b, s = p.op1()
ns, ss, st = p.op2()
stcp = p.op3()

```

The operations have no `in` parameters, therefore no arguments are passed to the proxy methods. Since `op1` and `op2` return multiple values, their result arrays are unpacked into separate values, whereas the return value of `op3` requires no unpacking.

Parameter Type Mismatches in Ruby

Although the Ruby compiler cannot check the types of arguments passed to a method, the Ice run time does perform validation on the arguments to a proxy invocation and reports any type mismatches as a `TypeError` exception.

Null Parameters in Ruby

Some Slice types naturally have "empty" or "not there" semantics. Specifically, sequences, dictionaries, and strings all can be `nil`, but the corresponding Slice types do not have the concept of a null value. To make life with these types easier, whenever you pass `nil` as a parameter or return value of type sequence, dictionary, or string, the Ice run time automatically sends an empty sequence, dictionary, or string to the receiver.

This behavior is useful as a convenience feature: especially for deeply-nested data types, members that are sequences, dictionaries, or strings automatically arrive as an empty value at the receiving end. This saves you having to explicitly initialize, for example, every string element in a large sequence before sending the sequence in order to avoid a run-time error. Note that using null parameters in this way does *not* create null semantics for Slice sequences, dictionaries, or strings. As far as the object model is concerned, these do not exist (only *empty* sequences, dictionaries, and strings do). For example, it makes no difference to the receiver whether you send a string as `nil` or as an empty string: either way, the receiver sees an empty string.

Optional Parameters in Ruby

Optional parameters use the same mapping as required parameters. The only difference is that `Ice::Unset` can be passed as the value of an optional parameter or return value. Consider the following operation:

Slice
<pre>optional(1) int execute(optional(2) string params, out optional(3) float value);</pre>

A client can invoke this operation as shown below:

Ruby
<pre>i, v = proxy.execute("--file log.txt") i, v = proxy.execute(Ice::Unset) if v != Ice::Unset puts "value = " + v.to_s end</pre>

A well-behaved program must always compare an optional parameter to `Ice::Unset` prior to using its value. Keep in mind that the `Ice::Unset` marker value has different semantics than `nil`. Since `nil` is a legal value for certain Slice types, the Ice run time requires a separate marker value so that it can determine whether an optional parameter is set. An optional parameter set to `nil` is considered to be set. If you need to distinguish between an unset parameter and a parameter set to `nil`, you can do so as follows:

Ruby

```

if optionalParam == Ice::Unset
  puts "optionalParam is unset"
elsif optionalParam == nil
  puts "optionalParam is None"
else
  puts "optionalParam = " + optionalParam
end

```

Exception Handling in Ruby

Any operation invocation may throw a [run-time exception](#) and, if the operation has an exception specification, may also throw [user exceptions](#). Suppose we have the following simple interface:

Slice

```

exception Tantrum {
  string reason;
};

interface Child {
  void askToCleanUp() throws Tantrum;
};

```

Slice exceptions are thrown as Ruby exceptions, so you can simply enclose one or more operation invocations in a `begin-rescue` block:

Ruby

```

child = ...      # Get child proxy...

begin
  child.askToCleanUp()
rescue Tantrum => t
  puts "The child says: #{t.reason}"
end

```

Typically, you will catch only a few exceptions of specific interest around an operation invocation; other exceptions, such as unexpected run-time errors, will usually be handled by exception handlers higher in the hierarchy. For example:

Ruby

```
def run()
  child = ...          # Get child proxy...
  begin
    child.askToCleanUp()
  rescue Tantrum => t
    puts "The child says: #{t.reason}"
    child.scold()      # Recover from error...
  end
  child.praise()      # Give positive feedback...
end

begin
  # ...
  run()
  # ...
rescue Ice::Exception => ex
  print ex.backtrace.join("\n")
end
```

This code handles a specific exception of local interest at the point of call and deals with other exceptions generically. (This is also the strategy we used for our first simple application in [Hello World Application](#).)

Ruby Mapping for Classes

On this page:

- [Basic Ruby Mapping for Classes](#)
- [Inheritance from Ice::Object in Ruby](#)
- [Class Data Members in Ruby](#)
- [Class Constructors in Ruby](#)
- [Class Operations in Ruby](#)
- [Receiving Objects in Ruby](#)
- [Class Factories in Ruby](#)

Basic Ruby Mapping for Classes

A Slice `class` maps to a Ruby class with the **same name**. For each Slice data member, the generated class contains an instance variable and accessors to read and write it, just as for structures and exceptions. Consider the following class definition:

Slice	
<pre>class TimeOfDay { short hour; // 0 - 23 short minute; // 0 - 59 short second; // 0 - 59 string format(); // Return time as hh:mm:ss };</pre>	

The Ruby mapping generates the following code for this definition:

Ruby

```

module TimeOfDay_mixin
  include ::Ice::Object_mixin

  # ...

  def inspect
    # ...
  end

  #
  # Operation signatures.
  #
  # def format()

  attr_accessor :hours, :minutes, :seconds
end
class TimeOfDay
  include TimeOfDay_mixin

  def initialize(hour=0, minute=0, second=0)
    @hour = hour
    @minute = minute
    @second = second
  end

  def TimeOfDay.ice_staticId()
    '::M::TimeOfDay'
  end

  # ...
end

```

There are a number of things to note about the generated code:

1. The generated class `TimeOfDay` includes the mixin module `TimeOfDay_mixin`, which in turn includes `Ice::Object_mixin`. This reflects the semantics of Slice classes in that all classes implicitly inherit from `Object`, which is the ultimate ancestor of all classes. Note that `Object` is *not* the same as `Ice::ObjectPrx`. In other words, you *cannot* pass a class where a proxy is expected and vice versa.
2. The constructor defines an instance variable for each Slice data member.
3. The class defines the class method `ice_staticId`.
4. A comment summarizes the method signatures for each Slice operation.

There is quite a bit to discuss here, so we will look at each item in turn.

Inheritance from `Ice::Object` in Ruby

In other language mappings, the inheritance relationship between `Object` and a user-defined Slice class is stated explicitly, in that the

generated class derives from a language-specific representation of `Object`. Although its class type allows single inheritance, Ruby's loosely-typed nature places less emphasis on class hierarchies and relies more on *duck typing*.

In Ruby, an object's type is typically less important than the methods it supports. *If it looks like a duck, and acts like a duck, then it is a duck.*

The Slice mapping for a class follows this convention by placing most of the necessary machinery in a mixin module that the generated class includes into its definition. The Ice run time requires an instance of a Slice class to include the mixin module and define values for the declared data members, but does not require that the object be an instance of the generated class.

As shown in the illustration below, classes have no relationship to `Ice::ObjectPrx` (which is at the base of the inheritance hierarchy for proxies), therefore you cannot pass a class where a proxy is expected (and vice versa).

Inheritance from `Ice::ObjectPrx` and `Object`.

An instance of a Slice class `C` supports a number of methods:

Ruby

```

def ice_isA(id, current=nil)

def ice_ping(current=nil)

def ice_ids(current=nil)

def ice_id(current=nil)

def C.ice_staticId()

def ice_preMarshal()

def ice_postUnmarshal()
  
```

The methods behave as follows:

- `ice_isA`
This method returns `true` if the object supports the given `type ID`, and `false` otherwise.
- `ice_ping`
As for interfaces, `ice_ping` provides a basic reachability test for the object.
- `ice_ids`
This method returns a string sequence representing all of the `type IDs` supported by this object, including `::Ice::Object`.
- `ice_id`
This method returns the actual run-time `type ID` of the object. If you call `ice_id` through a reference to a base instance, the

returned type id is the actual (possibly more derived) type ID of the instance.

- `ice_staticId`
This method returns the static [type ID](#) of the class.
- `ice_preMarshal`
If the object supports this method, the Ice run time invokes it just prior to marshaling the object's state, providing the opportunity for the object to validate its declared data members.
- `ice_postUnmarshal`
If the object supports this method, the Ice run time invokes it after unmarshaling the object's state. An object typically defines this method when it needs to perform additional initialization using the values of its declared data members.

The mixin module `Ice::Object_mixin` supplies default definitions of `ice_isA` and `ice_ping`. For each Slice class, the generated mixin module defines `ice_ids` and `ice_id`, and the generated class defines the `ice_staticId` method.

Note that neither `Ice::Object` nor the generated class override `hash` and `==`, so the default implementations apply.

Class Data Members in Ruby

By default, data members of classes are mapped exactly as for structures and exceptions: for each data member in the Slice definition, the generated class contains a corresponding instance variable and accessor methods.

[Optional data members](#) use the same mapping as required data members, but an optional data member can also be set to the marker value `Ice::Unset` to indicate that the member is unset. A well-behaved program must compare an optional data member to `Ice::Unset` before using the member's value:

```

Ruby

v = ...
if v.optionalMember == Ice::Unset
  puts "optionalMember is unset"
else
  puts "optionalMember = " + v.optionalMember
end
```

The `Ice::Unset` marker value has different semantics than `nil`. Since `nil` is a legal value for certain Slice types, the Ice run time requires a separate marker value so that it can determine whether an optional value is set. An optional value set to `nil` is considered to be set. If you need to distinguish between an unset value and a value set to `nil`, you can do so as follows:

```

Ruby

v = ...
if v.optionalMember == Ice::Unset
  puts "optionalMember is unset"
elsif v.optionalMember == nil
  puts "optionalMember is nil"
else
  puts "optionalMember = " + v.optionalMember
end
```

If you wish to restrict access to a data member, you can modify its visibility using the `protected` metadata directive. The presence of this directive causes the Slice compiler to generate the data member with protected visibility. As a result, the member can be accessed only by the class itself or by one of its subclasses. For example, the `TimeOfDay` class shown below has the `protected` metadata directive applied to each of its data members:

Slice

```
class TimeOfDay {
  ["protected"] short hour;    // 0 - 23
  ["protected"] short minute; // 0 - 59
  ["protected"] short second; // 0 - 59
  string format();             // Return time as hh:mm:ss
};
```

The Slice compiler produces the following generated code for this definition:

Ruby

```
module TimeOfDay_mixin
  include ::Ice::Object_mixin

  # ...

  #
  # Operation signatures.
  #
  # def format()

  attr_accessor :hours, :minutes, :seconds
  protected :hours, :hours=
  protected :minutes, :minutes=
  protected :seconds, :seconds=
end
class TimeOfDay
  include TimeOfDay_mixin

  def initialize(hour=0, minute=0, second=0)
    @hour = hour
    @minute = minute
    @second = second
  end

  # ...
end
```

For a class in which all of the data members are protected, the metadata directive can be applied to the class itself rather than to each member individually. For example, we can rewrite the `TimeOfDay` class as follows:

Slice

```
["protected"] class TimeOfDay {
    short hour;          // 0 - 23
    short minute;       // 0 - 59
    short second;       // 0 - 59
    string format();    // Return time as hh:mm:ss
};
```

Class Constructors in Ruby

Classes have a constructor that assigns to each data member a default value appropriate for its type:

Data Member Type	Default Value
string	Empty string
enum	First enumerator in enumeration
struct	Default-constructed value
Numeric	Zero
bool	False
sequence	Null
dictionary	Null
class/interface	Null

You can also declare different [default values](#) for data members of primitive and enumerated types.

For derived classes, the constructor has one parameter for each of the base class's data members, plus one parameter for each of the derived class's data members, in base-to-derived order.

Pass the marker value `Ice::Unset` as the value of any [optional data members](#) that you wish to be unset.

Class Operations in Ruby

Operations of classes are mapped to methods in the generated class. This means that, if a class contains operations (such as the `format` operation of our `TimeOfDay` class), objects representing instances of `TimeOfDay` must define equivalent methods. For example:

Ruby

```
class TimeOfDayI < TimeOfDay
    def format(current=nil)
        sprintf("%02d:%02d:%02d", @hour, @minute, @second)
    end
end
```

In this case our implementation class `TimeOfDayI` derives from the generated class `TimeOfDay`. An alternative is to include the generated mixin module, which makes it possible for the class to derive from a different base class if necessary:

Ruby

```
class TimeOfDayI < SomeOtherClass
  include TimeOfDay_mixin

  def format(current=nil)
    sprintf("%02d:%02d:%02d", @hour, @minute, @second)
  end
end
```

As explained [earlier](#), an implementation of a Slice class must include the mixin module but is not required to derive from the generated class.

Ruby allows an existing class to be reopened in order to augment or replace its functionality. This feature provides another way for us to implement a Slice class: reopen the generated class and define the necessary methods:

Ruby

```
class TimeOfDay
  def format(current=nil)
    sprintf("%02d:%02d:%02d", @hour, @minute, @second)
  end
end
```

As an added benefit, this strategy eliminates the need to define a class factory. The next section describes this subject in more detail.

A Slice class such as `TimeOfDay` that declares or inherits an operation is inherently abstract. Ruby does not support the notion of abstract classes or abstract methods, therefore the mapping merely summarizes the required method signatures in a comment for your convenience.

You may notice that the mapping for an operation adds an optional trailing parameter named `current`. For now, you can ignore this parameter and pretend it does not exist.

Receiving Objects in Ruby

We have discussed the ways you can implement a Slice class, but we also need to examine the semantics of receiving an object as the return value or as an out-parameter from an operation invocation. Consider the following simple interface:

Slice

```
interface Time {
  TimeOfDay get();
};
```

When a client invokes the `get` operation, the Ice run time must instantiate and return an instance of the `TimeOfDay` class. Unless we tell it otherwise, the Ice run time in Ruby does exactly that: it instantiates the generated class `TimeOfDay`. Although `TimeOfDay` is logically an abstract class because its Slice equivalent defined an operation, Ruby has no notion of abstract classes and therefore it is legal to create an instance of this class. Furthermore, there are situations in which this is exactly the behavior you want:

- when you have reopened the generated class to define its operations, or
- when your program uses only the data members of an object and does not invoke any of its operations.

On the other hand, if you have defined a Ruby class that implements the Slice class, you need the Ice run time to return an instance of your class and not an instance of the generated class. The Ice run time cannot magically know about your implementation class, therefore you must inform the Ice run time by installing a class factory.

Class Factories in Ruby

The Ice run time invokes a class factory when it needs to instantiate an object of a particular type. If no factory is found, the Ice run time instantiates the generated class as described [above](#). To install a factory, we use operations provided by the `Ice::Communicator` interface :

Slice

```

module Ice {
  local interface ObjectFactory {
    Object create(string type);
    void destroy();
  };

  local interface Communicator {
    void addObjectFactory(ObjectFactory factory,
string id);
    ObjectFactory findObjectFactory(string id);
    // ...
  };
};

```

To supply the Ice run time with a factory for our `TimeOfDayI` class, we must create an object that supports the `Ice::ObjectFactory` interface:

Ruby

```

class ObjectFactory
  def create(type)
    fail unless type == M::TimeOfDay::ice_staticId()
    TimeOfDayI.new
  end

  def destroy
    # Nothing to do
  end
end

```

The object factory's `create` method is called by the Ice run time when it needs to instantiate a `TimeOfDay` class. The factory's `destroy` method is called by the Ice run time when its communicator is destroyed.

The `create` method is passed the **type ID** of the class to instantiate. For our `TimeOfDay` class, the type ID is `"::M::TimeOfDay"`. Our implementation of `create` checks the type ID: if it matches, the method instantiates and returns a `TimeOfDayI` object. For other type IDs, the method fails because it does not know how to instantiate other types of objects.

Note that we used the `ice_staticId` method to obtain the type ID rather than embedding a literal string. Using a literal type ID string in

your code is discouraged because it can lead to errors that are only detected at run time. For example, if a Slice class or one of its enclosing modules is renamed and the literal string is not changed accordingly, a receiver will fail to unmarshal the object and the Ice run time will raise `NoObjectFactoryException`. By using `ice_staticId` instead, we avoid any risk of a misspelled or obsolete type ID, and we can discover at compile time if a Slice class or module has been renamed.

Given a factory implementation, such as our `ObjectFactory`, we must inform the Ice run time of the existence of the factory:

Ruby

```
ic = ... # Get Communicator...
ic.addObjectFactory(ObjectFactory.new, M::TimeOfDay::ice_staticId())
```

Now, whenever the Ice run time needs to instantiate a class with the type ID "`M::TimeOfDay`", it calls the `create` method of the registered `ObjectFactory` instance.

The `destroy` operation of the object factory is invoked by the Ice run time when the communicator is destroyed. This gives you a chance to clean up any resources that may be used by your factory. Do not call `destroy` on the factory while it is registered with the communicator — if you do, the Ice run time has no idea that this has happened and, depending on what your `destroy` implementation is doing, may cause undefined behavior when the Ice run time tries to next use the factory.

The run time guarantees that `destroy` will be the last call made on the factory, that is, `create` will not be called concurrently with `destroy`, and `create` will not be called once `destroy` has been called. However, calls to `create` can be made concurrently.

Note that you cannot register a factory for the same type ID twice: if you call `addObjectFactory` with a type ID for which a factory is registered, the Ice run time throws an `AlreadyRegisteredException`.

Finally, keep in mind that if a class has only data members, but no operations, you need not create and register an object factory to transmit instances of such a class.

Code Generation in Ruby

The Ruby mapping supports two forms of code generation: dynamic and static.

On this page:

- [Dynamic Code Generation in Ruby](#)
 - [Ice::loadSlice Options in Ruby](#)
 - [Locating Slice Files in Ruby](#)
 - [Loading Multiple Slice Files in Ruby](#)
 - [Limitations of Dynamic Code Generation in Ruby](#)
- [Static Code Generation in Ruby](#)
 - [Compiler Output in Ruby](#)
 - [Include Files in Ruby](#)
- [Static Versus Dynamic Code Generation in Ruby](#)
 - [Application Considerations for Code Generation in Ruby](#)
 - [Mixing Static and Dynamic Generation in Ruby](#)
- [slice2rb Command-Line Options](#)

Dynamic Code Generation in Ruby

Using dynamic code generation, Slice files are "loaded" at run time and dynamically translated into Ruby code, which is immediately compiled and available for use by the application. This is accomplished using the `Ice::loadSlice` method, as shown in the following example:

```

Ruby

```
Ice::loadSlice("Color.ice")
puts "My favorite color is #{M::Color.blue.to_s}"
```

```

For this example, we assume that `Color.ice` contains the following definitions:

```

Slice

```
module M {
 enum Color { red, green, blue };
};
```

```

Ice::loadSlice Options in Ruby

The `Ice::loadSlice` method behaves like a Slice compiler in that it accepts command-line arguments for specifying preprocessor options and controlling code generation. The arguments must include at least one Slice file.

The function has the following Ruby definition:

```

Ruby

```
def loadSlice(cmd, args=[])
```

```

The command-line arguments can be specified entirely in the first argument, `cmd`, which must be a string. The optional second argument can be used to pass additional command-line arguments as a list; this is useful when the caller already has the arguments in list form. The

function always returns `nil`.

For example, the following calls to `Ice::loadSlice` are functionally equivalent:

Ruby

```
Ice::loadSlice("-I/opt/IceRuby/slice Color.ice")
Ice::loadSlice("-I/opt/IceRuby/slice", ["Color.ice"])
Ice::loadSlice("", ["-I/opt/IceRuby/slice", "Color.ice"])
```

In addition to the [standard compiler options](#), `Ice::loadSlice` also supports the following command-line options:

- `--all`
Generate code for all Slice definitions, including those from included files.
- `--checksum`
Generate [checksums](#) for Slice definitions.

Locating Slice Files in Ruby

If your Slice files depend on Ice types, you can avoid hard-coding the path name of your Ice installation directory by calling the `Ice::getSliceDir` function:

Ruby

```
Ice::loadSlice("-I" + Ice::getSliceDir() + " Color.ice")
```

This function attempts to locate the `slice` subdirectory of your Ice installation using an algorithm that succeeds for the following scenarios:

- Installation of a binary Ice archive
- Installation of an Ice source distribution using `make install`
- Installation via a Windows installer
- RPM installation on Linux
- Execution inside a compiled Ice source distribution

If the `slice` subdirectory can be found, `getSliceDir` returns its absolute path name, otherwise the function returns `nil`.

Loading Multiple Slice Files in Ruby

You can specify as many Slice files as necessary in a single invocation of `Ice::loadSlice`, as shown below:

Ruby

```
Ice::loadSlice("Syscall.ice Process.ice")
```

Alternatively, you can call `Ice::loadSlice` several times:

Ruby

```
Ice::loadSlice("Syscall.ice")
Ice::loadSlice("Process.ice")
```

If a Slice file includes another file, the default behavior of `Ice::loadSlice` generates Ruby code only for the named file. For example, suppose `Syscall.ice` includes `Process.ice` as follows:

Slice

```
// Syscall.ice
#include <Process.ice>
...
```

If you call `Ice::loadSlice("-I. Syscall.ice")`, Ruby code is not generated for the Slice definitions in `Process.ice` or for any definitions that may be included by `Process.ice`. If you also need code to be generated for included files, one solution is to load them individually in subsequent calls to `Ice::loadSlice`. However, it is much simpler, not to mention more efficient, to use the `--all` option instead:

Ruby

```
Ice::loadSlice("--all -I. Syscall.ice")
```

When you specify `--all`, `Ice::loadSlice` generates Ruby code for all Slice definitions included directly or indirectly from the named Slice files.

There is no harm in loading a Slice file multiple times, aside from the additional overhead associated with code generation. For example, this situation could arise when you need to load multiple top-level Slice files that happen to include a common subset of nested files. Suppose that we need to load both `Syscall.ice` and `Kernel.ice`, both of which include `Process.ice`. The simplest way to load both files is with a single call to `Ice::loadSlice`:

Ruby

```
Ice::loadSlice("--all -I. Syscall.ice Kernel.ice")
```

Although this invocation causes the Ice extension to generate code twice for `Process.ice`, the generated code is structured so that the interpreter ignores duplicate definitions. We could have avoided generating unnecessary code with the following sequence of steps:

Ruby

```
Ice::loadSlice("--all -I. Syscall.ice")
Ice::loadSlice("-I. Kernel.ice")
```

In more complex cases, however, it can be difficult or impossible to completely avoid this situation, and the overhead of code generation is

usually not significant enough to justify such an effort.

Limitations of Dynamic Code Generation in Ruby

The `Ice::loadSlice` method must be called outside of any module scope. For example, the following code is incorrect:

Ruby

```
# WRONG
module M
  Ice::loadSlice("--all -I. Syscall.ice Kernel.ice")
  ...
end
```

Static Code Generation in Ruby

You should be familiar with static code generation if you have used other Slice language mappings, such as C++ or Java. Using static code generation, the Slice compiler `slice2rb` generates Ruby code from your Slice definitions.

Compiler Output in Ruby

For each Slice file `x.ice`, `slice2rb` generates Ruby code into a file named `x.rb` in the output directory. The default output directory is the current working directory, but a different directory can be specified using the `--output-dir` option.

Include Files in Ruby

It is important to understand how `slice2rb` handles include files. In the absence of the `--all` option, the compiler does not generate Ruby code for Slice definitions in included files. Rather, the compiler translates Slice `#include` statements into Ruby `require` statements in the following manner:

1. Determine the full pathname of the included file.
2. Create the shortest possible relative pathname for the included file by iterating over each of the include directories (specified using the `-I` option) and removing the leading directory from the included file if possible.
For example, if the full pathname of an included file is `/opt/App/slice/OS/Process.ice`, and we specified the options `-I/opt/App` and `-I/opt/App/slice`, then the shortest relative pathname is `OS/Process.ice` after removing `/opt/App/slice`.
3. Replace the `.ice` extension with `.rb`. Continuing our example from the previous step, the translated `require` statement becomes

```
require "OS/Process.rb"
```

As a result, you can use `-I` options to tailor the `require` statements generated by the compiler in order to avoid absolute pathnames and match the organizational structure of your application's source files.

Static Versus Dynamic Code Generation in Ruby

There are several issues to consider when evaluating your requirements for code generation.

Application Considerations for Code Generation in Ruby

The requirements of your application generally dictate whether you should use dynamic or static code generation. Dynamic code generation is convenient for a number of reasons:

- It avoids the intermediate compilation step required by static code generation.
- It makes the application more compact because the application requires only the Slice files, not the additional files produced by

- static code generation.
- It reduces complexity, which is especially helpful during testing, or when writing short or transient programs.

Static code generation, on the other hand, is appropriate in many situations:

- when an application uses a large number of Slice definitions and the startup delay must be minimized
- when it is not feasible to deploy Slice files with the application
- when a number of applications share the same Slice files
- when Ruby code is required in order to utilize third-party Ruby tools.

Mixing Static and Dynamic Generation in Ruby

You can safely use a combination of static and dynamic translation in an application. For it to work properly, you must correctly manage the include paths for Slice translation and the Ruby interpreter so that the statically-generated code can be imported properly by `require`.

For example, suppose you want to dynamically load the following Slice definitions:

Slice

```
#include <Glacier2/Session.ice>

module MyApp {
  interface MySession extends Glacier2::Session {
    // ...
  };
};
```

Whether the included file `Glacier2/Session.ice` is loaded dynamically or statically is determined by the presence of the `--all` option:

Ruby

```
sliceDir = "-I#{ENV['ICE_HOME']}/slice"

# Load Glacier2/Session.ice dynamically:
Ice::loadSlice(sliceDir + " --all MySession.ice")

# Load Glacier2/Session.ice statically:
Ice::loadSlice(sliceDir + " MySession.ice")
```

In this example, the first invocation of `loadSlice` uses the `--all` option so that code is generated dynamically for all included files. The second invocation omits `--all`, therefore the Ruby interpreter executes the equivalent of the following statement:

```
require "Glacier2/Session.rb"
```

As a result, before we can call `loadSlice` we must first ensure that the interpreter can locate the statically-generated file `Glacier2/Session.rb`. We can do this in a number of ways, including:

- adding the parent directory (e.g., `/opt/IceRuby/ruby`) to the `RUBYLIB` environment variable
- specifying the `-I` option when starting the interpreter
- modifying the search path at run time, as shown below:

```
$: .unshift( "/opt/IceRuby/ruby" )
```

`slice2rb` Command-Line Options

The Slice-to-Ruby compiler, `slice2rb`, offers the following command-line options in addition to the [standard options](#):

- `--all`
Generate code for all Slice definitions, including those from included files.
- `--checksum`
Generate [checksums](#) for Slice definitions.

The main Program in Ruby

On this page:

- [Initializing the Ice Run Time in Ruby](#)
- [The Ice::Application Class in Ruby](#)
 - [Catching Signals in Ruby](#)
 - [Ice::Application and Properties in Ruby](#)
 - [Limitations of Ice::Application in Ruby](#)

Initializing the Ice Run Time in Ruby

The main entry point to the Ice run time is represented by the local interface `Ice::Communicator`. You must initialize the Ice run time by calling `Ice::initialize` before you can do anything else in your program.

`Ice::initialize` returns a reference to an instance of `Ice::Communicator`:

Ruby

```

require 'Ice'

status = 0
ic = nil
begin
  ic = Ice::initialize(ARGV)
  # ...
rescue => ex
  puts ex
  status = 1
end

# ...

```

`Ice::initialize` accepts the argument list that is passed to the program by the operating system. The function scans the argument list for any [command-line options](#) that are relevant to the Ice run time; any such options are removed from the argument list so, when `Ice::initialize` returns, the only options and arguments remaining are those that concern your application. If anything goes wrong during initialization, `initialize` throws an exception.

Before leaving your program, you *must* call `Communicator.destroy`. The `destroy` operation is responsible for finalizing the Ice run time. In particular, `destroy` ensures that any outstanding threads are joined with and reclaims a number of operating system resources, such as file descriptors and memory. Never allow your program to terminate without calling `destroy` first; doing so has undefined behavior.

The general shape of our program is therefore as follows:

Ruby

```

require 'Ice'

status = 0
ic = nil
begin
  ic = Ice::initialize(ARGV)
  # ...
rescue => ex
  puts ex
  status = 1
end

if ic
  begin
    ic.destroy()
  rescue => ex
    puts ex
    status = 1
  end
end

exit(status)

```

Note that the code places the call to `Ice::initialize` into a `begin` block and takes care to return the correct exit status to the operating system. Also note that an attempt to destroy the communicator is made only if the initialization succeeded.

The `Ice::Application` Class in Ruby

The preceding program structure is so common that `Ice` offers a class, `Ice::Application`, that encapsulates all the correct initialization and finalization activities. The synopsis of the class is as follows (with some detail omitted for now):

Ruby

```

module Ice
  class Application
    def main(args, configFile=nil, initData=nil)

    def run(args)

    def Application.appName()

    def Application.communicator()
  end
end
end

```

The intent of this class is that you specialize `Ice::Application` and implement the abstract `run` method in your derived class. Whatever code you would normally place in your main program goes into `run` instead. Using `Ice::Application`, our program looks as follows:

Ruby

```

require 'Ice'

class Client < Ice::Application
  def run(args)
    # Client code here...
    return 0
  end
end

app = Client.new()
status = app.main(ARGV)
exit(status)

```

If you prefer, you can also reopen `Ice::Application` and define `run` directly:

Ruby

```
require 'Ice'

class Ice::Application
  def run(args)
    # Client code here...
    return 0
  end
end

app = Ice::Application.new()
status = app.main(ARGV)
exit(status)
```

You may also call `main` with an optional file name or an `InitializationData` structure. If you pass a `configuration file name` to `main`, the settings in this file are overridden by settings in a file identified by the `ICE_CONFIG` environment variable (if defined). Property settings supplied on the `command line` take precedence over all other settings.

The `Application.main` method does the following:

1. It installs an exception handler. If your code fails to handle an exception, `Application.main` prints the exception information before returning with a non-zero return value.
2. It initializes (by calling `Ice::initialize`) and finalizes (by calling `Communicator.destroy`) a communicator. You can get access to the communicator for your program by calling the static `communicator` accessor.
3. It scans the argument list for options that are relevant to the Ice run time and removes any such options. The argument list that is passed to your `run` method therefore is free of Ice-related options and only contains options and arguments that are specific to your application.
4. It provides the name of your application via the static `appName` method. The return value from this call is the first element of the argument vector passed to `Application.main`, so you can get at this name from anywhere in your code by calling `Ice::Application::appName` (which is often necessary for error messages).
5. It installs a signal handler that properly shuts down the communicator.

Using `Ice::Application` ensures that your program properly finalizes the Ice run time, whether your program terminates normally or in response to an exception or signal. We recommend that all your programs use this class; doing so makes your life easier. In addition `Ice::Application` also provides features for signal handling and configuration that you do not have to implement yourself when you use this class.

Catching Signals in Ruby

A program typically needs to perform some cleanup work before terminating, such as flushing database buffers or closing network connections. This is particularly important on receipt of a signal or keyboard interrupt to prevent possible corruption of database files or other persistent data.

To make it easier to deal with signals, `Ice::Application` encapsulates Ruby's signal handling capabilities, allowing you to cleanly shut down on receipt of a signal:

Ruby

```

class Application
  def Application.destroyOnInterrupt()

  def Application.ignoreInterrupt()

  def Application.callbackOnInterrupt()

  def Application.holdInterrupt()

  def Application.releaseInterrupt()

  def Application.interrupted()

  def interruptCallback(sig):
    # Default implementation does nothing.
  end
  # ...
end

```

The methods behave as follows:

- `destroyOnInterrupt`
This method installs a signal handler that destroys the communicator if it is interrupted. This is the default behavior.
- `ignoreInterrupt`
This method causes signals to be ignored.
- `callbackOnInterrupt`
This function configures `Ice::Application` to invoke `interruptCallback` when a signal occurs, thereby giving the subclass responsibility for handling the signal.
- `holdInterrupt`
This method temporarily blocks signal delivery.
- `releaseInterrupt`
This method restores signal delivery to the previous disposition. Any signal that arrives after `holdInterrupt` was called is delivered when you call `releaseInterrupt`.
- `interrupted`
This method returns `True` if a signal caused the communicator to shut down, `False` otherwise. This allows us to distinguish intentional shutdown from a forced shutdown that was caused by a signal. This is useful, for example, for logging purposes.
- `interruptCallback`
A subclass implements this function to respond to signals. The function may be called concurrently with any other thread and must not raise exceptions.

By default, `Ice::Application` behaves as if `destroyOnInterrupt` was invoked, therefore our program requires no change to ensure that the program terminates cleanly on receipt of a signal. (You can disable the signal-handling functionality of `Ice::Application` by passing the constant `NoSignalHandling` to the constructor. In that case, signals retain their default behavior, that is, terminate the process.) However, we add a diagnostic to report the occurrence of a signal, so our program now looks like:

Ruby

```
require 'Ice'

class MyApplication < Ice::Application
  def run(args)
    # Client code here...

    if Ice::Application::interrupted()
      print Ice::Application::appName() + ": terminating"
    end

    return 0
  end
end

app = MyApplication.new()
status = app.main(ARGV)
exit(status)
```

Ice::Application and Properties in Ruby

Apart from the functionality shown in this section, `Ice::Application` also takes care of initializing the Ice run time with property values. [Properties](#) allow you to configure the run time in various ways. For example, you can use properties to control things such as the thread pool size or the trace level for diagnostic output. The `main` method of `Ice::Application` accepts an optional second parameter allowing you to specify the name of a configuration file that will be processed during initialization.

Limitations of Ice::Application in Ruby

`Ice::Application` is a singleton class that creates a single communicator. If you are using multiple communicators, you cannot use `Ice::Application`. Instead, you must structure your code as we saw in [Hello World Application](#) (taking care to always destroy the communicator).

Using Slice Checksums in Ruby

The Slice compilers can optionally generate [checksums](#) of Slice definitions. For `slice2rb`, the `--checksum` option causes the compiler to generate code that adds checksums to the hash collection `Ice::SliceChecksums`. The checksums are installed automatically when the Ruby code is first parsed; no action is required by the application.

In order to verify a server's checksums, a client could simply compare the two hash objects using a comparison operator. However, this is not feasible if it is possible that the server might return a superset of the client's checksums. A more general solution is to iterate over the local checksums as demonstrated below:

Ruby

```
serverChecksums = ...
for i in Ice::SliceChecksums.keys
  if not serverChecksums.has_key?(i)
    # No match found for type id!
  elif Ice::SliceChecksums[i] != serverChecksums[i]
    # Checksum mismatch!
  end
end
end
```

In this example, the client first verifies that the server's dictionary contains an entry for each Slice type ID, and then it proceeds to compare the checksums.

- [Slice Checksums](#)

Example of a File System Client in Ruby

This page presents a very simple client to access a server that implements the file system we developed in [Slice for a Simple File System](#). The Ruby code shown here hardly differs from the code you would write for an ordinary Ruby program. This is one of the biggest advantages of using Ice: accessing a remote object is as easy as accessing an ordinary, local Ruby object. This allows you to put your effort where you should, namely, into developing your application logic instead of having to struggle with arcane networking APIs.

We now have seen enough of the client-side Ruby mapping to develop a complete client to access our remote file system. For reference, here is the Slice definition once more:

```

Slice

module Filesystem {
  interface Node {
    idempotent string name();
  };

  exception GenericError {
    string reason;
  };

  sequence<string> Lines;

  interface File extends Node {
    idempotent Lines read();
    idempotent void write(Lines text) throws GenericError;
  };

  sequence<Node*> NodeSeq;

  interface Directory extends Node {
    idempotent NodeSeq list();
  };
};
```

To exercise the file system, the client does a recursive listing of the file system, starting at the root directory. For each node in the file system, the client shows the name of the node and whether that node is a file or directory. If the node is a file, the client retrieves the contents of the file and prints them.

The body of the client code looks as follows:

```

Ruby

require 'Filesystem.rb'

# Recursively print the contents of directory "dir"
# in tree fashion. For files, show the contents of
# each file. The "depth" parameter is the current
# nesting level (for indentation).

def listRecursive(dir, depth)
```

```

indent = ''
depth = depth + 1
for i in (0...depth)
  indent += "\t"
end

contents = dir.list()

for node in contents
  subdir = Filesystem::DirectoryPrx::checkedCast(node)
  file = Filesystem::FilePrx::uncheckedCast(node)
  print indent + node.name() + " "
  if subdir
    puts "(directory):"
    listRecursive(subdir, depth)
  else
    puts "(file):"
    text = file.read()
    for line in text
      puts indent + "\t" + line
    end
  end
end
end

status = 0
ic = nil
begin
  # Create a communicator
  #
  ic = Ice::initialize(ARGV)

  # Create a proxy for the root directory
  #
  obj = ic.stringToProxy("RootDir:default -p 10000")

  # Down-cast the proxy to a Directory proxy
  #
  rootDir = Filesystem::DirectoryPrx::checkedCast(obj)

  # Recursively list the contents of the root directory
  #
  puts "Contents of root directory:"
  listRecursive(rootDir, 0)
rescue => ex
  puts ex
  print ex.backtrace.join("\n")
  status = 1
end

```

```
if ic
  # Clean up
  #
  begin
    ic.destroy()
  rescue => ex
    puts ex
    print ex.backtrace.join("\n")
    status = 1
  end
end
```

```
exit(status)
```

The program first defines the `listRecursive` function, which is a helper function to print the contents of the file system, and the main program follows. Let us look at the main program first:

1. The structure of the code follows what we saw in [Hello World Application](#). After initializing the run time, the client creates a proxy to the root directory of the file system. For this example, we assume that the server runs on the local host and listens using the default protocol (TCP/IP) at port 10000. The object identity of the root directory is known to be `RootDir`.
2. The client down-casts the proxy to `DirectoryPrx` and passes that proxy to `listRecursive`, which prints the contents of the file system.

Most of the work happens in `listRecursive`. The function is passed a proxy to a directory to list, and an indent level. (The indent level increments with each recursive call and allows the code to print the name of each node at an indent level that corresponds to the depth of the tree at that node.) `listRecursive` calls the `list` operation on the directory and iterates over the returned sequence of nodes:

1. The code does a `checkedCast` to narrow the `Node` proxy to a `Directory` proxy, as well as an `uncheckedCast` to narrow the `Node` proxy to a `File` proxy. Exactly one of those casts will succeed, so there is no need to call `checkedCast` twice: if the `Node` is-a `Directory`, the code uses the `DirectoryPrx` returned by the `checkedCast`; if the `checkedCast` fails, we *know* that the `Node` is-a `File` and, therefore, an `uncheckedCast` is sufficient to get a `FilePrx`.
In general, if you know that a down-cast to a specific type will succeed, it is preferable to use an `uncheckedCast` instead of a `checkedCast` because an `uncheckedCast` does not incur any network traffic.
2. The code prints the name of the file or directory and then, depending on which cast succeeded, prints "(directory)" or "(file)" following the name.
3. The code checks the type of the node:
 - If it is a directory, the code recurses, incrementing the indent level.
 - If it is a file, the code calls the `read` operation on the file to retrieve the file contents and then iterates over the returned sequence of lines, printing each line.

Assume that we have a small file system consisting of a two files and a a directory as follows:

A small file system.

The output produced by the client for this file system is:

```
Contents of root directory:
```

```
  README (file):
```

```
    This file system contains a collection of poetry.
```

```
  Coleridge (directory):
```

```
    Kubla_Khan (file):
```

```
      In Xanadu did Kubla Khan
```

```
      A stately pleasure-dome decree:
```

```
      Where Alph, the sacred river, ran
```

```
      Through caverns measureless to man
```

```
      Down to a sunless sea.
```

Note that, so far, our client is not very sophisticated:

- The protocol and address information are hard-wired into the code.
- The client makes more remote procedure calls than strictly necessary; with minor redesign of the Slice definitions, many of these calls can be avoided.

We will see how to address these shortcomings in our discussions of [IceGrid](#) and [object life cycle](#).

Properties and Configuration

Ice uses a configuration mechanism that allows you to control many aspects of the behavior of your Ice applications at run time, such as the maximum message size, the number of threads, or whether to produce network trace messages. The configuration mechanism is not only useful for configuring Ice, but also for configuring your own applications. The configuration mechanism is simple to use with a minimal API, yet flexible enough to cope with the needs of most applications.

- [Alternate Property Stores](#)
- [Command-Line Parsing and Initialization](#)
- [The Properties Interface](#)
- [Reading Properties](#)
- [Setting Properties](#)
- [Parsing Properties](#)

Properties Overview

Ice and its various subsystems are configured by properties. A property is a name-value pair, for example:

```
Ice.UDP.SndSize=65535
```

In this example, the *property name* is `Ice.UDP.SndSize`, and the *property value* is `65535`.

You can find a complete list of the properties used to configure Ice in the [property reference](#).

Note that Ice reads properties that control the Ice run time and its services (that is, properties that start with one of the reserved prefixes, such as `Ice`, `Glacier2`, etc.) only once on start-up, when you create a communicator. This means that you must set Ice-related properties to their correct values *before* you create a communicator. If you change the value of an Ice-related property after that point, it is likely that the new setting will simply be ignored.

On this page:

- [Property Categories](#)
- [Reserved Prefixes for Properties](#)
- [Property Name Syntax](#)
- [Property Value Syntax](#)
- [Unused Properties](#)

Property Categories

By convention, Ice properties use the following naming scheme:

```
<application>.<category>[.<sub-category>]
```

Note that the sub-category is optional and not used by all Ice properties.

This two- or three-part naming scheme is by convention only — if you use properties to configure your own applications, you can use property names with any number of categories.

Reserved Prefixes for Properties

Ice reserves properties with the following prefixes:

- `Ice`
- `IceBox`
- `IceGrid`
- `IcePatch2`
- `IceSSL`
- `IceStorm`
- `Freeze`
- `Glacier2`

You cannot use a property beginning with one of these prefixes to configure your own application.

Property Name Syntax

A property name consists of any number of characters. For example, the following are valid property names:

```

foo
Foo
foo.bar
foo bar    White space is allowed
foo=bar    Special characters are allowed
.
```

Note that there is no special significance to a period in a property name. (Periods are used to make property names more readable and are not treated specially by the property parser.)

Property names cannot contain leading or trailing white space. (If you create a property name with leading or trailing white space, that white space is silently stripped.)

Property Value Syntax

A property value consists of any number of characters. The following are examples of property values:

```

65535
yes
This is a = property value.
../../config
```

Unused Properties

During the destruction of a communicator, the Ice run time can optionally emit a warning for properties that were set but never read. To enable this warning, set `Ice.Warn.UnusedProperties` to a non-zero value. This property is useful for detecting mis-spelled properties, such as `Filesystem.MaxFileSize`. By default, the warning is disabled.

See Also

- [Property Reference](#)

Configuration File Syntax

This page describes the syntax of an Ice configuration file.

On this page:

- [Configuration File Format](#)
- [Special Characters in Configuration Files](#)

Configuration File Format

A configuration file contains any number of name-value pairs, with each pair on a separate line. Empty lines and lines consisting entirely of white space characters are ignored. The # character introduces a comment that extends to the end of the current line.

Configuration files can be ASCII text files or use the UTF-8 character encoding with a byte order marker (BOM) at the beginning of the file.

Here is a simple configuration file:

```
# Example config file for Ice

Ice.MessageSizeMax = 2048      # Largest message size is 2MB
Ice.Trace.Network=3           # Highest level of tracing for network
Ice.Trace.Protocol=          # Disable protocol tracing
```

White space within property keys and values is preserved, whether escaped with a backslash or not escaped.

Leading and trailing white space is always ignored for property *names* (whether the white space is escaped or not), for example:

```
# Key white space example

Prop1      = 1                # Key is "Prop1"
Prop2      = 2                # Key is "Prop2"
\ Prop3 \  = 3                # Key is "Prop3"
My Prop1   = 1                # Key is "My Prop1"
My\ Prop2  = 2                # Key is "My Prop2"
```

For property values, you can preserve leading and trailing white space by escaping the white space with a backslash, for example:

```
# Value white space example

My.Prop1 = a property        # Value is "a property"
My.Prop2 =   a   property    # Value is "a   property"
My.Prop3 = \ \ a   property\ \ # Value is " a   property  "
My.Prop4 = \ \ a \ \ property\ \ # Value is " a   property  "
My.Prop5 = a \\ property     # Value is "a \ property"
```

This example shows that leading and trailing white space for property values is ignored unless escaped with a backslash whereas, white

space that is surrounded by non-white space characters is preserved exactly, whether it is escaped or not. As usual, you can insert a literal backslash into a property value by using a double backslash.

If you set the same property more than once, the last setting prevails and overrides any previous setting. Note that assigning nothing to a property clears that property (that is, sets it to the empty string).

Ice treats properties that contain the empty string (such as `Ice.Trace.Protocol` in the preceding example) like a property that is not set at all, and we recommend that your Ice-based applications do the same. With `getProperty`, `getPropertyAsInt`, `getPropertyAsIntWithDefault`, `getPropertyAsList` and `getPropertyAsListWithDefault`, you cannot distinguish between a property that is not set and a property set to the empty string; however, `getPropertyWithDefault` allows you to make this distinction, for example:

```
// C++

// returns 3 if not set or set to the empty string
int traceProtocol =
properties->getPropertyAsIntWithDefault("Ice.Trace.Protocol", 3);

// returns "3" if not set but "" if set to the empty string
string traceProtocolString =
properties->getPropertyWithDefault("Ice.Trace.Protocol", "3");
```

Property values can include characters from non-English alphabets. The Ice run time expects the configuration file to use UTF-8 encoding for such characters. (With C++, you can specify a [string converter](#) when you read the file.)

Special Characters in Configuration Files

The characters = and # have special meaning in a configuration file:

- = marks the end of the property name and the beginning of the property value
- # starts a comment that extends to the end of the line

These characters must be escaped when they appear in a property name. Consider the following examples:

```
foo\=bar=1      # Name is "foo=bar", value is "1"
foo\#bar  = 2   # Name is "foo#bar", value is "2"
foo bar  =3     # Name is "foo bar", value is "3"
```

In a property value, a # character must be escaped to prevent it from starting a comment, but an = character does not require an escape. Consider these examples:

```
A=1           # Name is "A", value is "1"
B= 2 3 4      # Name is "B", value is "2 3 4"
C=5=\#6 # 7   # Name is "C", value is "5=#6"
```

Note that, two successive backslashes in a property value become a single backslash. To get two consecutive backslashes, you must escape each one with another backslash:

```
AServer=\\\\server\\dir    # Value is "\\server\\dir"  
BServer=\\server\\dir    # Value is "\\server\\dir"
```

The preceding example also illustrates that, if a backslash is not followed by a backslash, #, or =, the backslash and the character following it are both preserved.

See Also

- [Using Configuration Files](#)
- [Reading Properties](#)
- [Setting Properties on the Command Line](#)
- [Communicator Initialization](#)
- [C++ Strings and Character Encoding](#)

Setting Properties on the Command Line

In addition to setting properties in a [configuration file](#), you can also set properties on the command line, for example:

```
server --Ice.UDP.SndSize=65535 --IceSSL.Trace.Security=2
```

Any command line option that begins with `--` and is followed by one of the [reserved prefixes](#) is read and converted to a property setting when you create a communicator. Property settings on the command line override settings in a configuration file. If you set the same property more than once on the same command line, the last setting overrides any previous ones.

For convenience, any property not explicitly set to a value is set to the value `1`. For example,

```
server --Ice.Trace.Protocol
```

is equivalent to

```
server --Ice.Trace.Protocol=1
```

Note that this feature only applies to properties that are set on the command line, but not to properties that are set from a configuration file.

You can also clear a property from the command line as follows:

```
server --Ice.Trace.Protocol=
```

As for properties set from a configuration file, assigning nothing to a property clears that property.

See Also

- [Properties Overview](#)
- [Using Configuration Files](#)

Using Configuration Files

The ability to configure an application's properties externally provides a great deal of flexibility: you can use any combination of command-line options and configuration files to achieve the desired settings, all without having to modify your application. This page describes two ways of loading property settings from a file.

On this page:

- [Prerequisites for Using Configuration Files](#)
- [The ICE_CONFIG Environment Variable](#)
- [The Ice.Config Property](#)

Prerequisites for Using Configuration Files

The Ice run time automatically loads a configuration file during the creation of a *property set*, which is an instance of the `Ice::Properties` interface. Every communicator has its own property set from which it derives its configuration. If an application does not supply a property set when it calls `Ice::initialize` (or the equivalent in other language mappings), the Ice run time internally creates a *property set* for the new communicator.

Note however that Ice loads a configuration file automatically only when the application creates a property set using an argument vector. This occurs when the application passes an argument vector to create a property set explicitly, or when the application passes an argument vector to `Ice::initialize`.

Both of the mechanisms described below can also retrieve property settings from [additional sources](#).

The ICE_CONFIG Environment Variable

Ice automatically loads the contents of the configuration file named in the `ICE_CONFIG` environment variable (assuming the [prerequisites](#) are met). For example:

```
export ICE_CONFIG=/usr/local/filesystem/config
./server
```

This causes the server to read its property settings from the configuration file in `/usr/local/filesystem/config`.

If you use the `ICE_CONFIG` environment variable together with command-line options for other properties, the settings on the command line override the settings in the configuration file. For example:

```
export ICE_CONFIG=/usr/local/filesystem/config
./server --Ice.MessageSizeMax=4096
```

This sets the value of the `Ice.MessageSizeMax` property to 4096 regardless of any setting of this property in `/usr/local/filesystem/config`.

You can use multiple configuration files by specifying a list of configuration file names separated by commas. For example:

```
export ICE_CONFIG=/usr/local/filesystem/config,./config
./server
```

This causes property settings to be retrieved from `/usr/local/filesystem/config`, followed by any settings in the file `config` in the current directory; settings in `./config` override settings `/usr/local/filesystem/config`.

The Ice.Config Property

The `Ice.Config` property has special meaning to the Ice run time: it determines the path name of a configuration file from which to read property settings. For example:

```
./server --Ice.Config=/usr/local/filesystem/config
```

This causes property settings to be read from the configuration file in `/usr/local/filesystem/config`.

The `--Ice.Config` command-line option overrides any setting of the `ICE_CONFIG` environment variable, that is, if the `ICE_CONFIG` environment variable is set and you also use the `--Ice.Config` command-line option, the configuration file specified by the `ICE_CONFIG` environment variable is ignored.

If you use the `--Ice.Config` command-line option together with settings for other properties, the settings on the command line override the settings in the configuration file. For example:

```
./server --Ice.Config=/usr/local/filesystem/config --Ice.MessageSizeMax=4096
```

This sets the value of the `Ice.MessageSizeMax` property to 4096 regardless of any setting of this property in `/usr/local/filesystem/config`. The placement of the `--Ice.Config` option on the command line has no influence on this precedence. For example, the following command is equivalent to the preceding one:

```
./server --Ice.MessageSizeMax=4096 --Ice.Config=/usr/local/filesystem/config
```

Settings of the `Ice.Config` property inside a configuration file are ignored, that is, you can set `Ice.Config` only on the command line.

If you use the `--Ice.Config` option more than once, only the last setting of the option is used and the preceding ones are ignored. For example:

```
./server --Ice.Config=file1 --Ice.Config=file2
```

This is equivalent to using:

```
./server --Ice.Config=file2
```

You can use multiple configuration files by specifying a list of configuration file names separated by commas. For example:

```
./server --Ice.Config=/usr/local/filesystem/config,./config
```

This causes property settings to be retrieved from `/usr/local/filesystem/config`, followed by any settings in the file `config` in the current directory; settings in `./config` override settings `/usr/local/filesystem/config`.

Alternate Property Stores

In addition to regular files, Ice also supports storing property settings in the Windows registry and Java resources.

On this page:

- [Loading Properties from the Windows Registry](#)
- [Loading Properties from Java Resources](#)

Loading Properties from the Windows Registry

You can use the Windows registry to store property settings. Property settings must be stored with a key underneath `HKEY_LOCAL_MACHINE`. To inform the Ice run time of this key, you must set the `Ice.Config` property to the key. For example:

```
client --Ice.Config=HKLM\MyCompany\MyApp
```

The Ice run time examines the value of `Ice.Config`; if that value begins with `HKLM`, the remainder of the property is taken to be a key to a number of string values. For the preceding example, the Ice run time looks for the key `HKEY_LOCAL_MACHINE\MyCompany\MyApp`. The string values stored under this key are used to initialize the properties.

The name of each string value is the name of the property (such as `Ice.Trace.Network`). Note that the value must be a string (even if the property setting is numeric). For example, to set `Ice.Trace.Network` to 3, you must store the string "3" as the value, not a binary or `DWORD` value.

String values in the registry can be regular strings (`REG_SZ`) or expandable strings (`REG_EXPAND_SZ`). Expandable strings allow you to include symbolic references to environment variables (such as `%ICE_HOME%`).

Depending on whether you use 32-bit or 64-bit binaries, you must set the registry keys in the corresponding 32-bit or 64-bit registry. See <http://support.microsoft.com/kb/305097> for more information.

Loading Properties from Java Resources

The Ice run time for Java supports the ability to load a configuration file as a class loader resource, which is especially useful for deploying an Ice application in a self-contained JAR file. For example, suppose we define `ICE_CONFIG` as shown below:

```
export ICE_CONFIG=app_config
```

During the creation of a property set (which often occurs implicitly when initializing a new communicator), Ice asks the Java run time to search the application's class path for a file named `app_config`. This file might reside in the same JAR file as the application's class files, or in a different JAR file in the class path, or it might be a regular file located in one of the directories in the class path. If Java is unable to locate the configuration file in the class path, Ice attempts to open the file in the local file system.

The class path resource always takes precedence over a regular file. In other words, if a class path resource and a regular file are both present with the same path name, Ice always loads the class path resource in preference to the regular file.

The path name for a class path resource uses a relative Unix-like format such as `subdir/myfile`. Java searches for the resource relative to each JAR file or subdirectory in an application's class path.

Command-Line Parsing and Initialization

On this page:

- [Parsing Command Line Options](#)
- [The Ice.ProgramName Property](#)

Parsing Command Line Options

When you initialize the Ice run time by calling `Ice::initialize` (C++/Ruby), `Ice.Util.initialize` (Java/C#), `Ice.initialize` (Python), or `Ice_initialize` (PHP), you can pass an argument vector to the initialization call.

For C++, `Ice::initialize` accepts a C++ *reference* to `argc`:

```
C++
```

```
namespace Ice {
    CommunicatorPtr initialize(int& argc, char* argv[]);
}
```

`Ice::initialize` parses the argument vector and initializes its property settings accordingly. In addition, it removes any arguments from `argv` that are property settings. For example, assume we invoke a server as:

```
$ ./server --myoption --Ice.Config=config -x a --Ice.Trace.Network=3 -y
opt file
```

Initially, `argc` has the value 9, and `argv` has ten elements: the first nine elements contain the program name and the arguments, and the final element, `argv[argc]`, contains a null pointer (as required by the ISO C++ standard). When `Ice::initialize` returns, `argc` has the value 7 and `argv` contains the following elements:

```
./server
--myoption
-x
a
-y
opt
file
0           # Terminating null pointer
```

This means that you should initialize the Ice run time before you parse the command line for your application-specific arguments. That way, the Ice-related options are stripped from the argument vector for you so you do not need to explicitly skip them. If you use the `Ice::Application` helper class, the `run` member function is passed an argument vector with the Ice-related options already stripped. The same is true for the `runWithSession` member function called by the `Glacier2::Application` helper class.

For Java, `Ice.Util.initialize` is overloaded. The signatures are:

Java

```
package Ice;
public final class Util {

    public static Communicator
    initialize();

    public static Communicator
    initialize(String[] args);

    public static Communicator
    initialize(StringSeqHolder args);

    public static Communicator
    initialize(InitializationData id);

    public static Communicator
    initialize(String[] args, InitializationData id);

    public static Communicator
    initialize(StringSeqHolder args, InitializationData id);

    // ...
}
```

The versions that accept an argument vector of type `String[]` do not strip Ice-related options for you, so, if you use one of these methods, your code must ignore options that start with one of the [preserved prefixes](#). The versions that accept a `StringSeqHolder` behave like the C++ version and strip the Ice-related options from the passed argument vector.

In C#, the argument vector is passed by reference to the `initialize` method, allowing it to strip the Ice-related options:

C#

```

namespace Ice {

    public sealed class Util {

        public static Communicator
        initialize();

        public static Communicator
        initialize(ref string[] args);

        public static Communicator
        initialize(InitializationData id);

        public static Communicator
        initialize(ref string[] args, InitializationData id);

        // ...

    }
}

```

The Python, Ruby, and PHP implementations of `initialize` have the same semantics as C++ and .NET; they expect the argument vector to be passed as a list from which all Ice-related options are removed.

If you use the `Ice.Application` helper class, the `run` method is passed the cleaned-up argument vector. The `Ice.Application` class is described separately for each language mapping.

The `Ice.ProgramName` Property

For C++, Python, and Ruby, `initialize` sets the `Ice.ProgramName` property to the name of the current program (`argv[0]`). In C#, `initialize` sets `Ice.ProgramName` to the value of `System.AppDomain.CurrentDomain.FriendlyName`. Your application code can read this property and use it for activities such as logging diagnostic or trace messages.

Even though `Ice.ProgramName` is initialized for you, you can still override its value from a [configuration file](#) or by setting the property on the command line.

For Java, the program name is not supplied as part of the argument vector — if you want to use the `Ice.ProgramName` property in your application, you must set it before initializing a communicator.

- [Communicator Initialization](#)
- [Glacier2 Helper Classes](#)

The Properties Interface

You can use the same [configuration file](#) and [command-line](#) mechanisms to set application-specific properties. For example, we could introduce a property to control the maximum file size for our file system application:

```
# Configuration file for file system application

Filesystem.MaxFileSize=1024    # Max file size in kB
```

The Ice run time stores the `Filesystem.MaxFileSize` property like any other property and makes it accessible via the `Properties` interface.

To access property values from within your program, you need to acquire the communicator's properties by calling `getProperties`:

Slice

```
module Ice {

    local interface Properties; // Forward declaration

    local interface Communicator {

        Properties getProperties();

        // ...
    };
};
```

The `Properties` interface is shown below:

Slice

```

module Ice {
  local dictionary<string, string> PropertyDict;

  local interface Properties {

    string getProperty(string key);
    string getPropertyWithDefault(string key, string value);
    int getPropertyAsInt(string key);
    int getPropertyAsIntWithDefault(string key, int value);
    PropertyDict getPropertiesForPrefix(string prefix);

    void setProperty(string key, string value);

    StringSeq getCommandLineOptions();
    StringSeq parseCommandLineOptions(string prefix,
StringSeq options);
    StringSeq parseIceCommandLineOptions(StringSeq options);

    void load(string file);

    Properties clone();
  };
};

```

Most of the operations involve [reading properties](#), [setting properties](#), and [parsing properties](#).

The `Properties` interface also provides two utility operations that are useful if you need to work with multiple communicators that use different property sets:

- `clone`
This operation makes a copy of an existing property set. The copy contains exactly the same properties and values as the original.
- `load`
This operation accepts a path name to a configuration file and initializes the property set from that file. If the specified file cannot be read (for example, because it does not exist or the caller does not have read permission), the operation throws a `FileNotFoundException`. In Java, the given path name can refer to a [class loader resource](#) or a regular file.

- [Reading Properties](#)
- [Setting Properties](#)
- [Parsing Properties](#)
- [Alternate Property Stores](#)

Reading Properties

The `Properties` interface provides the following operations for reading property values:

- `string getProperty(string key)`
This operation returns the value of the specified property. If the property is not set, the operation returns the empty string.
- `string getPropertyWithDefault(string key, string value)`
This operation returns the value of the specified property. If the property is not set, the operation returns the supplied default value.
- `int getPropertyAsInt(string key)`
This operation returns the value of the specified property as an integer. If the property is not set or contains a string that does not parse as an integer, the operation returns zero.
- `int getPropertyAsIntWithDefault(string key, int value)`
This operation returns the value of the specified property as an integer. If the property is not set or contains a string that does not parse as an integer, the operation returns the supplied default value.
- `StringSeq getPropertyAsList(string key)`
This operation returns the value as a list of strings. The strings must be separated by whitespace or a comma. If a string contains whitespace or a comma, it must be enclosed using single or double quotes; quotes can be themselves escaped in a quoted string, for example O'Reilly can be written as O'Reilly, "O'Reilly" or "O\Reilly". If the property is not set or set to an empty value, the operation returns an empty list.
- `StringSeq getPropertyAsListWithDefault(string key, StringSeq value)`
This operation returns the value as a list of strings (see `getPropertyAsList` above). If the property is not set or set to an empty value, the operation returns the supplied default value.
- `PropertyDict getPropertiesForPrefix(string prefix)`
This operation returns all properties that begin with the specified prefix as a dictionary of type `PropertyDict`. This operation is useful if you want to extract the properties for a specific subsystem. For example, `getPropertiesForPrefix("Filesystem")` returns all properties that start with the prefix `Filesystem`, such as `Filesystem.MaxFileSize`. You can then use the usual dictionary lookup operations to extract the properties of interest from the returned dictionary.

With these operations, using application-specific properties now becomes the simple matter of initializing a communicator as usual, getting access to the communicator's properties, and examining the desired property value. For example:

```

C++

```

// ...

Ice::CommunicatorPtr ic;

// ...

ic = Ice::initialize(argc, argv);

// Get the maximum file size.
//
Ice::PropertiesPtr props = ic->getProperties();
Ice::Int maxSize
= props->getPropertyAsIntWithDefault("Filesystem.MaxFileSize", 1024);

// ...

```

```

Assuming that you have created a configuration file that sets the `Filesystem.MaxFileSize` property (and that you have set the `ICE_CONFIG` variable or the `--Ice.Config` option accordingly), your application will pick up the configured value of the property.

The technique shown above allows you to obtain application-specific properties from a *configuration file*. If you also want the ability to set application-specific properties on the command line, you will need to [parse command-line options](#) for your prefix. (Calling `initialize` to create a communicator only parses those command line options having a [reserved prefix](#).)

- [The Properties Interface](#)
- [Using Configuration Files](#)
- [Setting Properties](#)
- [Parsing Properties](#)

Setting Properties

The `setProperty` operation on the `Properties` interface sets a property to the specified value:

Slice
<pre> module Ice { local interface Properties { void setProperty(string key, string value); // ... }; }; </pre>

You can clear a property by setting it to the empty string.

For properties that control the Ice run time and its services (that is, properties that start with one of the [reserved prefixes](#)), this operation is useful only if you call it *before* you call `initialize`. This is because property values are usually read by the Ice run time only once, when you call `initialize`, so the Ice run time does not pay attention to a property value that is changed after you have initialized a communicator. Of course, this begs the question of how you can set a property value and have it also recognized by a communicator.

To permit you to set properties before initializing a communicator, the Ice run time provides an overloaded helper function called `createProperties` that creates a property set. In C++, the function is in the `Ice` namespace:

C++
<pre> namespace Ice { PropertiesPtr createProperties(const StringConverterPtr& = 0); PropertiesPtr createProperties(StringSeq&, const PropertiesPtr& = 0, const StringConverterPtr& = 0); PropertiesPtr createProperties(int&, char*[], const PropertiesPtr& = 0, const StringConverterPtr& = 0); } </pre>

The `StringConverter` parameter allows you to parse properties whose values contain non-ASCII characters and to correctly convert these characters into the native codeset. The converter that is passed to `createProperties` remains attached to the returned property set for the life time of the property set.

The function is overloaded to accept either an `argc/argv` pair or a `StringSeq`, to aid in [parsing properties](#).

In Java, the functions are static methods of the `Util` class inside the `Ice` package:

Java

```

package Ice;

public final class Util
{
    public static Properties
    createProperties();

    public static Properties
    createProperties(StringSeqHolder args);

    public static Properties
    createProperties(StringSeqHolder args, Properties defaults);

    public static Properties
    createProperties(String[] args);

    public static Properties
    createProperties(String[] args, Properties defaults);

    // ...
}

```

In C#, the `Util` class in the `Ice` namespace supplies equivalent methods:

C#

```

namespace Ice {
    public sealed class Util {
        public static Properties createProperties();
        public static Properties createProperties(ref string[] args);
        public static Properties
        createProperties(ref string[] args, Properties defaults);
    }
}

```

The Python and Ruby methods reside in the `Ice` module:

```

def createProperties(args=[], defaults=None)

```

In PHP, use the `Ice_createProperties` method:

PHP

```
function Ice_createProperties(args=array(), defaults=null)
```

As for `initialize`, `createProperties` strips Ice-related command-line options from the passed argument vector. (For Java, only the versions that accept a `StringSeqHolder` do this.)

The functions behave as follows:

- The parameter-less version of `createProperties` simply creates an empty property set. It does *not* check `ICE_CONFIG` for a configuration file to parse.
- The other overloads of `createProperties` accept an argument vector and a default property set. The returned property set contains all the property settings that are passed as the default, plus any property settings in the argument vector. If the argument vector sets a property that is also set in the passed default property set, the setting in the argument vector overrides the default. The overloads that accept an argument vector also look for the `--Ice.Config` option; if the argument vector specifies a configuration file, the configuration file is parsed. The order of precedence of property settings, from lowest to highest, is:
 - Property settings passed in the default parameter
 - Property settings set in the configuration file
 - Property settings in the argument vector.
 The overloads that accept an argument vector also look for the setting of the `ICE_CONFIG` environment variable and, if that variable specifies a configuration file, parse that file. (However, an explicit `--Ice.Config` option in the argument vector or the `defaults` parameter overrides any setting of the `ICE_CONFIG` environment variable.)

`createProperties` is useful if you want to ensure that a property is set to a particular value, regardless of any setting of that property in a configuration file or in the argument vector. Here is an example:

C++

```
// Get the initialized property set.
//
Ice::PropertiesPtr props = Ice::createProperties(argc, argv);

// Make sure that network and protocol tracing are off.
//
props->setProperty("Ice.Trace.Network", "0");
props->setProperty("Ice.Trace.Protocol", "0");

// Initialize a communicator with these properties.
//
Ice::InitializationData id;
id.properties = props;
Ice::CommunicatorPtr ic = Ice::initialize(id);

// ...
```

The equivalent Java code looks as follows:

Java

```
Ice.StringSeqHolder argsH = new Ice.StringSeqHolder(args);
Ice.Properties properties = Ice.Util.createProperties(argsH);
properties.setProperty("Ice.Warn.Connections", "0");
properties.setProperty("Ice.Trace.Protocol", "0");
Ice.InitializationData id = new Ice.InitializationData();
id.properties = properties;
communicator = Ice.Util.initialize(id);
```

We first convert the argument array to an initialized `StringSeqHolder`. This is necessary so `createProperties` can strip Ice-specific settings. In that way, we first obtain an initialized property set, then override the settings for the two tracing properties, and then set the properties in the `InitializationData` structure.

The equivalent Python code is shown next:

Python

```
props = Ice.createProperties(sys.argv)
props.setProperty("Ice.Trace.Network", "0")
props.setProperty("Ice.Trace.Protocol", "0")
id = Ice.InitializationData()
id.properties = props
ic = Ice.initialize(id)
```

This is the equivalent code in Ruby:

Ruby

```
props = Ice::createProperties(ARGV)
props.setProperty("Ice.Trace.Network", "0")
props.setProperty("Ice.Trace.Protocol", "0")
id = Ice::InitializationData.new
id.properties = props
ic = Ice::initialize(id)
```

Finally, we present the code in PHP:

PHP

```
$props = Ice_createProperties($args);  
$props->setProperty("Ice.Trace.Network", "0");  
$props->setProperty("Ice.Trace.Protocol", "0");  
$id = new Ice_InitializationData();  
$id->properties = $props;  
$ic = Ice_initialize($id);
```

Parsing Properties

The `Properties` interface provides several operations for converting properties to and from command-line options.

On this page:

- [Converting Properties to Command-Line Options](#)
- [Converting Command-Line Options to Properties](#)
- [Converting Reserved Command-Line Options to Properties](#)

Converting Properties to Command-Line Options

The `getCommandLineOptions` operation converts an initialized set of properties into a sequence of equivalent command-line options:

```

Slice
module Ice {
    local interface Properties {

        StringSeq getCommandLineOptions();

        // ...
    };
};

```

For example, if you have set the `Filesystem.MaxFileSize` property to 1024 and call `getCommandLineOptions`, the setting is returned as the string `--Filesystem.MaxFileSize=1024`. This operation is useful for diagnostic purposes, for example, to dump the setting of all properties to a [logging facility](#), or if you want to fork a new process with the same property settings as the current process.

Converting Command-Line Options to Properties

The `parseCommandLineOptions` operation examines the passed argument vector for command-line options that have the specified prefix:

```

Slice
module Ice {
    local interface Properties {

        StringSeq parseCommandLineOptions(string prefix, StringSeq
options);

        // ...
    };
};

```

All options having the form `--prefix.Key=Value` are converted to property settings (that is, they initialize the corresponding properties). The operation returns an argument vector containing the options that did not match the prefix.

The value for `prefix` has an implicit trailing period if one is not present. For example, when calling `parseCommandLineOptions` with a prefix value of "File", the option `--File.Owner=root` would match but the option `--Filesystem.MaxFileSize=1024` would not match.

The operation parses command-line options using the same [syntax rules](#) as for properties in a configuration file. However, the user's

command shell can cause differences in parsing behavior. Suppose we define the following property in a configuration file:

```
MyApp.Home=C:\Program Files\MyApp
```

The presence of whitespace in the property definition is not an issue in a configuration file but can be an issue on the command line, where the equivalent option is `--MyApp.Home=C:\Program Files\MyApp`. If the user is not careful, the program may receive this as two separate options: `--MyApp.Home=C:\Program` and `Files\MyApp`. In the end, it is the user's responsibility to ensure that the property's complete key and value are contained within a single command-line option.

Because `parseCommandLineOptions` expects a sequence of strings, but C++ programs are used to dealing with `argc` and `argv`, Ice provides two utility functions that convert an `argc/argv` vector into a sequence of strings and vice-versa:

```
C++
```

```
namespace Ice {

    StringSeq argsToStringSeq(int argc, char* argv[]);

    void stringSeqToArgs(const StringSeq& args,
        int& argc, char* argv[]);

}
```

You need to use `parseCommandLineOptions` (and the utility functions) if you want to permit application-specific properties to be set from the command line. For example, to allow the `--FileSystem.MaxFileSize` option to be used on the command line, we need to initialize our program as follows:

C++

```

int
main(int argc, char* argv[])
{
    // Create an empty property set.
    //
    Ice::PropertiesPtr props = Ice::createProperties();

    // Convert argc/argv to a string sequence.
    //
    Ice::StringSeq args = Ice::argsToStringSeq(argc, argv);

    // Strip out all options beginning with --Filesystem.
    //
    args = props->parseCommandLineOptions("Filesystem", args);

    // args now contains only those options that were not
    // stripped. Any options beginning with --Filesystem have
    // been converted to properties.

    // Convert remaining arguments back to argc/argv vector.
    //
    Ice::stringSeqToArgs(args, argc, argv);

    // Initialize communicator.
    //
    Ice::InitializationData id;
    id.properties = props;
    Ice::CommunicatorPtr ic = Ice::initialize(argc, argv, id);

    // At this point, argc/argv only contain options that
    // set neither an Ice property nor a Filesystem property,
    // so we can parse these options as usual.
    //
    // ...
}

```

Using this code, any options beginning with `--Filesystem` are converted to properties and are available via the property lookup operations as usual. The call to `initialize` then removes any Ice-specific command-line options so, once the communicator is created, `argc/argv` only contains options and arguments that are not related to setting either a filesystem or an Ice property.

An easier way to achieve the same thing is to use the overload of `Ice::initialize` that accepts a string sequence, instead of an `argc/argv` pair:

C++

```

int
main(int argc, char* argv[])
{
    // Create an empty property set.
    //
    Ice::PropertiesPtr props = Ice::createProperties();

    // Convert argc/argv to a string sequence.
    //
    Ice::StringSeq args = Ice::argsToStringSeq(argc, argv);

    // Strip out all options beginning with --Filesystem.
    //
    args = props->parseCommandLineOptions("Filesystem", args);

    // args now contains only those options that were not
    // stripped. Any options beginning with --Filesystem have
    // been converted to properties.

    // Initialize communicator.
    //
    Ice::InitializationData id;
    id.properties = props;
    Ice::CommunicatorPtr ic = Ice::initialize(args, id);

    // At this point, args only contains options that
    // set neither an Ice property nor a Filesystem property,
    // so we can parse these options as usual.
    //
    // ...
}

```

This version of the code avoids having to convert the string sequence back into an `argc/argv` pair before calling `Ice::initialize`.

Converting Reserved Command-Line Options to Properties

The `parseIceCommandLineOptions` operation behaves like `parseCommandLineOptions`, but removes the reserved Ice-specific options from the argument vector:

Slice

```
module Ice {
    local interface Properties {

        StringSeq parseIceCommandLineOptions(StringSeq options);

        // ...
    };
};
```

This operation is also used internally by the Ice run time to parse Ice-specific options in `initialize`.

Communicator and other Core Local Features

This section presents several core features of the Ice run-time, that are purely local to your client or server application.

Topics

- [Communicators](#)
- [Communicator Initialization](#)
- [Object Identity](#)
- [Plug-in Facility](#)

Communicators

The main entry point to the Ice run time is represented by the local interface `Ice::Communicator`. An instance of `Ice::Communicator` is associated with a number of run-time resources:

- **Client-side thread pool**
The client-side [thread pool](#) is used to process replies to asynchronous method invocations (AMI), to avoid deadlocks in callbacks, and to process incoming requests on [bidirectional connections](#).
- **Server-side thread pool**
Threads in this [pool](#) accept incoming connections and handle requests from clients.
- **Configuration properties**
Various aspects of the Ice run time can be configured via properties. Each communicator has its own set of such [configuration properties](#).
- **Object factories**
In order to instantiate [classes](#) that are derived from a known base type, the communicator maintains a set of object factories that can instantiate the class on behalf of the Ice run time. Object factories are discussed in each client-side language mapping.
- **Logger object**
A [logger](#) object implements the `Ice::Logger` interface and determines how log messages that are produced by the Ice run time are handled.
- **Default router**
A router implements the `Ice::Router` interface. Routers are used by [Glacier2](#) to implement the firewall functionality of Ice.
- **Default locator**
A [locator](#) is an object that resolves an object identity to a proxy. A locator object is implemented by a location service.
- **Plug-in manager**
[Plug-ins](#) are objects that add features to a communicator. For example, [IceSSL](#) is implemented as a plug-in. Each communicator has a plug-in manager that implements the `Ice::PluginManager` interface and provides access to the set of plug-ins for a communicator.
- **Object adapters**
[Object adapters](#) dispatch incoming requests and take care of passing each request to the correct servant.

Object adapters and objects that use different communicators are completely independent from each other. Specifically:

- Each communicator uses its own thread pool. This means that if, for example, one communicator runs out of threads for incoming requests, only objects using that communicator are affected. Objects using other communicators have their own thread pool and are therefore unaffected.
- Collocated invocations across different communicators are not optimized, whereas collocated invocations using the same communicator bypass much of the overhead of call dispatch.

Typically, servers use only a single communicator but, occasionally, multiple communicators can be useful. For example, [IceBox](#), uses a separate communicator for each Ice service it loads to ensure that different services cannot interfere with each other. Multiple communicators are also useful to avoid thread starvation: if one service runs out of threads, this leaves the remaining services unaffected.

The communicator's interface is defined in Slice. Part of this interface looks as follows:

Slice

```

module Ice {
    local interface Communicator {
        string proxyToString(Object* obj);
        Object* stringToProxy(string str);
        PropertyDict proxyToProperty(Object* proxy, string property);
        Object* propertyToProxy(string property);
        Identity stringToIdentity(string str);
        string identityToString(Identity id);
        ObjectAdapter createObjectAdapter(string name);
        ObjectAdapter createObjectAdapterWithEndpoints(string name,
string endpoints);
        ObjectAdapter createObjectAdapterWithRouter(string name,
Router* rtr);
        void shutdown();
        void waitForShutdown();
        bool isShutdown();
        void destroy();
        // ...
    };
    // ...
};

```

The communicator offers a number of operations:

- proxyToString
stringToProxy

These operations allow you to convert a proxy into its stringified representation and vice versa. Instead of calling `proxyToString` on the communicator, you can also use the `ice_toString` proxy method to stringify it. However, you can only stringify non-null proxies that way — to stringify a null proxy, you must use `proxyToString`. (The stringified representation of a null proxy is the empty string.)

- proxyToProperty
propertyToProxy

`proxyToProperty` returns the set of [proxy properties](#) for the supplied proxy. The `property` parameter specifies the base name for the properties in the returned set. `propertyToProxy` retrieves the configuration property with the given name and converts its value into a proxy. A null proxy is returned if no property is found with the specified name.

- identityToString
stringToIdentity

These operations allow you to convert an [identity](#) to a string and vice versa.

- createObjectAdapter
createObjectAdapterWithEndpoints
createObjectAdapterWithRouter

These operations create a new [object adapter](#). Each object adapter is associated with zero or more [transport endpoints](#). Typically, an object adapter has a single transport endpoint. However, an object adapter can also offer multiple endpoints. If so, these endpoints each lead to the same set of objects and represent alternative means of accessing these objects. This is useful, for example, if a server is behind a firewall but must offer access to its objects to both internal and external clients; by binding the adapter to both the internal and external interfaces, the objects implemented in the server can be accessed via either interface.

An object adapter also can have no endpoint at all. In that case, the adapter can only be reached via colocated invocations originating from the same communicator as is used by the adapter.

Whereas `createObjectAdapter` determines its transport endpoints from configuration information, `createObjectAdapterWithEndpoints` allows you to supply the transport endpoints for the new adapter. Typically, you should use `createObjectAdapter` in preference to `createObjectAdapterWithEndpoints`. Doing so keeps transport-specific information, such as host names and port numbers, out of the source code and allows you to reconfigure the application by changing a property (and so avoid recompilation when a transport endpoint needs to be changed).

`createObjectAdapterWithRouter` creates a routed object adapter that allows clients to receive callbacks from servers that are behind a router.

The newly-created adapter uses its name as a prefix for a collection of [configuration properties](#) that tailor the adapter's behavior. By default, the adapter prints a warning if other properties are defined having the same prefix, but you can disable this warning using the property `Ice.Warn.UnknownProperties`.

- `shutdown`

This operation shuts down the server side of the Ice run time:

- Operation invocations that are in progress at the time `shutdown` is called are allowed to complete normally. `shutdown` does *not* wait for these operations to complete; when `shutdown` returns, you know that no new incoming requests will be dispatched, but operations that were already in progress at the time you called `shutdown` may still be running. You can wait for still-executing operations to complete by calling `waitForShutdown`.
- Operation invocations that arrive after the server has called `shutdown` either fail with a `ConnectFailedException` or are transparently redirected to a new instance of the server (via `IceGrid`).
- Note that `shutdown` initiates deactivation of all object adapters associated with the communicator, so attempts to use an adapter once `shutdown` has completed raise an `ObjectAdapterDeactivatedException`.

- `waitForShutdown`

On the server side, this operation suspends the calling thread until the communicator has shut down (that is, until no more operations are executing in the server). This allows you to wait until the server is idle before you destroy the communicator.

On the client side, `waitForShutdown` simply waits until another thread has called `shutdown` or `destroy`.

- `isShutdown`

This operation returns true if `shutdown` has been invoked on the communicator. A return value of true does not necessarily indicate that the shutdown process has completed, only that it has been initiated. An application that needs to know whether shutdown is complete can call `waitForShutdown`. If the blocking nature of `waitForShutdown` is undesirable, the application can invoke it from a separate thread.

- `destroy`

This operation destroys the communicator and all its associated resources, such as threads, communication endpoints, object adapters, and memory resources. Once you have destroyed the communicator (and therefore destroyed the run time for that communicator), you must not call any other Ice operation (other than to create another communicator).

It is imperative that you call `destroy` before you leave the `main` function of your program. Failure to do so results in undefined behavior.

Calling `destroy` before leaving `main` is necessary because `destroy` waits for all running threads to terminate before it returns. If you leave `main` without calling `destroy`, you will leave `main` with other threads still running; many threading packages do not allow you to do this and end up crashing your program.

If you call `destroy` without calling `shutdown`, the call waits for all executing operation invocations to complete before it returns (that is, the implementation of `destroy` implicitly calls `shutdown` followed by `waitForShutdown`). `shutdown` (and, therefore, `destroy`) deactivates all object adapters that are associated with the communicator. Since `destroy` blocks until all operation invocations complete, a servant will deadlock if it invokes `destroy` on its own communicator while executing a dispatched operation.

On the client side, calling `destroy` while operations are still executing causes those operations to terminate with a `CommunicatorDestroyedException`.

Communicator Initialization

During the creation of a communicator, the Ice run time initializes a number of features that affect the communicator's operation. Once set, these features remain in effect for the life time of the communicator, that is, you cannot change these features after you have created a communicator. Therefore, if you want to customize these features, you must do so when you create the communicator.

The following features can be customized at communicator creation time:

- the [property set](#)
- the [logger object](#)
- the [instrumentation observer](#)
- the narrow and wide [string converters](#) (C++ only)
- the [thread notification hook](#)
- the [dispatcher](#)
- the compact ID resolver (used by the [streaming interfaces](#) when extracting Ice objects)
- the [class loader](#) (Java only)
- the [batch request interceptor](#)

To establish these features, you initialize a structure or class of type `InitializationData` with the relevant settings. For C++ the structure is defined as follows:

C++

```

namespace Ice {
    struct InitializationData {
        PropertiesPtr properties;
        LoggerPtr logger;
        Instrumentation::CommunicatorObserverPtr observer;
        StringConverterPtr stringConverter;
        WstringConverterPtr wstringConverter;
        ThreadNotificationPtr threadHook;
        DispatcherPtr dispatcher;
        CompactIdResolverPtr compactIdResolver;
        BatchRequestInterceptorPtr batchRequestInterceptor;
    };
}

```

For languages other than C++, `InitializationData` is a class with all data members public. (The data members supported by this class vary with each language mapping.)

For C++, `Ice::initialize` is overloaded as follows:

C++

```

namespace Ice {
    CommunicatorPtr initialize(int&, char*[],
        const InitializationData& = InitializationData(),
        Int = ICE_INT_VERSION);
    CommunicatorPtr initialize(StringSeq&,
        const InitializationData& = InitializationData(),
        Int = ICE_INT_VERSION);
    CommunicatorPtr initialize(
        const InitializationData& = InitializationData()
        Int = ICE_INT_VERSION);
}

```

The versions of `initialize` that accept an argument vector look for Ice-specific command-line options and remove them from the argument vector, as described in the [C++ language mapping](#). The version without an `argc/argv` pair is useful if you want to prevent property settings for a program from being changed by command-line arguments — you can use the [Properties](#) interface for this purpose.

To set a feature, you set the corresponding field in the `InitializationData` structure and pass the structure to `initialize`. For example, to establish a custom logger of type `MyLogger`, you can use:

```

Ice::InitializationData id;
id.logger = new MyLoggerI;
Ice::CommunicatorPtr ic = Ice::initialize(argc, argv, id);

```

For Java, C#, and Objective-C, `Ice.Util.initialize` is overloaded similarly (as is `Ice.initialize` for Python, `Ice::initialize` for Ruby, and `Ice_initialize` for PHP), so you can pass an `InitializationData` instance either with or without an argument vector.

For **Objective-C**, the method name is `createCommunicator`.

Note that you must supply an [argument vector](#) if you want `initialize` to look for a configuration file in the `ICE_CONFIG` environment variable.

Object Identity

On this page:

- [The Ice::Identity Type](#)
- [Syntax for Stringified Identities](#)
- [Identity Helper Functions](#)

The Ice::Identity Type

Each Ice object has an object identity defined as follows:

```

Slice
module Ice {
    struct Identity {
        string name;
        string category;
    };
};

```

As you can see, an object identity consists of a pair of strings, a `name` and a `category`. The complete object identity is the combination of `name` and `category`, that is, for two identities to be equal, both `name` and `category` must be the same. The `category` member is usually the empty string, unless you are using [servant locators](#), [default servants](#) or callbacks with [Glacier2](#).

If `name` is an empty string, `category` must be the empty string as well. (An identity with an empty `name` and a non-empty `category` is illegal.) If a proxy contains an identity in which `name` is empty, Ice interprets that proxy as a null proxy.

Object identities can be represented as strings; the `category` part appears first and is followed by the `name`; the two components are separated by a `/` character, for example:

```
Factory/File
```

In this example, `Factory` is the `category`, and `File` is the `name`. If the `name` or `category` member themselves contain a `/` character, the stringified representation escapes the `/` character with a `\`, for example:

```
Factories\ /Factory/Node\ /File
```

In this example, the `category` is `Factories/Factory` and the `name` is `Node/File`.

Syntax for Stringified Identities

You rarely need to write identities as strings because, typically, your code will be using the [identity helper functions](#) `identityToString` and `stringToIdentity`, or simply deal with proxies instead of identities. However, on occasion, you will need to use stringified identities in configuration files. If the identities happen to contain meta-characters (such as a slash or backslash), or characters outside the printable ASCII range, these characters must be escaped in the stringified representation. Here are rules that the Ice run time applies when parsing a stringified identity:

1. The parser scans the stringified identity for an unescaped slash character (`/`). If such a slash character can be found, the substrings to the left and right of the slash are parsed as the `category` and `name` members of the identity, respectively; if no such slash character can be found, the entire string is parsed as the `name` member of the identity, and the `category` member is the empty string.
2. Each of the `category` (if present) and `name` substrings is parsed according to the following rules:

- All characters in the string must be in the ASCII range 32 (space) to 126 (~); characters outside this range cause the parse to fail.
- Any character that is not part of an escape sequence is treated as that character.
- The parser recognizes the following escape sequences and replaces them with their equivalent character:
 - \\ (backslash)
 - \' (single quote)
 - \" (double quote)
 - \b (space)
 - \f (form feed)
 - \n (new line)
 - \r (carriage return)
 - \t (tab)
- An escape sequence of the form \o, \oo, or \ooo (where o is a digit in the range 0 to 7) is replaced with the ASCII character with the corresponding octal value. Parsing for octal digits allows for at most three consecutive digits, so the string \0763 is interpreted as the character with octal value 76 (>) followed by the character 3. Parsing for octal digits terminates as soon as it encounters a character that is not in the range 0 to 7, so \7x is the character with octal value 7 (bell) followed by the character x. Octal escape sequences must be in the range 0 to 255 (octal 000 to 377); escape sequences outside this range cause a parsing error. For example, \539 is an illegal escape sequence.
- If a character follows a backslash, but is not part of a recognized escape sequence, the backslash is ignored, so \x is the character x.

Identity Helper Functions

To make conversion of identities to and from strings easier, Ice provides functions to convert an `Identity` to and from a native string, using the string format described in the preceding paragraph.

In C++, these helper functions are in the Ice namespace:

```

C++

namespace Ice
{
    std::string identityToString(const Identity&);
    Identity    stringToIdentity(const std::string&);
}

```

For Java, the utility functions are in the `Ice.Util` class and are defined as:

```

Java

package Ice;

public final class Util {
    public static String  identityToString(Identity id);
    public static Identity stringToIdentity(String s);
}

```

For C#, the utility functions are in the `Ice.Util` class and are defined as:

C#

```
namespace Ice
{
    public sealed class Util
    {
        public static string  identityToString(Identity id);
        public static Identity stringToIdentity(string s);
    }
}
```

The Python functions are in the `Ice` module:

Python

```
def identityToString(ident)
def stringToIdentity(str)
```

The PHP functions are in the `Ice` namespace:

PHP

```
function identityToString($str)
function stringToIdentity($ident)
```

The Ruby functions are in the `Ice` module:

Ruby

```
def Ice.identityToString(str)
def Ice.stringToIdentity(ident)
```

The local interface `Communicator` provides two equivalent operations, `identityToString` and `stringToIdentity`:

Slice

```
module Ice
{
    local interface Communicator {
        Identity stringToIdentity(string str);
        string  identityToString(Identity ident);
    };
};
```

In Ice 3.6.1 and prior releases, Ice provides these helper functions in C++, Objective-C, Ruby, PHP and Python only on the Communicator interface; the freestanding functions were accidentally left out.

Plug-in Facility

Ice provides a plug-in facility that allows you to load new features into your application, without changing this application's code. Depending on the programming language, a plug-in is packaged as a shared library or a static library, a set of Java classes, or a .NET assembly.

You control the loading and initialization of plug-ins with Ice configuration properties, and the plug-ins themselves are configured through Ice configuration properties.

Ice relies on plug-ins to implement a number of features, such as IceSSL (a secure transport for Ice over SSL/TLS).

This section describes the plug-in facility in more detail and demonstrates how to implement an Ice plug-in.

Plug-in API

On this page:

- [The Plugin Interface](#)
- [C++ Plug-in Factory](#)
- [Java Plug-in Factory](#)
- [C# Plug-in Factory](#)

The Plugin Interface

The plug-in facility defines a `local` Slice interface that all plug-ins must implement:

Slice
<pre> module Ice { local interface Plugin { void initialize(); void destroy(); }; }; </pre>

The lifecycle of an Ice plug-in is structured to accommodate dependencies between plug-ins, such as when a logger plug-in needs to use IceSSL for its logging activities. Consequently, a plug-in object's lifecycle consists of four phases:

- **Construction**
The Ice run time uses a language-specific factory API for instantiating plug-ins. During construction, a plug-in can acquire resources but must not spawn new threads or perform activities that depend on other plug-ins.
- **Initialization**
After all plug-ins have been constructed, the Ice run time invokes `initialize` on each plug-in. The order in which plug-ins are initialized is undefined by default but can be [customized](#) using a configuration property. If a plug-in has a dependency on another plug-in, you must configure the Ice run time so that initialization occurs in the proper order. In this phase it is safe for a plug-in to spawn new threads; it is also safe for a plug-in to interact with other plug-ins and use their services, as long as those plug-ins have already been initialized. If `initialize` raises an exception, the Ice run time invokes `destroy` on all plug-ins that were successfully initialized (in the reverse order of initialization) and raises the original exception to the application.
- **Active**
The active phase spans the time between initialization and destruction. Plug-ins must be designed to operate safely in the context of multiple threads.
- **Destruction**
The Ice run time invokes `destroy` on each plug-in in the reverse order of initialization.

A plug-in's `destroy` implementation must not make remote invocations.

This lifecycle is repeated for each new communicator that an application creates and destroys.

C++ Plug-in Factory

In C++, a plug-in factory is a function with C linkage and the following signature:

C++

```
extern "C"
{
Ice::Plugin*
functionName(const Ice::CommunicatorPtr& communicator,
             const std::string& name,
             const Ice::StringSeq& args)
{
    ...
}
}
```

You can define the function with any name you wish.

Since the function uses C linkage, it must return the plug-in object as a regular C++ pointer and not as an Ice smart pointer. Furthermore, the function must not raise C++ exceptions; if an error occurs, the function must return zero. The arguments to the function consist of the communicator that is in the process of being initialized, the name assigned to the plug-in, and any arguments that were specified in the [plug-in's configuration](#).

If your plug-in and the associated factory function are packaged in a shared library or DLL loaded at run time, you need to export this function from the shared library or DLL. We provide the macro `ICE_DECLSPEC_EXPORT` for this purpose:

C++

```
#if defined(_WIN32)
#   define ICE_DECLSPEC_EXPORT __declspec(dllexport)
#elif defined(__GNUC__)
#   define ICE_DECLSPEC_EXPORT __attribute__((visibility ("default")))
#elif defined(__SUNPRO_CC)
#   define ICE_DECLSPEC_EXPORT __global
...

```

Simply add `ICE_DECLSPEC_EXPORT` to the definition of your plug-in factory:

C++

```
extern "C"
{
ICE_DECLSPEC_EXPORT Ice::Plugin*
functionName(const Ice::CommunicatorPtr& communicator,
             const std::string& name,
             const Ice::StringSeq& args)
{
    ...
}
}
```

If your application doesn't want to rely on the dynamic loading of your plug-in shared library or DLL at run time, or if your plug-in is packaged in a static library, it's also possible to link the plug-in into your application and call `Ice::registerPluginFactory` in your main

application's code to register the plug-in before you initialize Ice communicators. For example:

```

C++

MyApp::MyApp()
{
    // Load/link the "IceSSL" plug-in before communicator initialization

    Ice::registerPluginFactory("IceSSL", createIceSSL, false);
}

```

The `registerPluginFactory` function registers the plug-in's factory function with the Ice run time. It returns `void`, and accepts the following parameters:

- `const string&`
The name of the plug-in.
- `PLUGIN_FACTORY`
A pointer to the plug-in factory function.
- `bool`
When `true`, the plug-in is always loaded (created) during communicator initialization, even if `Ice.Plugin.name` is not set. When `false`, the plug-in is loaded (created) during communication initialization only if `Ice.Plugin.name` is set to a non-empty value (e.g.: `Ice.Plugin.IceSSL=1`).

Java Plug-in Factory

In Java, a plug-in factory must implement the `Ice.PluginFactory` interface:

```

Java

package Ice;

public interface PluginFactory {
    Plugin create(Communicator communicator, String name,
String[] args);
}

```

The arguments to the `create` method consist of the communicator that is in the process of being initialized, the name assigned to the plug-in, and any arguments that were specified in the [plug-in's configuration](#).

The `create` method can return `null` to indicate that a general error occurred, or it can raise `PluginInitializationException` to provide more detailed information. If any other exception is raised, the Ice run time wraps it inside an instance of `PluginInitializationException`.

C# Plug-in Factory

In .NET, a plug-in factory must implement the `Ice.PluginFactory` interface:

C#

```
namespace Ice {
    public interface PluginFactory
    {
        Plugin create(Communicator communicator, string name,
            string[] args);
    }
}
```

The arguments to the `create` method consist of the communicator that is in the process of being initialized, the name assigned to the plug-in, and any arguments that were specified in the [plug-in's configuration](#).

The `create` method can return `null` to indicate that a general error occurred, or it can raise `PluginInitializationException` to provide more detailed information. If any other exception is raised, the Ice run time wraps it inside an instance of `PluginInitializationException`.

See Also

- [Plug-in Configuration](#)
- [Advanced Plug-in Topics](#)

Plug-in Configuration

Plug-ins are installed using a [configuration property](#) of the following form:

```
Ice.Plugin.Name=entry_point [arg ...]
```

In most cases you can assign an arbitrary name to a plug-in. In the case of [IceSSL](#), however, the plug-in requires that its name be `IceSSL`.

The value of `entry_point` is a language-specific representation of the plug-in's factory. In C++, it consists of the path name of the shared library or DLL containing the factory function, along with the name of the factory function. In Java and .NET, the entry point specifies the factory class.

The language-specific nature of plug-in properties can present a problem when applications that are written in multiple implementation languages attempt to share a configuration file. Ice supports an alternate syntax for plug-in properties that alleviates this issue:

```
Ice.Plugin.name.cpp=...      # C++ plug-in
Ice.Plugin.name.java=...     # Java plug-in
Ice.Plugin.name.clr=...      # .NET (Common Language Runtime) plug-in
```

Plug-in properties having a suffix of `.cpp`, `.java`, or `.clr` are loaded only by the appropriate Ice run time and ignored by others.

After extracting the plug-in's entry point from the property value, any remaining text is parsed using semantics similar to that of command-line arguments. Whitespace separates the arguments, and any arguments that contain whitespace must be enclosed in quotes:

```
Ice.Plugin.MyPlugin=entry_point --load "C:\Data Files\config.dat"
```

Ice passes these arguments to the plug-in's entry point during loading.

Advanced Plug-in Topics

This page discusses additional aspects of the Ice plug-in facility that may be of use to applications with special requirements.

On this page:

- [Plug-in Dependencies](#)
- [The Plug-in Manager](#)
- [Delayed Plug-in Initialization](#)

Plug-in Dependencies

If a plug-in has a dependency on another plug-in, you must ensure that Ice initializes the plug-ins in the proper order. Suppose that a custom plug-in depends on `IceSSL`; for example, it may need to make secure invocations on another server. We start with the following C++ configuration:

```
Ice.Plugin.IceSSL=IceSSL:createIceSSL
Ice.Plugin.MyPlugin=MyPlugin:createMyPlugin
```

The problem with this configuration is that it does not specify the order in which the plug-ins should be loaded and initialized. If the Ice run time happens to initialize `MyPlugin` first, the plug-in's `initialize` method will fail if it attempts to use the services of the uninitialized `IceSSL` plug-in.

To remedy the situation, we need to add one more property:

```
Ice.Plugin.IceSSL=IceSSL:createIceSSL
Ice.Plugin.MyPlugin=MyPlugin:createMyPlugin
Ice.PluginLoadOrder=IceSSL, MyPlugin
```

Using the `Ice.PluginLoadOrder` property we can guarantee that the plug-ins are loaded in the correct order.

Plug-ins added manually via the [plug-in manager](#) are appended to the end of the plug-in list, in order of addition. The last plug-in added is the first to be destroyed.

The Plug-in Manager

`PluginManager` is the name of an internal Ice object that is responsible for managing all aspects of Ice plug-ins. This object supports a local Slice interface of the same name, and an application can obtain a reference to this object using the following communicator operation:

```

Slice
module Ice {
  local interface Communicator {
    PluginManager getPluginManager();
    // ...
  };
};
```

The `PluginManager` interface offers three operations:

Slice

```

module Ice {
  local interface PluginManager {
    void initializePlugins();
    Plugin getPlugin(string name);
    void addPlugin(string name, Plugin pi);
  };
};

```

The `initializePlugins` operation is used in special cases when an application needs to manually initialize one or more plug-ins, as discussed in the next section.

The `getPlugin` operation returns a reference to a specific plug-in. The `name` argument must match an installed plug-in, otherwise the operation raises `NotRegisteredException`. This operation is useful when a plug-in exports an interface that an application can use to query or customize its attributes or behavior.

Finally, `addPlugin` provides a way for an application to install a plug-in directly, without the use of a configuration property. This plug-in's `initialize` operation will be invoked if `initializePlugins` has not yet been called on the plug-in manager. If `initializePlugins` has already been called before a plug-in is added, Ice does not invoke `initialize` on the plug-in, but does invoke `destroy` during communicator destruction.

Delayed Plug-in Initialization

It is sometimes necessary for an application to manually configure a plug-in prior to its initialization. For example, SSL keys are often protected by a passphrase, but a developer may be understandably reluctant to specify that passphrase in a configuration file because it would be exposed in clear text. The developer would likely prefer to configure the `IceSSL` plug-in with a password callback instead; however, this must be done before the plug-in is initialized and attempts to load the SSL key. The solution is to configure the Ice run time so that it postpones the initialization of its plug-ins:

```
Ice.InitPlugins=0
```

When `Ice.InitPlugins` is set to zero, initializing plug-ins becomes the application's responsibility. The example below demonstrates how to perform this initialization:

C++

```

Ice::CommunicatorPtr ic = ...
Ice::PluginManagerPtr pm = ic->getPluginManager();
IceSSL::PluginPtr ssl = pm->getPlugin("IceSSL");
ssl->setPasswordPrompt(...);
pm->initializePlugins();

```

After obtaining the `IceSSL` plug-in and establishing the password callback, the application invokes `initializePlugins` on the plug-in manager object to commence plug-in initialization.

Proxies

The introduction to proxies provided in [Terminology](#) describes a proxy as a local artifact that makes a remote invocation as easy to use as a regular function call. In fact, processing remote invocations is just one of a proxy's many responsibilities. A proxy also encapsulates the information necessary to contact the object, including its [identity](#) and addressing details such as [endpoints](#). [Proxy methods](#) provide access to configuration and connection information, and act as factories for creating new proxies. Finally, a proxy initiates the establishment of a [new connection](#) when necessary.

Obtaining Proxies

This page describes the ways an application can obtain a proxy.

On this page:

- [Obtaining a Proxy from a String](#)
- [Obtaining a Proxy from Properties](#)
- [Obtaining a Proxy using Factory Methods](#)
- [Obtaining a Proxy by Invoking Operations](#)

Obtaining a Proxy from a String

The communicator operation `stringToProxy` creates a proxy from its `stringified` representation, as shown in the following C++ example:

```
C++
```

```
Ice::ObjectPrx p = communicator->stringToProxy("ident:tcp -p 5000");
```

Obtaining a Proxy from Properties

Rather than hard-coding a stringified proxy as the previous example demonstrated, an application can gain more flexibility by externalizing the proxy in a configuration property. For example, we can define a property that contains our stringified proxy as follows:

```
MyApp.Proxy=ident:tcp -p 5000
```

We can use the communicator operation `propertyToProxy` to convert the property's value into a proxy, as shown below in Java:

```
Java
```

```
Ice.ObjectPrx p = communicator.propertyToProxy("MyApp.Proxy");
```

As an added convenience, `propertyToProxy` allows you to define subordinate properties that configure the proxy's local settings. The properties below demonstrate this feature:

```
MyApp.Proxy=ident:tcp -p 5000
MyApp.Proxy.PreferSecure=1
MyApp.Proxy.EndpointSelection=Ordered
```

These additional properties simplify the task of customizing a proxy (as you can with [proxy methods](#)) without the need to change the application's code. The properties shown above are equivalent to the following statements:

Java

```
Ice.ObjectPrx p = communicator.stringToProxy("ident:tcp -p 5000");
p = p.ice_preferSecure(true);
p = p.ice_endpointSelection(Ice.EndpointSelectionType.Ordered);
```

The list of [supported proxy properties](#) includes the most commonly-used proxy settings. The communicator prints a warning by default if it does not recognize a subordinate property. You can disable this warning using the property `Ice.Warn.UnknownProperties`.

Note that proxy properties can themselves have proxy properties. For example, the following sets the `PreferSecure` property on the default locator's router:

```
Ice.Default.Locator.Router.PreferSecure=1
```

Obtaining a Proxy using Factory Methods

[Proxy factory methods](#) allow you to modify aspects of an existing proxy. Since proxies are immutable, factory methods always return a new proxy if the desired modification differs from the proxy's current configuration. Consider the following C# example:

C#

```
Ice.ObjectPrx p = communicator.stringToProxy("...");
p = p.ice_oneway();
```

`ice_oneway` is considered a factory method because it returns a proxy configured to use oneway invocations. If the original proxy uses a different invocation mode, the return value of `ice_oneway` is a new proxy object.

The `checkedCast` and `uncheckedCast` methods can also be considered factory methods because they return new proxies that are narrowed to a particular Slice interface. A call to `checkedCast` or `uncheckedCast` typically follows the use of other factory methods, as shown below:

C#

```
Ice.ObjectPrx p = communicator.stringToProxy("...");
Ice.LocatorPrx loc =
Ice.LocatorPrxHelper.checkedCast(p.ice_secure(true));
```

Note however that, once a proxy has been narrowed to a Slice interface, it is not normally necessary to perform another down-cast after using a factory method. For example, we can rewrite this example as follows:

C#

```
Ice.ObjectPrx p = communicator.stringToProxy("...");
Ice LocatorPrx loc = Ice.LocatorPrxHelper.checkedCast(p);
loc = (Ice.LocatorPrx)p.ice_secure(true);
```

A language-specific cast may be necessary, as shown here for C#, because the factory methods are declared to return the type `ObjectPrx`, but the proxy object itself retains its narrowed type. The only exceptions are the factory methods `ice_facet` and `ice_identity`. Calls to either of these methods may produce a proxy for an object of an unrelated type, therefore they return a base proxy that you must subsequently down-cast to an appropriate type.

Obtaining a Proxy by Invoking Operations

An application can also obtain a proxy as the result of an Ice invocation. Consider the following Slice definitions:

Slice

```
interface Account { ... };
interface Bank {
    Account* findAccount(string id);
};
```

Invoking the `findAccount` operation returns a proxy for an `Account` object. There is no need to use `checkedCast` or `uncheckedCast` on this proxy because it has already been narrowed to the `Account` interface. The C++ code below demonstrates how to invoke `findAccount`:

C++

```
BankPrx bank = ...
AccountPrx acct = bank->findAccount(id);
```

Of course, the application must have already obtained a proxy for the bank object using one of the techniques shown above.

Proxy Methods

Although the core proxy functionality is supplied by a language-specific base class, we can describe the proxy methods in terms of Slice operations as shown below:

Slice
<pre> bool ice_isA(string id); void ice_ping(); StringSeq ice_ids(); string ice_id(); Communicator ice_getCommunicator(); string ice_toString(); Object* ice_identity(Identity id); Identity ice_getIdentity(); Object* ice_adapterId(string id); string ice_getAdapterId(); Object* ice_endpoints(EndpointSeq endpoints); EndpointSeq ice_getEndpoints(); Object* ice_endpointSelection(EndpointSelectionType t); EndpointSelectionType ice_getEndpointSelection(); Object* ice_context(Context ctx); Context ice_getContext(); Object* ice_facet(string facet); string ice_getFacet(); Object* ice_twoway(); bool ice_isTwoway(); Object* ice_oneway(); bool ice_isOneway(); Object* ice_batchOneway(); bool ice_isBatchOneway(); Object* ice_datagram(); bool ice_isDatagram(); Object* ice_batchDatagram(); bool ice_isBatchDatagram(); Object* ice_secure(bool b); bool ice_isSecure(); EncodingVersion ice_getEncodingVersion(); Object* ice_encodingVersion(EncodingVersion v); Object* ice_preferSecure(bool b); bool ice_isPreferSecure(); Object* ice_compress(bool b); Object* ice_timeout(int timeout); Object* ice_router(Router* rtr); Router* ice_getRouter(); Object* ice_locator(Locator* loc); Locator* ice_getLocator(); Object* ice_locatorCacheTimeout(int seconds); int ice_getLocatorCacheTimeout(); Object* ice_collocationOptimized(bool b); bool ice_isCollocationOptimized(); </pre>

```
Object* ice_invocationTimeout(int timeout);  
int ice_getInvocationTimeout();  
Object* ice_connectionId(string id);  
string ice_getConnectionId();  
Connection ice_getConnection();  
Connection ice_getCachedConnection();  
Object* ice_connectionCached(bool b);  
bool ice_isConnectionCached();  
void ice_flushBatchRequests();
```

```
bool ice_invoke(string operation, OperationMode mode,
               ByteSeq inParams, out ByteSeq outParams);
```

These methods can be categorized as follows:

- Remote inspection: methods that return information about the remote object. These methods make remote invocations and therefore accept an optional trailing argument of type `Ice::Context`.
- Local inspection: methods that return information about the proxy's local configuration.
- Factory: methods that return new proxy instances configured with different features.
- Request processing: methods that flush batch requests and send "dynamic" Ice invocations.

Proxies are immutable, so factory methods allow an application to obtain a new proxy with the desired configuration. Factory methods essentially clone the original proxy and modify one or more features of the new proxy.

Many of the factory methods are not supported by [fixed proxies](#), which are used in conjunction with [bidirectional connections](#). Attempting to invoke one of these methods causes the Ice run time to raise `FixedProxyException`.

The core proxy methods are explained in greater detail in the following table:

Method	Description	Remote
<code>ice_isA</code>	Returns <code>true</code> if the remote object supports the type indicated by the <code>id</code> argument, otherwise <code>false</code> . This method can only be invoked on a twoway proxy.	Yes
<code>ice_ping</code>	Determines whether the remote object is reachable. Does not return a value.	Yes
<code>ice_ids</code>	Returns the type IDs of the types supported by the remote object. The return value is an array of strings. This method can only be invoked on a twoway proxy.	Yes
<code>ice_id</code>	Returns the type ID of the most-derived type supported by the remote object. This method can only be invoked on a twoway proxy.	Yes
<code>ice_getCommunicator</code>	Returns the communicator that was used to create this proxy.	No
<code>ice_toString</code>	Returns the string representation of the proxy.	No
<code>ice_identity</code>	Returns a new proxy having the given identity .	No
<code>ice_getIdentity</code>	Returns the identity of the Ice object represented by the proxy.	No
<code>ice_adapterId</code>	Returns a new proxy having the given adapter ID .	No
<code>ice_getAdapterId</code>	Returns the proxy's adapter ID , or an empty string if no adapter ID is configured.	No
<code>ice_endpoints</code>	Returns a new proxy having the given endpoints .	No
<code>ice_getEndpoints</code>	Returns a sequence of <code>Endpoint</code> objects representing the proxy's endpoints .	No
<code>ice_endpointSelection</code>	Returns a new proxy having the given endpoint selection policy (random or ordered).	No
<code>ice_getEndpointSelection</code>	Returns the endpoint selection policy for the proxy.	No
<code>ice_context</code>	Returns a new proxy having the given request context .	No
<code>ice_getContext</code>	Returns the request context associated with the proxy.	No
<code>ice_facet</code>	Returns a new proxy having the given facet name .	No
<code>ice_getFacet</code>	Returns the name of the facet associated with the proxy, or an empty string if no facet has been set.	No
<code>ice_twoway</code>	Returns a new proxy for making twoway invocations.	No
<code>ice_isTwoway</code>	Returns <code>true</code> if the proxy uses twoway invocations, otherwise <code>false</code> .	No
<code>ice_oneway</code>	Returns a new proxy for making oneway invocations .	No

<code>ice_isOneway</code>	Returns <code>true</code> if the proxy uses oneway invocations , otherwise <code>false</code> .	No
<code>ice_batchOneway</code>	Returns a new proxy for making batch oneway invocations .	No
<code>ice_isBatchOneway</code>	Returns <code>true</code> if the proxy uses batch oneway invocations , otherwise <code>false</code> .	No
<code>ice_datagram</code>	Returns a new proxy for making datagram invocations .	No
<code>ice_isDatagram</code>	Returns <code>true</code> if the proxy uses datagram invocations , otherwise <code>false</code> .	No
<code>ice_batchDatagram</code>	Returns a new proxy for making batch datagram invocations .	No
<code>ice_isBatchDatagram</code>	Returns <code>true</code> if the proxy uses batch datagram invocations , otherwise <code>false</code> .	No
<code>ice_secure</code>	Returns a new proxy whose endpoints may be filtered depending on the boolean argument. If <code>true</code> , only endpoints using secure transports are allowed, otherwise all endpoints are allowed.	No
<code>ice_getEncodingVersion</code>	Returns the encoding version that is used to encode requests invoked on this proxy.	No
<code>ice_encodingVersion</code>	Returns a new proxy that uses the given encoding version to encode requests. Raises <code>UnsupportedEncodingException</code> if the version is invalid.	No
<code>ice_isSecure</code>	Returns <code>true</code> if the proxy uses only secure endpoints, otherwise <code>false</code> .	No
<code>ice_preferSecure</code>	Returns a new proxy whose endpoints are filtered depending on the boolean argument. If <code>true</code> , endpoints using secure transports are given precedence over endpoints using non-secure transports. If <code>false</code> , the default behavior gives precedence to endpoints using non-secure transports.	No
<code>ice_isPreferSecure</code>	Returns <code>true</code> if the proxy prefers secure endpoints, otherwise <code>false</code> .	No
<code>ice_compress</code>	Returns a new proxy whose protocol compression capability is determined by the boolean argument. If <code>true</code> , the proxy uses protocol compression if it is supported by the endpoint. If <code>false</code> , protocol compression is never used.	No
<code>ice_timeout</code>	Returns a new proxy whose endpoints all have the given connection timeout value in milliseconds. A value of <code>-1</code> disables timeouts.	No
<code>ice_router</code>	Returns a new proxy configured with the given router proxy.	No
<code>ice_getRouter</code>	Returns the router that is configured for the proxy (null if no router is configured).	No
<code>ice_locator</code>	Returns a new proxy with the specified locator .	No
<code>ice_getLocator</code>	Returns the locator that is configured for the proxy (null if no locator is configured).	No
<code>ice_locatorCacheTimeout</code>	Returns a new proxy with the specified locator cache timeout in seconds. When binding a proxy to an endpoint, the run time caches the proxy returned by the locator and uses the cached proxy while the cached proxy has been in the cache for less than the timeout. Proxies older than the timeout cause the run time to rebind via the locator. A value of <code>0</code> disables caching entirely, and a value of <code>-1</code> means that cached proxies never expire. The default value is <code>-1</code> .	No
<code>ice_getLocatorCacheTimeout</code>	Returns the locator cache timeout value in seconds.	No
<code>ice_collocationOptimized</code>	Returns a new proxy configured for collocation optimization . If <code>true</code> , collocated optimizations are enabled. The default value is <code>true</code> .	No
<code>ice_isCollocationOptimized</code>	Returns <code>true</code> if the proxy uses collocation optimization , otherwise <code>false</code> .	No
<code>ice_invocationTimeout</code>	Returns a new proxy configured with the specified invocation timeout in milliseconds. A value of <code>-1</code> means an invocation never times out. A value of <code>-2</code> provides backward compatibility with Ice versions prior to 3.6 by disabling invocation timeouts and using connection timeouts to wait for the response of an invocation.	No
<code>ice_getInvocationTimeout</code>	Returns the invocation timeout value in milliseconds.	No

<code>ice_connectionId</code>	Returns a new proxy having the given connection ID .	No
<code>ice_getConnectionId</code>	Returns the connection ID , or an empty string if no connection ID has been configured.	No
<code>ice_getConnection</code> <code>begin_ice_getConnection</code>	Returns an object representing the connection used by the proxy. If the proxy is not currently associated with a connection, the Ice run time attempts to establish a connection first, which means this method can potentially block while network operations are in progress. Use the asynchronous method to avoid blocking.	No
<code>ice_getCachedConnection</code>	Returns an object representing the connection used by the proxy, or null if the proxy is not currently associated with a connection.	No
<code>ice_connectionCached</code>	Enables or disables connection caching for the proxy.	No
<code>ice_isConnectionCached</code>	Returns <code>true</code> if the proxy uses connection caching , otherwise <code>false</code> .	No
<code>ice_flushBatchRequests</code> <code>begin_ice_flushBatchRequests</code>	Sends a batch of operation invocations synchronously or asynchronously.	Yes
<code>ice_invoke</code> <code>begin_ice_invoke</code>	Allows dynamic invocation of an operation without the need for compiled Slice definitions. Requests can be sent synchronously or asynchronously .	Yes

Proxy Endpoints

Proxy endpoints are the client-side equivalent of [object adapter endpoints](#). A proxy endpoint identifies the protocol information used to contact a remote object, as shown in the following example:

```
tcp -h frosty.zeroc.com -p 10000
```

This endpoint states that an object is reachable via TCP on the host `frosty.zeroc.com` and the port `10000`.

A proxy must have, or be able to obtain, at least one endpoint in order to be useful. A *direct proxy* contains one or more endpoints:

```
MyObject:tcp -h frosty.zeroc.com -p 10000:ssl -h frosty.zeroc.com -p
10001
```

In this example the object with the identity `MyObject` is available at two separate endpoints, one using TCP and the other using SSL.

If a direct proxy does not contain the `-h` option (that is, no host is specified), the Ice run time uses the value of the `Ice.Default.Host` property. If `Ice.Default.Host` is not defined, the `localhost` interface is used.

An *indirect proxy* uses a [locator](#) to retrieve the endpoints dynamically. One style of indirect proxy contains an [adapter identifier](#):

```
MyObject @ MyAdapter
```

When this proxy requires the endpoints associated with `MyAdapter`, it requests them from the locator.

The other style of indirect proxy is a proxy with just an object identity, called a [well-known proxy](#):

```
MyObject
```

- [Object Adapter Endpoints](#)
- [Locators](#)

Filtering Proxy Endpoints

A proxy's configuration determines how its [endpoints](#) are used. For example, a proxy configured for secure communication will only use endpoints having a secure protocol, such as SSL.

The [factory methods](#) listed in the table below allow applications to manipulate endpoints indirectly. Calling one of these methods returns a new proxy whose endpoints are used in accordance with the proxy's new configuration.

Method	Description
<code>ice_secure</code>	Selects only endpoints using a secure protocol (e.g., SSL).
<code>ice_datagram</code>	Selects only endpoints using a datagram protocol (e.g., UDP).
<code>ice_batchDatagram</code>	Selects only endpoints using a datagram protocol (e.g., UDP).
<code>ice_twoway</code>	Selects only endpoints capable of making twoway invocations (e.g., TCP, SSL). For example, this disables datagram endpoints.
<code>ice_oneway</code>	Selects only endpoints capable of making reliable oneway invocations (e.g., TCP, SSL). For example, this disables datagram endpoints.
<code>ice_batchOneway</code>	Selects only endpoints capable of making reliable oneway batch invocations (e.g., TCP, SSL). For example, this disables datagram endpoints.

Upon return, the set of endpoints in the new proxy is unchanged from the old one. However, the new proxy's configuration drives a filtering process that the Ice run time performs during [connection establishment](#).

The factory methods do not raise an exception if they produce a proxy with no viable endpoints. For example, the C++ statement below creates such a proxy:

```

C++
proxy = communicator->stringToProxy("id:tcp -p 10000")->ice_datagram();
```

It is always possible that a proxy could become viable after additional factory methods are invoked, therefore the Ice run time does not raise an exception until connection establishment is attempted. At that point, the application can expect to receive `NoEndpointException` if the filtering process eliminates all endpoints.

An application can also create a proxy with a specific set of endpoints using the `ice_endpoints` factory method, whose only argument is a sequence of `Ice::Endpoint` objects. At present, an application is not able to create new instances of `Ice::Endpoint`, but rather can only incorporate instances obtained by calling `ice_getEndpoints` on a proxy. Note that `ice_getEndpoints` may return an empty sequence if the proxy has no endpoints, as is the case with an [indirect proxy](#).

- [Proxy Endpoints](#)
- [Proxy Methods](#)
- [Connection Establishment](#)

Proxy Defaults and Overrides

It is important to understand how proxies are influenced by Ice configuration properties and settings. The relevant properties can be classified into two categories: defaults and overrides.

On this page:

- [Proxy Default Properties](#)
- [Proxy Override Properties](#)

Proxy Default Properties

Default properties affect proxies created as the result of an Ice invocation, or by calling `stringToProxy` or `propertyToProxy` on a `communicator`. These properties do not influence proxies created by **proxy factory methods**.

For example, suppose we define the following default property:

```
Ice.Default.PreferSecure=1
```

We can verify that the property has the desired affect using the following C++ code:

C++

```
Ice::ObjectPrx p = communicator->stringToProxy(...);
assert(p->ice_isPreferSecure());
```

Furthermore, we can verify that the property does not affect proxies returned by factory methods:

```
Ice::ObjectPrx p2 = p->ice_preferSecure(false);
assert(!p2->ice_isPreferSecure());
Ice::ObjectPrx p3 = p2->ice_oneway();
assert(!p3->ice_isPreferSecure());
```

Proxy Override Properties

Defining an **override property** causes the Ice run time to ignore any equivalent proxy setting and use the override property value instead. For example, consider the following property definition:

```
Ice.Override.Secure=1
```

This property instructs the Ice run time to use only secure endpoints, producing the same semantics as calling `ice_secure(true)` on every proxy. However, the property does not alter the settings of an existing proxy, but rather directs the Ice run time to use secure endpoints regardless of the proxy's security setting. We can verify that this is the case using the following C++ code:

C++

```
Ice::ObjectPrx p = communicator->stringToProxy(...);  
p = p->ice_secure(false);  
assert(!p->ice_isSecure()); // The security setting is retained.
```

Proxy-Based Load Balancing

Ice supports two types of load balancing:

- Locator-based load balancing
- Proxy-based load balancing

An application can use only one type or combine both to achieve the desired behavior. This page discusses proxy-based load balancing; refer to [Locator Semantics for Clients](#) for information on load balancing with a locator.

On this page:

- [Proxy Connection Caching](#)
- [Proxies with Multiple Endpoints](#)
- [Per-Request Load Balancing](#)

Proxy Connection Caching

Before we discuss load balancing, it's important to understand the relationship between proxies and connections.

By default a proxy remembers its connection and uses it for all invocations until that connection is closed. You can prevent a proxy from caching its connection by calling the `ice_connectionCached` proxy method with an argument of false. Once connection caching is disabled, each invocation on a proxy causes the Ice run time to execute its connection establishment process.

Note that each invocation on such a proxy does not necessarily cause the Ice run time to establish a new connection. It only means that the Ice run time does not assume that it can reuse the connection of the proxy's previous invocation. Whether the Ice run time actually needs to [establish a new connection](#) for the next invocation depends on several factors.

As with any feature, you should only use it when the benefits outweigh the risks. With respect to a proxy's connection caching behavior, there is certainly a small amount of computational overhead associated with executing the connection establishment process for each invocation, as well as the risk of significant overhead each time a new connection is actually created.

Proxies with Multiple Endpoints

A proxy can contain zero or more endpoints. A proxy with no endpoints typically means it's an indirect proxy that requires a [location service](#) to convert the proxy's symbolic information into endpoints at run time. Otherwise, a direct proxy contains at least one endpoint.

Regardless of whether endpoints are specified directly or indirectly, a proxy having multiple endpoints implies at a minimum that the target object is available via multiple network interfaces, but often also means the object is replicated to improve scalability and reliability. Such a proxy provides a client with several load balancing options even when no location service is involved. The proxy's own configuration drives the run-time behavior, depending on how the client configures the proxy's [endpoint selection type](#) and [connection caching](#) settings.

For example, suppose that a proxy contains several endpoints. In its default configuration, a proxy uses the `Random` endpoint selection type and caches its connection. Upon the first invocation, the Ice run time selects one of the proxy's endpoints at random and uses that connection for all subsequent invocations until the connection is closed. For some applications, this form of load balancing may be sufficient.

Suppose now that we use the `Ordered` endpoint selection type instead. In this case, the Ice run time always attempts to establish connections using the endpoints in the order they appear in the proxy. Normally an application uses this configuration when there is a preferred order to the servers. Again, once connected, the Ice run time uses whichever connection was chosen indefinitely.

Per-Request Load Balancing

When we disable the connection caching behavior of a proxy with multiple endpoints, its semantics undergo a significant change. Using the `Random` [endpoint selection type](#), the Ice run time selects one of the endpoints at random and [establishes a connection](#) to it if one is not already established, and this process is repeated *prior to each subsequent invocation*. This is called *per-request load balancing* because each request can potentially be directed to a different server.

Using the `Ordered` endpoint selection type is not as common in this scenario; its main purpose would be to fall back on a secondary server if the primary server is not available, but it causes the Ice run time to attempt to contact the primary server during each request.

Here's some code that shows how to configure the proxy:

C++

```
Ice::ObjectPrx proxy = communicator->stringToProxy("hello:tcp -h  
10.0.0.1 -p 2000:tcp -h 10.0.0.2 -p 2001");  
proxy = proxy->ice_connectionCached(false);  
proxy = proxy->ice_endpointSelection(Ice::Random);  
// If also using a locator:  
proxy = proxy->ice_locatorCacheTimeout(...);
```

We create a proxy with two endpoints, then use the factory methods to disable connection caching and set the endpoint selection type. The `Random` setting means that, after we've made a few invocations with the proxy, the Ice run time will have established connections to both endpoints. After incurring the initial expense of opening the connections, each subsequent invocation will randomly use one of the existing connections.

If you're also using a location service, you may want to modify the proxy's `locator cache timeout` to force the Ice run time in the client to query the locator more frequently.

Indirect Proxy with Object Adapter Identifier

A proxy with an object adapter identifier (`@adapterId` in stringified form) is a form of [indirect proxy](#). Such a proxy consists of an object identity, an object adapter identifier and (optionally) proxy options such as `-t` (for two-way proxies), as described on [Proxy and Endpoint Syntax](#).

For example:

```
Root@fsadapter      # proxy to Root object hosted by object adapter
fsadapter (two-way proxy by default)
Root@fsadapter -o   # oneway proxy
```

When you invoke an operation on such an indirect proxy, Ice first *resolves* the object adapter identifier—Ice checks if it corresponds to a local object adapter, or retrieves the endpoints published by this object adapter.

The resolution proceeds as follows:

1. If [collocation optimization](#) is enabled (the default), Ice checks if an [object adapter](#) associated with the same communicator as the proxy has the desired object adapter identifier (set through [ReplicaGroupId](#) or [AdapterId](#)). If there is such an object adapter, Ice then sends requests to this object adapter using collocation optimization. The [holding state](#) of the object adapters is ignored for this search and subsequent collocated dispatches.
2. Otherwise, if no local object adapters carries the desired object adapter identifier (or collocation optimization is disabled), and a [locator](#) or is configured with the communicator:
 - a. Ice looks up this object adapter identifier in its [locator cache](#).
 - b. If this lookup fails, Ice resolves this object adapter identifier using the locator.
3. In case the preceding steps can't locate the object adapter, the invocation fails with `NoEndpointException`.

See Also

- [Locators](#)
- [Well-Known Proxies](#)

Well-Known Proxy

A proxy with no endpoint or object adapter identifier (`@adapterId` in stringified form) is called a well-known proxy. A well-known proxy consists of an object identity plus (optionally) proxy options such as `-t` (for two-way proxies), as described on [Proxy and Endpoint Syntax](#). Well-known proxies are a form of [indirect proxies](#).

For example:

```
Root          # well-known proxy to Root object (two-way by default)
Root -o       # oneway proxy
```

When you invoke an operation on a well-known proxy, Ice locates the target object as follows:

1. If [collocation optimization](#) is enabled (the default), Ice looks up the object identity in the [Active Servant Map](#) (ASM) of all [object adapters](#) associated with the same communicator as this well-known proxy. The servant locators and default servants registered with these object adapters are not consulted. If the object is found in one of these ASMs, Ice then sends requests to this object using collocation optimization. The [holding state](#) of the object adapter is ignored for this search and subsequent collocated dispatches to the servant.
2. Otherwise, if Ice does not find this object identity in one of these local ASMs (or collocation optimization is disabled), and a [locator](#) is configured with the communicator:
 - a. Ice looks up this object identity in its [locator cache](#).
 - b. If this lookup fails, Ice resolves this object identity using the locator.
3. In case the preceding steps can't locate the target object or endpoints, the invocation fails with `NoEndpointException`.

Syntax for Stringified Proxies

Synopsis

```
identity -f facet -e encoding -p protocol -t -o -O -d -D -s @ adapter_id : endpoints
```

Description

A stringified proxy consists of an identity, proxy options, and an optional object adapter identifier or endpoint list. White space (the space, tab (\t), line feed (\n), and carriage return (\r) characters) act as token delimiters; if a white space character appears as part of a component of a stringified proxy (such as the identity), it must be quoted or escaped as described below.

A proxy containing an identity with no endpoints is a [well-known proxy](#); a proxy with an identity and an object adapter identifier represents an indirect proxy that will be resolved using the [Ice locator](#).

Proxy options configure the invocation mode:

<code>-f facet</code>	Select a facet of the Ice object.
<code>-e encoding</code>	Specify the Ice encoding version to use when an invocation on this proxy marshals parameters.
<code>-p protocol</code>	Specify the Ice protocol version to use when sending a request with this proxy.
<code>-t</code>	Configures the proxy for twoway invocations (default).
<code>-o</code>	Configures the proxy for oneway invocations.
<code>-O</code>	Configures the proxy for batch oneway invocations.
<code>-d</code>	Configures the proxy for datagram invocations.
<code>-D</code>	Configures the proxy for batch datagram invocations.
<code>-s</code>	Configures the proxy for secure invocations.

The proxy options `-t`, `-o`, `-O`, `-d`, and `-D` are mutually exclusive.

The object identity *identity* is structured as [*category*/]*name*, where the *category* component and slash separator are optional. If *identity* contains white space or either of the characters `:` or `@`, it must be enclosed in single or double quotes. The *category* and *name* components are UTF-8 strings that use the encoding described below. Any occurrence of a slash (`/`) in *category* or *name* must be escaped with a backslash (i.e., `\`).

The *facet* argument of the `-f` option represents a [facet](#) name. If *facet* contains white space, it must be enclosed in single or double quotes. A facet name is a UTF-8 string that uses the encoding described below.

The object adapter identifier *adapter_id* is a UTF-8 string that uses the encoding described below. If *adapter_id* contains white space, it must be enclosed in single or double quotes.

Single or double quotes can be used to prevent white space characters from being interpreted as delimiters. Double quotes prevent interpretation of a single quote as an opening or closing quote, for example:

```
"a string with a ' quote"
```

Single quotes prevent interpretation of a double quote as an opening or closing quote. For example:

```
'a string with a " quote'
```

Escape sequences such as `\b` are interpreted within single and double quotes.

UTF-8 strings are encoded using ASCII characters for the ordinal range 32--126 (inclusive). Characters outside this range must be encoded using escape sequences (`\b`, `\f`, `\n`, `\r`, `\t`) or octal notation (e.g., `\007`). Single and double quotes can be escaped using a backslash, as can the backslash itself.

If *endpoints* are specified, they must be separated with a colon (`:`) and formatted as described in the [endpoint syntax](#). The order of endpoints in the stringified proxy is not necessarily the order in which connections are attempted during binding: when a stringified proxy is converted into a proxy instance, by default, the endpoint list is randomized as a form of load balancing. You can change this default behavior using the properties `Ice.Default.EndpointSelection` and `name.EndpointSelection`.

If the `-s` option is specified, only those endpoints that support secure invocations are considered during binding. If no valid endpoints are found, the application receives `Ice::NoEndpointException`.

Otherwise, if the `-s` option is not specified, the endpoint list is ordered so that non-secure endpoints have priority over secure endpoints during binding. In other words, connections are attempted on all non-secure endpoints before any secure endpoints are attempted.

The `-e` and `-p` options specify the encoding and protocol versions supported by the target object, respectively. The Ice run time in the client is responsible for using a compatible version of the encoding or protocol, where *compatible* means the same major version and a minor version that is equal to or less than the specified minor version. If the `-e` option is not defined, the proxy uses the default version specified by `Ice.Default.EncodingVersion`.

If an unknown option is specified, or the stringified proxy is malformed, the application receives `Ice::ProxyParseException`. If an endpoint is malformed, the application receives `Ice::EndpointParseException`.

Syntax for Stringified Endpoints

Synopsis

```
endpoint : endpoint
```

Description

An endpoint list comprises one or more endpoints separated by a colon (`:`).

An endpoint has the following format:

```
protocol option
```

The supported protocols are `tcp`, `udp`, `ssl`, `ws`, `wss`, and `default`. If `default` is used, it is replaced by the value of the `Ice.Default.Protocol` property. If an endpoint is malformed, or an unknown protocol is specified, the application receives `Ice::EndpointParseException`. The `ssl` and `wss` protocols are only available if the `IceSSL` plug-in is installed.

Ice uses endpoints for two similar but distinct purposes:

1. In a client context (that is, in a proxy), endpoints determine how Ice establishes a connection to a server.
2. In a server context (that is, in an object adapter's configuration), endpoints define the addresses and transports over which new incoming connections are accepted. These endpoints are also embedded in the proxies created by the object adapter, unless a separate set of "published" endpoints are explicitly configured.

The sections that follow discuss the addressing component of endpoints, as well as the protocols and their supported options.

See [Object Adapter Endpoints](#) for examples.

Address Syntax

Synopsis

```
host : hostname | x.x.x.x (IPv4)
host : hostname | ":x:x:x:x:x:x" (IPv6)
```

Description

Ice supports Internet Protocol (IP) versions 4 and 6 in all language mappings.

Support for these protocols is configured using the properties `Ice.IPv4` and `Ice.IPv6` (both enabled by default).

In the endpoint descriptions below, the `host` parameter represents either a host name that is resolved via the Domain Name System (DNS), an IPv4 address in dotted quad notation, or an IPv6 address in 128-bit hexadecimal format and enclosed in double quotes. Due to limitation of the DNS infrastructure, host and domain names are restricted to the ASCII character set.

The presence (or absence) of the `host` parameter has a significant influence on the behavior of the Ice run time. The table below describes these semantics:

Value	Client Semantics	Server Semantics
None	If <code>host</code> is not specified in a proxy, Ice uses the value of the <code>Ice.Default.Host</code> property. If that property is not defined, outgoing connections are only attempted over loopback interfaces.	If <code>host</code> is not specified in an object adapter endpoint, Ice uses the value of the <code>Ice.Default.Host</code> property. If that property is not defined, the adapter behaves as if the wildcard symbol <code>*</code> was specified (see below).
Host name	The host name is resolved via DNS. Outgoing connections are attempted to each address returned by the DNS query.	The host name is resolved via DNS, and the object adapter listens on the network interface corresponding to the first address returned by the DNS query. The specified host name is embedded in proxies created by the adapter.
IPv4 address	An outgoing connection is attempted to the given address.	The object adapter listens on the network interface corresponding to the address. The specified address is embedded in proxies created by the adapter.
IPv6 address	An outgoing connection is attempted to the given address.	The object adapter listens on the network interface corresponding to the address. The specified address is embedded in proxies created by the adapter.
0.0.0.0 (IPv4)	A "wildcard" IPv4 address that causes Ice to try all local interfaces when establishing an outgoing connection.	The adapter listens on all IPv4 network interfaces (including the loopback interface), that is, binds to <code>INADDR_ANY</code> for IPv4. Endpoints for all addresses except loopback are published in proxies (unless loopback is the only available interface, in which case only loopback is published).
": : " (IPv6)	A "wildcard" IPv6 address that causes Ice to try all local interfaces when establishing an outgoing connection.	Equivalent to <code>*</code> (see below).
* (IPv4, IPv6)	Not supported in proxies.	The adapter listens on all network interfaces (including the loopback interface), that is, binds to <code>INADDR_ANY</code> for the enabled protocols (IPv4 and/or IPv6). Endpoints for all addresses except loopback and IPv6 link-local are published in proxies (unless loopback is the only available interface, in which case only loopback is published).

There is one additional benefit in specifying a wildcard address for `host` (or not specifying it at all) in an object adapter's endpoint: if the list of network interfaces on a host may change while the application is running, using a wildcard address for `host` ensures that the object adapter automatically includes the updated interfaces. Note however that the list of published endpoints is not changed automatically; rather, the application must explicitly [refresh the object adapter's endpoints](#). For diagnostic purposes, you can set the configuration property `Ice.Trace.Network=3` to cause Ice to log the current list of local addresses that it is substituting for the wildcard address.

When IPv4 and IPv6 are enabled, an object adapter endpoint that uses an IPv6 (or `*` wildcard) address can accept both IPv4 and IPv6 connections.

Java's default network stack always accepts both IPv4 and IPv6 connections regardless of the settings of `Ice.IPv6`. Thus, in Java, an object adapter endpoint that uses the IPv4 wildcard will accept both IPv4 and IPv6 connections. You can configure the Java run time to use

only IPv4 by starting your application with the following JVM option:

```

Java
java -Djava.net.preferIPv4Stack=true ...

```

TCP Endpoint Syntax

Synopsis

```
tcp -h host -p port -t timeout -z --sourceAddress addr
```

Description

A `tcp` endpoint supports the following options:

Option	Description	Client Semantics	Server Semantics
<code>-h <i>host</i></code>	Specifies the host name or IP address of the endpoint. If not specified, the value of <code>Ice.Default.Host</code> is used instead.	See Address Syntax .	See Address Syntax .
<code>-p <i>port</i></code>	Specifies the port number of the endpoint.	Determines the port to which a connection attempt is made (required).	The port will be selected by the operating system if this option is not specified or <code>port</code> is zero.
<code>-t <i>timeout</i></code>	Specifies the endpoint timeout in milliseconds.	The value for <code>timeout</code> must either be infinite to specify no timeout, or an integer greater than zero representing the <code>timeout</code> in milliseconds used by the client to open or close connections and to read or write data. If a timeout occurs, the application receives <code>Ice::TimeoutException</code> . If this option is not specified, it defaults to the value of <code>Ice.Default.Timeout</code> .	The value for <code>timeout</code> must either be infinite to specify no timeout, or an integer greater than zero representing the timeout in milliseconds used by the server to accept or close connections and to read or write data (see Timeouts in Object Adapter Endpoints and Connection Timeouts). <code>timeout</code> also controls the timeout that is published in proxies created by the object adapter. If this option is not specified, it defaults to the value of <code>Ice.Default.Timeout</code> .
<code>-z</code>	Specifies bzip2 compression.	Determines whether compressed requests are sent.	Determines whether compression is advertised in proxies created by the adapter.
<code>--sourceAddress <i>addr</i></code>	Binds outgoing socket connections to the network interface associated with <code>addr</code> .	The value for <code>addr</code> must be a numeric IPv4 or IPv6 address. If this option is not specified, it defaults to the value of <code>Ice.Default.SourceAddress</code> . This feature is not supported on WinRT.	Not supported

UDP Endpoint Syntax

Synopsis

```
udp -h host -p port -z --ttl TTL --interface INTF --sourceAddress addr
```

Description

A `udp` endpoint supports either unicast or multicast delivery; the address resolved by `host` argument determines the delivery mode. To use multicast in IPv4, select an IP address in the range 233.0.0.0 to 239.255.255.255. In IPv6, use an address that begins with `ff`, such

as `ff01::1:1`.

A `udp` endpoint supports the following options:

Option	Description	Client Semantics	Server Semantics
<code>-h host</code>	Specifies the host name or IP address of the endpoint. If not specified, the value of <code>Ice.Default.Host</code> is used instead.	See Address Syntax .	See Address Syntax .
<code>-p port</code>	Specifies the port number of the endpoint.	Determines the port to which datagrams are sent (required).	The port will be selected by the operating system if this option is not specified or port is zero.
<code>-z</code>	Specifies bzip2 compression.	Determines whether compressed requests are sent.	Determines whether compression is advertised in proxies created by the adapter.
<code>--ttl TTL</code>	Specifies the time-to-live (also known as "hops") of multicast messages.	Determines whether multicast messages are forwarded beyond the local network. If not specified, or the value of <code>TTL</code> is <code>-1</code> , multicast messages are not forwarded. The maximum value is <code>255</code> .	N/A
<code>--interface INTF</code>	Specifies the network interface or group for multicast messages (see below).	Selects the network interface for outgoing multicast messages. If not specified, multicast messages are sent using the default interface.	Selects the network interface to use when joining the multicast group. If not specified, the group is joined on the default network interface.
<code>--sourceAddress addr</code>	Binds outgoing socket connections to the network interface associated with <code>addr</code> .	The value for <code>addr</code> must be a numeric IPv4 or IPv6 address. If this option is not specified, it defaults to the value of <code>Ice.Default.SourceAddress</code> . This feature is not supported on WinRT.	Not supported

Deprecated options

With the 1.0 encoding, UDP endpoints supported 2 additional options: the `-e major.minor` and `-v major.minor` options. These 2 options specified which encoding and protocol was supported by the endpoint. These two options are deprecated with the 1.1 encoding and are ignored (a deprecation warning will be emitted when parsed by the communicator `stringToProxy` method). The supported protocol and encoding is specified on the proxy with the 1.1 encoding.

Multicast Interfaces

When `host` denotes a multicast address, the `--interface INTF` option selects a particular network interface to be used for communication. The format of `INTF` depends on the language and IP version:

- C++ and .NET
`INTF` can be an interface name, such as `eth0`, or an IP address. If using IPv6, it can also be an interface index. Interface names on Windows may contain spaces, such as `Local Area Connection`, therefore they must be enclosed in double quotes.
- Java
`INTF` can be an interface name, such as `eth0`, or an IP address. On Windows, Java maps interface names to Unix-style nicknames.

SSL Endpoint Syntax

Synopsis

```
ssl -h host -p port -t timeout -z --sourceAddress addr
```

Description

An `ssl` endpoint supports the same options as for `tcp` endpoints.

WS Endpoint Syntax

Synopsis

```
ws -r resource -h host -p port -t timeout -z --sourceAddress addr
```

Description

A `ws` (WebSocket) endpoint supports all `tcp endpoint` options in addition to the following:

Option	Description	Client Semantics	Server Semantics
<code>-r resource</code>	A URI specifying the resource associated with this endpoint. If not specified, the default value is <code>/</code> .	The value for <code>resource</code> is passed as the target for <code>GET</code> in the WebSocket upgrade request.	The web server configuration must direct the given <code>resource</code> to this endpoint.

WSS Endpoint Syntax

Synopsis

```
wss -r resource -h host -p port -t timeout -z --sourceAddress addr
```

Description

A `wss` (Secure WebSocket) endpoint supports all `ssl endpoint` options in addition to the following:

Option	Description	Client Semantics	Server Semantics
<code>-r resource</code>	A URI specifying the resource associated with this endpoint. If not specified, the default value is <code>/</code> .	The value for <code>resource</code> is passed as the target for <code>GET</code> in the WebSocket upgrade request.	The web server configuration must direct the given <code>resource</code> to this endpoint.

Opaque Endpoint Syntax

Synopsis

```
opaque -t type -e encoding -v value
```

Description

Proxies can contain endpoints that are not universally understood by Ice processes. For example, a proxy can contain an SSL endpoint; if that proxy is marshaled to a receiver without the IceSSL plug-in, the SSL endpoint does not make sense to the receiver.

Ice preserves such unknown endpoints when they are received over the wire. For the preceding example, if the receiver remarshals the proxy and sends it back to an Ice process that does have the IceSSL plug-in, that process can invoke on the proxy using its SSL transport. This mechanism allows proxies containing endpoints for arbitrary transports to pass through processes that do not understand these endpoints without losing information.

If an Ice process stringifies a proxy containing an unknown endpoint, it writes the endpoint as an opaque endpoint. For example:

```
opaque -t 2 -e 1.0 -v CTEyNy4wLjAuMREnAAD/////AA==
```

This is how a process without the IceSSL plug-in stringifies an SSL endpoint. When a process with the IceSSL plug-in unstringifies this endpoint and converts it back into a string, it produces:

```
ssl -h 127.0.0.1 -p 10001
```

An `opaque` endpoint supports the following options:

Option	Description
<code>-t type</code>	Specifies the transport for the endpoint. Transports are indicated by positive integers (1 for TCP, 2 for SSL, and 3 for UDP).
<code>-e encoding</code>	Specifies the encoding version used to encode the endpoint marshaled data.
<code>-v value</code>	Specifies the marshaled encoding of the endpoint in base-64 encoding.

Exactly one each of the `-t` and `-v` options must be present in an `opaque` endpoint. If `-e` is not specified, the current encoding supported by the Ice runtime is assumed.

Request Contexts

Methods on a proxy are overloaded with a trailing parameter representing a *request context*. The Slice definition of this parameter is as follows:

```

Slice

```
module Ice {
 dictionary<string, string> Context;
};
```

```

As you can see, a context is a dictionary that maps strings to strings or, conceptually, a context is a collection of name-value pairs. The contents of this dictionary (if any) are implicitly marshaled with every request to the server, that is, if the client populates a context with a number of name-value pairs and uses that context for an invocation, the name-value pairs that are sent by the client are available to the server.

On the server side, the operation implementation can access the received `Context` via the `ctx` member of the `Ice::Current` parameter and extract the name-value pairs that were sent by the client.

Context names beginning with an underscore are reserved for use by Ice.

Topics

- [Explicit Request Contexts](#)
- [Per-Proxy Request Contexts](#)
- [Implicit Request Contexts](#)
- [Design Considerations for Request Contexts](#)

See Also

- [The Current Object](#)

Explicit Request Contexts

[Request contexts](#) provide a means of sending an unlimited number of parameters from client to server without having to mention these parameters in the signature of an operation. For example, consider the following definition:

```
Slice
```

```

struct Address {
    // ...
};

interface Person {
    string setAddress(Address a);
    // ...
};

```

Assuming that the client has a proxy to a `Person` object, it could do something along the following lines:

```
C++
```

```

PersonPrx p = ...;
Address a = ...;

Ice::Context ctx;
ctx["write policy"] = "immediate";

p->setAddress(a, ctx);

```

In Java, the same code would look as follows:

```
Java
```

```

PersonPrx p = ...;
Address a = ...;

java.util.Map<String, String> ctx = new java.util.HashMap<String,
String>();
ctx.put("write policy", "immediate");

p.setAddress(a, ctx);

```

In C#, the code is almost identical:

C#

```
using System.Collections.Generic;

PersonPrx p = ...;
Address a = ...;

Dictionary<string, string> ctx = new Dictionary<string, string>();
ctx["write policy"] = "immediate";

p.setAddress(a, ctx);
```

On the server side, we can extract the policy value set from the `Current` object to influence how the implementation of `setAddress` works. A C++ implementation might look like this:

C++

```
void
PersonI::setAddress(const Address& a, const Ice::Current& c)
{
    Ice::Context::const_iterator i = c.ctx.find("write policy");
    if (i != c.ctx.end() && i->second == "immediate") {

        // Update the address details and write through to the
        // data base immediately...

    } else {

        // Write policy was not set (or had a bad value), use
        // some other database write strategy.

    }
}
```

For this example, the server examines the value of the context with the key `"write policy"` and, if that value is `"immediate"`, writes the update sent by the client straight away; if the write policy is not set or contains a value that is not recognized, the server presumably applies a more lenient write policy (such as caching the update in memory and writing it later).

- [The Current Object](#)

Per-Proxy Request Contexts

Instead of passing a context [explicitly](#) with an invocation, you can also use a *per-proxy context*. Per-proxy contexts allow you to set a context on a particular proxy once and, thereafter, whenever you use that proxy to invoke an operation, the previously-set context is sent with each invocation.

On this page:

- [Configuring a Per-Proxy Request Context Programmatically](#)
- [Configuring a Per-Proxy Request Context using Properties](#)

Configuring a Per-Proxy Request Context Programmatically

The proxy methods `ice_context` and `ice_getContext` set and retrieve the context, respectively. The Slice definitions of these methods would look as follows:

Slice
<pre>Object* ice_context(Context ctx); Context ice_getContext();</pre>

`ice_context` creates a new proxy that stores the given context. Calling `ice_getContext` returns the stored context, or an empty dictionary if no per-proxy context has been configured for the proxy.

Here is an example in C++:

C++
<pre>Ice::Context ctx; ctx["write policy"] = "immediate"; PersonPrx p1 = ...; PersonPrx p2 = p1->ice_context(ctx); Address a = ...; p1->setAddress(a); // Sends no context p2->setAddress(a); // Sends ctx implicitly Ice::Context ctx2; ctx2["write policy"] = "delayed"; p2->setAddress(a, ctx2); // Sends ctx2 instead</pre>

As the example illustrates, once we have created the `p2` proxy, any invocation via `p2` automatically sends the configured context. The final line of the example shows that it is also possible to explicitly send a context for an invocation even if the proxy is configured with a context — an explicit context always overrides any per-proxy context.

Note that, once you have set a per-proxy context, that context becomes immutable: if you subsequently change the context you have passed to `ice_context`, such a change does not affect the per-proxy context of any proxies you previously created with that context because each proxy on which you set a per-proxy context stores its own copy of the dictionary.

Configuring a Per-Proxy Request Context using Properties

As of Ice 3.6, you can also configure a context with proxy properties when you use the communicator operation `propertyToProxy`. Suppose we obtain a proxy like this:

C++

```
Ice::CommunicatorPtr communicator = ...;
Ice::ObjectPrx proxy = communicator->propertyToProxy("PersonProxy");
```

We can statically configure a context for this proxy using the following properties:

```
PersonProxy=person:tcp -p 5000
PersonProxy.Context.write policy=immediate
PersonProxy.Context.failure mode=persistent
```

The `Context` property has the form `name.Context.key=value`, where `key` and `value` can be any [legal property symbols](#).

The proxy returned by `propertyToProxy` already contains the context key/value pairs specified in the configuration properties. To make any modifications to the context at run time, you'll need to retrieve the proxy's context dictionary using `ice_getContext`, modify the dictionary as necessary, and finally obtain a new proxy by calling `ice_context`, as we described above.

- [Proxy Methods](#)
- [Proxy Properties](#)

Implicit Request Contexts

On this page:

- [Using Implicit Request Contexts](#)
- [Scope of the Implicit Context](#)

Using Implicit Request Contexts

In addition to [explicit](#) and [per-proxy](#) request contexts, you can also establish an implicit context on a communicator. This implicit context is sent with all invocations made via proxies created by that communicator, provided that you do not supply an explicit context with the call.

Access to this implicit context is provided by the `Communicator` interface:

```

Slice

module Ice {
    local interface Communicator
    {
        ImplicitContext getImplicitContext();

        // ...
    };
};

```

`getImplicitContext` returns the implicit context object. If a communicator has no implicit context, the operation returns null.

You can manipulate the contents of the implicit context via the `ImplicitContext` interface:

```

Slice

local interface ImplicitContext
{
    Context getContext();
    void setContext(Context newContext);

    string get(string key);
    string put(string key, string value);
    string remove(string key);
    bool containsKey(string key);
};

```

The `getContext` operation returns the currently-set context dictionary. The `setContext` operation replaces the currently-set context in its entirety.

The remaining operations allow you to manipulate specific entries:

- `get`
This operation returns the value associated with `key`. If `key` was not previously set, the operation returns the empty string.
- `put`
This operation adds the key-value pair specified by `key` and `value`. It returns the previous value associated with `key`; if no value was previously associated with `key`, it returns the empty string. It is legal to add the empty string as a value.

- `remove`
This operation removes the key-value pair specified by `key`. It returns the previously-set value (or the empty string if `key` was not previously set).
- `containsKey`
This operation returns true if `key` is currently set and false, otherwise. You can use this operation to distinguish between a key-value pair that was explicitly added with an empty string as a value, and a key-value pair that was never added at all.

Scope of the Implicit Context

You establish the implicit context on a communicator by setting a property, `Ice.ImplicitContext`. This property controls whether a communicator has an implicit context and, if so, at what scope the context applies. The property can be set to the following values:

- `None`
With this setting (or if `Ice.ImplicitContext` is not set at all), the communicator has no implicit context, and `getImplicitContext` returns null.
- `Shared`
The communicator has a single implicit context that is shared by all threads. Access to the context via its `ImplicitContext` interface is interlocked, so different threads can concurrently manipulate the context without risking data corruption or reading stale values.
- `PerThread`
The communicator maintains a separate implicit context for each thread. This allows you to propagate contexts that depend on the sending thread (for example, to send per-thread transaction IDs).

Design Considerations for Request Contexts

On this page:

- [Request Context Interactions](#)
- [Request Context Use Cases](#)
- [Recommendations for Request Contexts](#)

Request Context Interactions

If you use [explicit](#), [per-proxy](#), and [implicit](#) contexts, it is important to be aware of their interactions:

- If you send an explicit context with an invocation, *only* that context is sent with the call, regardless of whether the proxy has a per-proxy context and whether the communicator has an implicit context.
- If you send an invocation via a proxy that has a per-proxy context, and the communicator also has an implicit context, the contents of the per-proxy and implicit context dictionaries are combined, so the *combination* of context entries of both contexts is transmitted to the server. If the per-proxy context and the implicit context contain the same key, but with different values, the *per-proxy* value takes precedence.

Request Context Use Cases

The purpose of `Ice::Context` is to permit services to be added to Ice that require some contextual information with every request. Contextual information can be used by services such as a transaction service (to provide the context of a currently established transaction) or a security service (to provide an authorization token to the server). [IceStorm](#) uses the context to provide an optional `cost` parameter to the service that influences how the service propagates messages to down-stream subscribers, and [Glacier2](#) uses the context to influence request routing.

In general, services that require such contextual information can be implemented much more elegantly using contexts because this hides explicit Slice parameters that would otherwise have to be supplied by the application programmer with every call. For a request-forwarding intermediary service such as IceStorm or Glacier2, using a parameter is not an option because the service does not know the signatures of the requests that it is forwarding, but the service does have access to the context. For this use case, the context is a convenient way for the caller to annotate a request.

In addition, contexts, because they are optional, permit a single Slice definition to apply to implementations that use the context, as well as to implementations that do not use it. In this way, to add transactional semantics to an existing service, you do not need to modify the Slice definitions to add an extra parameter to each operation. (Adding an extra parameter would not only be inconvenient for clients, but would also split the type system into two halves: without contexts, we would need different Slice definitions for transactional and non-transactional implementations of (conceptually) a single service.)

Finally, per-proxy contexts permit context information to be passed through intermediate parts of your program without cooperation of those intermediate parts. For example, suppose you set a per-proxy context on a proxy and then pass that proxy to another function. When that function uses the proxy to invoke an operation, the per-proxy context will still be sent. In other words, per-proxy contexts allow you to transparently propagate information via intermediaries that are ignorant of the presence of any context.

Keep in mind though that this works only within a single process. If you stringify a proxy or transmit it as a parameter over the wire, the per-proxy context is *not* preserved. (Ice does not write the per-proxy context into stringified proxies and does not marshal the per-proxy context when a proxy is marshaled.)

Recommendations for Request Contexts

Contexts are a powerful mechanism for transparent propagation of context information, *if used correctly*. In particular, you may be tempted to use contexts as a means of versioning an application as it evolves over time. For example, version 2 of your application may accept two parameters on an operation that, in version 1, used to accept only a single parameter. Using contexts, you could supply the second parameter as a name-value pair to the server and avoid changing the Slice definition of the operation in order to maintain backward compatibility.

We *strongly* urge you to resist any temptation to use contexts in this manner. The strategy is fraught with problems:

- **Missing context**
There is nothing that would compel a client to actually send a context when the server expects to receive a context: if a client forgets to send a context, the server, somehow, has to make do without it (or throw an exception).
- **Missing or incorrect keys**
Even if the client does send a context, there is no guarantee that it has set the correct key. (For example, a simple spelling error can cause the client to send a value with the wrong key.)

- **Incorrect values**

The value of a context is a string, but the application data that is to be sent might be a number, or it might be something more complex, such as a structure with several members. This forces you to encode the value into a string and decode the value again on the server side. Such parsing is tedious and error prone, and far less efficient than sending strongly-typed parameters. In addition, the server has to deal with string values that fail to decode correctly (for example, because of an encoding error made by the client).

None of the preceding problems can arise if you use proper Slice parameters: parameters cannot be accidentally omitted and they are strongly typed, making it much less likely for the client to accidentally send a meaningless value. Furthermore, as of Ice 3.5 you can use [optional parameters](#) to modify the signature of an operation without breaking backward compatibility. For a large-scale solution to application versioning, we recommend using [ICE facets](#).

Contexts are meant to be used to transmit simple tokens (such as a transaction identifier) for services that cannot be reasonably implemented without them; you should restrict your use of contexts to that purpose and resist any temptation to use contexts for any other purpose.

Finally, be aware that, if a request is routed via one or more Ice routers, contexts may be dropped by intermediate routers if they consider them illegal. This means that, in general, you cannot rely on an arbitrary context value that is created by an application to actually still be present when a request arrives at the server — only those context values that are known to routers and that are considered legitimate are passed on. It follows that you should not abuse contexts to pass things that really should be passed as parameters.

Invocation Timeouts

On this page:

- [Overview of Invocation Timeouts](#)
- [Configuring the Default Invocation Timeout](#)
- [Configuring Invocation Timeouts for Proxies](#)
- [Invocation Timeout Failures](#)

Overview of Invocation Timeouts

Invocation timeouts let an application specify the maximum amount of time it's willing to wait for invocations to complete. If the timeout expires, the application receives `InvocationTimeoutException` as the result of an invocation.

Use [connection timeouts](#) to detect network failures in a reasonable period of time.

Invocation timeouts were introduced in Ice 3.6. In earlier Ice versions, connection timeouts were also used as invocation timeouts.

Configuring the Default Invocation Timeout

The property `Ice.Default.InvocationTimeout` establishes the default timeout value for invocations. This property has a default value of `-1`, which means invocations do not time out by default. If defined to `-2`, invocation timeouts are disabled and the Ice run time behaves like Ice versions `< 3.6`: it uses [connection timeouts](#) (defined on the endpoints) to wait for the response of the invocation. This setting is provided only for backward compatibility and might be deprecated in a future Ice major release.

Consider this setting:

```
Ice.Default.InvocationTimeout=5000
```

This configuration causes all invocations to time out if they do not complete within five seconds. Generally speaking however, it's unlikely that a single timeout value will be appropriate for all of the operations that an application invokes. It's more common for applications to configure invocation timeouts on a per-proxy basis, as we describe in the next section.

Configuring Invocation Timeouts for Proxies

You have a couple of options for configuring invocation timeouts at the proxy level:

- Use a proxy property
- Call `ice_invocationTimeout`

Assuming you've defined a configuration property containing a proxy that your application reads using `propertyToProxy`, you can statically configure an invocation timeout as follows:

```
# Assumes the application calls propertyToProxy("MyProxy")
MyProxy=theIdentity:tcp -p 5000
MyProxy.InvocationTimeout=2500 # 2.5 seconds
```

The `InvocationTimeout` proxy property specifies the invocation timeout that will be used for all invocations made via the proxy returned by `propertyToProxy`.

To configure an invocation timeout at run time, use the `ice_invocationTimeout` factory method to obtain a new proxy with the desired timeout:

C++

```
FileSystem::FilePrx myFile = ...;
FileSystem::FilePrx timeoutFile = myFile->ice_invocationTimeout(2500);
// 2.5 seconds
```

Invocation Timeout Failures

An application that configures invocation timeouts must be prepared to catch `InvocationTimeoutException`:

C++

```
FileSystem::FilePrx myFile = ...;
FileSystem::FilePrx timeoutFile = myFile->ice_invocationTimeout(2500);

try {
    Lines text = timeoutFile->read();    // Read with timeout
} catch (const Ice::InvocationTimeoutException &) {
    cerr << "invocation timed out" << endl;
}

Lines text = myFile->read();            // Read without timeout
```

The effects of an invocation timeout are limited to the client; no indication is sent to the server, which may still be busy dispatching the request. The Ice run time in the client ignores a reply for this request if the server eventually sends one.

Ice does **not** perform [automatic retries](#) for invocation timeouts.

Automatic Retries

Ice may automatically retry a proxy invocation after a failure. This is a powerful feature that, when used in the proper situations, can significantly improve the robustness of your application without any additional programming effort. The retry facility is governed by one overriding principle: always respect at-most-once semantics. [At-most-once semantics](#) dictate that the Ice run time in the client must never retry a failed proxy invocation unless Ice guarantees that the server has not already received the request, or unless the application declares that it is safe for Ice to violate at-most-once semantics for the request.

To understand the importance of obeying at-most-once semantics, consider the following Slice definition:

Slice
<pre>interface Account { long withdraw(long amount); };</pre>

The `withdraw` operation removes funds from an account. If an invocation of `withdraw` fails, automatically retrying the request introduces the risk of a duplicate withdrawal unless Ice is absolutely sure that the server has not already executed the request.

This page examines automatic retries in more detail.

On this page:

- [Automatic Retries for Request Failures](#)
- [Automatic Retries for Idempotent Operations](#)
- [Configuring Automatic Retries](#)
 - [Retry Intervals](#)
 - [Retry Logging](#)
- [Timeouts and Automatic Retries](#)
- [Connections and Automatic Retries](#)
 - [Connection Errors](#)
 - [Connection Status](#)

Automatic Retries for Request Failures

Ice considers a request to have failed if any of the following conditions are true:

- A connection could not be established
- A connection was lost before the reply was received
- A timeout expired
- An exception occurred while sending the request or receiving the reply
- An error occurred in the server while dispatching the request that causes the server to return an `UnknownException` or `RequestFailedException`

<p>Ice considers an invocation that results in a user exception to be successful and therefore excludes it from consideration for automatic retries.</p>
--

Ice must determine the answers to several questions to decide whether to retry a failed request:

1. What kind of error caused the request to fail?

Ice does not bother retrying a request if it knows the same error is going to occur again. For example, Ice never retries an invocation that raises a `MarshalException`, which indicates that there was a problem while encoding or decoding a message. Retrying such an invocation is unlikely to change the outcome. It also doesn't retry [invocation timeouts](#), if a server didn't respond within the invocation timeout period, it's unlikely that a retry would provide better results.

Ice also never retries exceptions that derive from `RequestFailedException` because they indicate a permanent failure. One such subclass is `OperationNotExistException`, whose occurrence signals a serious problem in the application. For instance, it might mean that the client and server are using incompatible Slice definitions, or that the client is trying to invoke operations on the wrong object. The exception to this rule is `ObjectNotExistException`, which Ice does consider to be worthy of retry if the proxy in question is `indirect` because it gives an application the ability to transparently migrate an Ice object.

In addition to user exceptions and subclasses of `RequestFailedException`, a server can also return an instance of `UnknownException`, `UnknownLocalException`, or `UnknownUserException` to indicate that it encountered an unexpected exception while dispatching the request. These exceptions *are* eligible for retry.

2. When did the error occur?

If the error is still a candidate for retry, Ice needs to know whether the server has received the request. Naturally, the Ice run time in the client cannot possibly know that information until the server confirms it by sending a reply. However, to be conservative Ice assumes that the server has received the request as soon as Ice has written the *entire* protocol message to the client's local transport buffers. If the error occurred before Ice managed to write the complete message, retrying the request would not violate at-most-once semantics.

The Ice run time in the server also has the ability to notify the client that a request was not dispatched and therefore that it is safe for the Ice run time in the client to retry the request without violating at-most-once semantics. For example, this situation can occur when the server is shutting down while there are pending requests that have yet to be executed. Sending this notification allows a client to transparently fail over to another server.

3. Does the application require strict adherence to at-most-once semantics for this request?

An application can grant permission for Ice to violate at-most-once semantics for certain Slice operations by marking them as *idempotent*, causing Ice to retry a request that otherwise would be ineligible because the server has already received it. We discuss idempotent operations in more detail [below](#).

If Ice determines that an invocation cannot be retried, it raises the exception that caused the request failure to the application. On the other hand, if Ice does retry the invocation and the subsequent retries also fail, Ice raises the *last* exception to the application. For example, if the first attempt fails with `ConnectionRefusedException` and the retry fails with `ConnectTimeoutException`, the invocation raises `ConnectTimeoutException` to the application.

Automatic Retries for Idempotent Operations

Annotating a Slice operation with the `idempotent` keyword notifies Ice that it can safely violate at-most-once semantics:

```

Slice
interface Account
{
    long withdraw(long amount);
    idempotent long getBalance();
};

```

Although `withdraw` clearly requires the stricter treatment, there is no harm in automatically retrying the `getBalance` operation even if the server executes the same request more than once.

In general, "read-only" operations are good candidates for the `idempotent` keyword whereas many mutating operations are not. However, the risk of duplicate requests is acceptable even for some kinds of mutating operations:

```

Slice
interface Account
{
    long withdraw(long amount);
    idempotent long getBalance();
    idempotent void changeAddress(string newAddress);
};

```

Here we have marked `changeAddress` as idempotent because executing the request twice has the same effect as executing it only once.

The benefit of the `idempotent` keyword and the associated relaxation of retry semantics is that an invocation that otherwise might have raised an exception has at least one more chance to succeed. Furthermore, the application does not need to initiate the retry, and in fact the retry activities are completely transparent: if a subsequent retry succeeds, the application receives its results as if nothing went wrong. The

invocation only raises an exception once Ice has reached its configured retry limits.

Configuring Automatic Retries

Retry Intervals

The `Ice.RetryIntervals` property configures the retry behavior for a communicator and affects invocations on every proxy created by that communicator. (Retry behavior cannot be configured on a per-proxy basis.) The value of this property consists of a series of integers separated by whitespace. The number of integers determines how many retry attempts Ice makes, and the value of each entry represents a delay in milliseconds. If this property is not defined, the default behavior is to retry once immediately after the first failure, which is equivalent to the following property definition:

```
Ice.RetryIntervals=0
```

You may want a more elaborate configuration for your application, such as a gradual increase in the delay between retries:

```
Ice.RetryIntervals=0 100 500 1000
```

With this setting, Ice retries immediately as in the default case. If the first retry attempt also fails, Ice waits 100 milliseconds before trying again, then 500 milliseconds, and finally tries one more time after waiting one second.

In some situations you may need to disable retries completely. For example, an application might implement its own retry logic and therefore require immediate notification when a failure occurs. Clients that establish a session with a [Glacier2 router](#) also need to disable retries. To prevent automatic retries, use a value of `-1`:

```
Ice.RetryIntervals=-1
```

Retry Logging

To monitor Ice's retry activities, configure your program with the property `Ice.Trace.Retry` set to a non-zero value:

```
Ice.Trace.Retry=1
```

When retry tracing is enabled, Ice logs a message each time it attempts a retry; the log message includes a description of the exception that prompted the retry. Ice also logs a message when it reaches the retry limit.

You can configure Ice to log even more information about retries by setting the property to 2:

```
Ice.Trace.Retry=2
```

This setting prompts Ice to include additional details about connections and endpoints.

Timeouts and Automatic Retries

If a proxy invocation fails due to a [connection timeout](#), the application must be prepared for Ice to raise a `TimeoutException`. However, a developer that is testing connection timeouts in an application may be initially confused to discover that it's taking twice as long as expected for Ice to raise the exception. Automatic retries are usually the reason for this situation.

For example, suppose that a proxy is configured with a ten seconds connection timeout and automatic retries are enabled with the default setting. If an invocation on that proxy fails due to a connection timeout and Ice determines that the invocation is eligible for retry (using the criteria described [above](#)), Ice immediately tries the invocation again and waits for another connection timeout period to expire before finally raising `TimeoutException`. From the application's perspective, the invocation fails after approximately twenty seconds.

Consequently, you can compute an approximate worst-case connection timeout value as follows:

$$T = t * (N + 1) + D$$

where t is the connection timeout value, N is the number of retry intervals, and D is the sum of the retry intervals (the total delay between retries). Consider our example again:

```
Ice.RetryIntervals=0 10000 20000 30000
```

Using this configuration with a ten second connection timeout, our approximate worst-case timeout is $10 * 5 + 60 = 110$ seconds.

Connections and Automatic Retries

The behavior of automatic retries is intimately tied to the presence (and absence) of connections. This section describes the errors that cause Ice to close connections, and provides more details about how connections influence retries.

Connection Errors

Ice automatically closes a connection in response to certain fatal error conditions. Of these, the one that is the most likely to affect Ice applications is a [connection timeout](#). Other errors that prompt Ice to close a connection include the following:

- a socket failure while performing I/O on the connection
- receiving an improperly formatted message
- dispatching an operation to a Java servant raises `OutOfMemoryError` or `AssertionError`

When Ice closes a connection in response to one of these errors, all other outstanding requests on the same connection also fail and may be retried if eligible.

Connection Status

One factor that influences retry behavior is the status of the connection on which the failed request was attempted. If the failure caused Ice to close the connection (as discussed in the previous section), or if the request failed because Ice could not [establish a connection](#), Ice must try to obtain another connection before it can retry the request.

It is also important to understand that Ice may not retry the invocation on the original endpoint *even if the connection that was used for the initial request remains open*. The retry behavior in this case depends on several criteria:

- whether the proxy [caches its connection](#)
- whether the proxy contains [multiple endpoints](#)
- whether other connections exist to any of the proxy's endpoints
- the proxy's configured [endpoint selection type](#)

Generally speaking, you must configure your application carefully if you need fine-grained control over Ice's retry behavior.

Oneway Invocations

On this page:

- [Design Considerations for Oneway Invocations](#)
- [Creating Oneway Proxies](#)

Design Considerations for Oneway Invocations

A [oneway invocation](#) is sent on the client side by writing the request to the client's local transport buffers; the invocation completes and returns control to the application code as soon as it has been accepted by the local transport. Of course, this means that a oneway invocation is unreliable: it may never be sent (for example, because of a network failure) or it may not be accepted in the server (for example, because the target object does not exist).

This is an issue in particular if you use [Active Connection Management](#) (ACM): if a server closes a connection at the wrong moment, it's possible for the client to lose already-buffered oneway requests. If your client uses oneway (or [batched oneway](#)) requests, we recommend that you either disable ACM for the server side, or enable ACM heartbeats in the client to ensure the connection remains active. In addition, if clients use oneway requests and your application initiates server shutdown, it is the responsibility of your application to ensure either that it can cope with the potential loss of buffered oneway requests, or that it does not shut down the server at the wrong moment (while clients still have oneway requests that are buffered, but not yet sent).

If anything goes wrong with a oneway request, the client-side application code does not receive any notification of the failure; the only errors that are reported to the client are local errors that occur on the client side during call invocation (such as failure to establish a connection, for example).

As a consequence of oneway invocation, if you call `ice_ping` on a oneway proxy, successful completion does *not* indicate that the target object exists and could successfully be contacted — you will receive an exception only if something goes wrong on the client side, but not if something goes wrong on the server side. Therefore, if you want to use `ice_ping` with a oneway proxy and be certain that the target object exists and can successfully be contacted, you must first convert the oneway proxy into a twoway proxy. For example, in C++:

```

C++

SomeObjectPrx onewayPrx = ...; // Get a oneway proxy

try {
    onewayPrx->ice_twoway()->ice_ping();
} catch(const Ice::Exception&)
    cerr << "object not reachable" << endl;
}
```

Oneway invocations are received and processed on the server side like any other incoming request. If necessary, a server can distinguish a oneway invocation by examining the `requestId` member of `Ice::Current`: a non-zero value denotes a twoway request, whereas a value of zero indicates a oneway request.

Oneway invocations do not incur any return traffic from the server to the client: the server never sends a [reply message](#) in response to a oneway invocation. This means that oneway invocations can result in large efficiency gains, especially for large numbers of small messages, because the client does not have to wait for the reply to each message to arrive before it can send the next message.

In order to be able to invoke an operation as oneway, two conditions must be met:

- The operation must have a `void` return type, must not have any out-parameters, and must not have an exception specification.

This requirement reflects the fact that the server does not send a reply for a oneway invocation to the client: without such a reply, there is no way to return any values or exceptions to the client. If you attempt to invoke an operation that returns values to the client as a oneway operation, the Ice run time throws a `TwowayOnlyException`.

- The proxy on which the operation is invoked must support a stream-oriented transport (such as TCP or SSL).

Oneway invocations require a stream-oriented transport. (To get something like a oneway invocation for datagram transports, you need to use a [datagram invocation](#).) If you attempt to create a oneway proxy for an object that does not offer a stream-oriented transport, the Ice run time throws a `NoEndpointException`.

Despite their theoretical unreliability, in practice, oneway invocations are reliable (but not infallible [1]): they are sent via a stream-oriented

transport, so they cannot get lost except when the connection is [shutting down](#) or fails entirely. In particular, the transport uses its usual flow control, so the client cannot overrun the server with messages. On the client-side, the Ice run time will block if the client's transport buffers fill up, so the client-side application code cannot overrun its local transport.

Consequently, oneway invocations normally do not block the client-side application code and return immediately, provided that the client does not consistently generate messages faster than the server can process them. If the rate at which the client invokes operations exceeds the rate at which the server can process them, the client-side application code will eventually block in an operation invocation until sufficient room is available in the client's transport buffers to accept the invocation. If your application requires that oneway requests never block the calling thread, you can use asynchronous oneway invocations instead.

Regardless of whether the client exceeds the rate at which the server can process incoming oneway invocations, the execution of oneway invocations in the server proceeds asynchronously: the client's invocation completes before the message even arrives at the server.

One thing you need to keep in mind about oneway invocations is that they may appear to be reordered in the server: because oneway invocations are sent via a stream-oriented transport, they are guaranteed to be received in the order in which they were sent. However, the server's [thread pool](#) may dispatch each invocation in its own thread; because threads are scheduled preemptively, this may cause an invocation sent later by the client to be dispatched and executed before an invocation that was sent earlier. If oneway requests must be dispatched in order, you can use one of the serialization techniques described in [Thread Pool Design Considerations](#).

For these reasons, oneway invocations are usually best suited to simple updates that are otherwise stateless (that is, do not depend on the surrounding context or the state established by previous invocations).

Creating Oneway Proxies

Ice selects between twoway, oneway, and [datagram invocations](#) via the proxy that is used to invoke the operation. By default, all proxies are created as twoway proxies. To invoke an operation as oneway, you must create a new proxy configured specifically for oneway invocations. The `ice_oneway` [factory method](#) is provided for this purpose. The Slice definition of `ice_oneway` would look as follows:

Slice
<pre>Object* ice_oneway();</pre>

We can call `ice_oneway` to create a oneway proxy and then use the proxy to invoke an operation as follows:

C++

```

Ice::ObjectPrx o = communicator->stringToProxy(/* ... */);

// Get a oneway proxy.
//
Ice::ObjectPrx oneway;
try {
    oneway = o->ice_oneway();
} catch (const Ice::NoEndpointException&) {
    cerr << "No endpoint for oneway invocations" << endl;
}

// Down-cast to actual type.
//
PersonPrx onewayPerson = PersonPrx::uncheckedCast(oneway);

// Invoke an operation as oneway.
//
try {
    onewayPerson->someOp();
} catch (const Ice::TwowayOnlyException&) {
    cerr << "someOp() is not oneway" << endl;
}

```

Note that we use an `uncheckedCast` to down-cast the proxy from `ObjectPrx` to `PersonPrx`: for a oneway proxy, we cannot use a `checkedCast` because a `checkedCast` requires a reply from the server but, of course, a oneway proxy does not permit that reply. If instead you want to use a safe down-cast, you can first down-cast the twoway proxy to the actual object type and then obtain the oneway proxy:

C++

```

Ice::ObjectPrx o = communicator->stringToProxy(/* ... */);

// Safe down-cast to actual type.
//
PersonPrx person = PersonPrx::checkedCast(o);

if (person) {
    // Get a oneway proxy.
    //
    PersonPrx onewayPerson;
    try {
        onewayPerson = person->ice_oneway();
    } catch (const Ice::NoEndpointException&) {
        cerr << "No endpoint for oneway invocations" << endl;
    }

    // Invoke an operation as oneway.
    //
    try {
        onewayPerson->someOp();
    } catch (const Ice::TwowayOnlyException&) {
        cerr << "someOp() is not oneway" << endl;
    }
}

```

Note that, while the second version of this code is somewhat safer (because it uses a safe down-cast), it is also slower (because the safe down-cast incurs the cost of an additional twoway message).

Datagram Invocations

On this page:

- [Design Considerations for Datagram Invocations](#)
- [Creating Datagram Proxies](#)
- [Using UDP Multicast](#)

Design Considerations for Datagram Invocations

Datagram invocations are the equivalent of **oneway invocations** for datagram transports. As for oneway invocations, datagram invocations can be sent only for operations that have a `void` return type and do not have out-parameters or an exception specification. Attempts to use a datagram invocation with an operation that does not meet these criteria result in a `TwowayOnlyException`. In addition, datagram invocations can only be used if the proxy's endpoints include at least one UDP transport; otherwise, the Ice run time throws a `NoEndpointException`.

The semantics of datagram invocations are similar to oneway invocations: no return traffic flows from the server to the client and proceed asynchronously with respect to the client; a datagram invocation completes as soon as the client's transport has accepted the invocation into its buffers. However, datagram invocations differ in one respect from oneway invocations in that datagram invocations optionally support multicast semantics. Furthermore, datagram invocations have additional error semantics:

- Individual invocations may be lost or received out of order.

On the wire, datagram invocations are sent as true datagrams, that is, individual datagrams may be lost, or arrive at the server out of order. As a result, not only may operations be dispatched out of order, an individual invocation out of a series of invocations may be lost. (This cannot happen for oneway invocations because, if a connection fails, *all* invocations are lost once the connection breaks down.)

- UDP packets may be duplicated by the transport.

Because of the nature of UDP routing, it is possible for datagrams to arrive in duplicate at the server. This means that, for datagram invocations, Ice does *not* guarantee **at-most-once semantics**: if UDP datagrams are duplicated, the same invocation may be dispatched more than once in the server.

- UDP packets are limited in size.

The maximum size of an IP datagram is 65,535 bytes. Of that, the IP header consumes 20 bytes, and the UDP header consumes 8 bytes, leaving 65,507 bytes as the maximum payload. If the marshaled form of an invocation, including the Ice **request header** exceeds that size, the invocation is lost. (Exceeding the size limit for a UDP datagram is indicated to the application by a `DatagramLimitException`.)

Because of their unreliable nature, datagram invocations are best suited to simple update messages that are otherwise stateless. In addition, due to the high probability of loss of datagram invocations over wide area networks, you should restrict use of datagram invocations to local area networks, where they are less likely to be lost. (Of course, regardless of the probability of loss, you must design your application such that it can tolerate lost or duplicated messages.)

Creating Datagram Proxies

To invoke an operation as datagram, you must create a new proxy configured specifically for datagram invocations. The `ice_datagram` **factory method** is provided for this purpose. The Slice definition of `ice_datagram` would look as follows:

Slice

```
Object* ice_datagram();
```

We can call `ice_datagram` to create a oneway proxy and then use the proxy to invoke an operation as follows:

C++

```

Ice::ObjectPrx o = communicator->stringToProxy(/* ... */);

// Get a datagram proxy.
//
Ice::ObjectPrx datagram;
try {
    datagram = o->ice_datagram();
} catch (const Ice::NoEndpointException&) {
    cerr << "No endpoint for datagram invocations" << endl;
}

// Down-cast to actual type.
//
PersonPrx datagramPerson = PersonPrx::uncheckedCast(datagram);

// Invoke an operation as a datagram.
//
try {
    datagramPerson->someOp();
} catch (const Ice::TwowayOnlyException&) {
    cerr << "someOp() is not oneway" << endl;
}

```

As for the [oneway example](#), you can alternatively choose to first do a safe down-cast to the actual type of interface and then obtain the datagram proxy, rather than relying on an unsafe down-cast, as shown above. However, doing so may be disadvantageous for two reasons:

- Safe down-casts are sent via a stream-oriented transport. This means that using a safe down-cast will result in opening a connection for the sole purpose of verifying that the target object has the correct type. This is expensive if all the other traffic to the object is sent via datagrams.
- If the proxy does not offer a stream-oriented transport, the `checkedCast` fails with a `NoEndpointException`, so you can use this approach only for proxies that offer both a UDP endpoint and a TCP/IP and/or SSL endpoint.

Using UDP Multicast

The UDP transport included in Ice for C++, Java and .NET also supports IP multicast. Assuming it's enabled on your host, using IP multicast in your application can be as simple as changing the host in the UDP endpoint to an IPv4 or IPv6 address in the multicast range:

```

# Object Adapter endpoint:
Discover.Endpoints=udp -h 239.255.1.1 -p 10000

# Corresponding proxy endpoint:
Discover.Proxy=discover:udp -h 239.255.1.1 -p 10000

```

You can optionally select the network interface to use for multicast endpoints by including the `--interface` option.

In one respect, using multicast in Ice is no different than using regular datagram invocations; all of the [design considerations](#) mentioned above still apply. However, the fact that there could be any number of listeners (or none at all) adds new possibilities for your application

design. The Ice distribution includes a simple example of a multicast application in `demo/Ice/multicast`.

Consider using the [IceDiscovery](#) plug-in if your objective in using multicast is the discovery of available servers.

- [Terminology](#)
- [Oneway Invocations](#)
- [The Ice Protocol](#)

Batched Invocations

Oneway and **datagram** invocations are normally sent as individual messages, that is, the Ice run time sends the oneway or datagram invocation to the server immediately, as soon as the client makes the call. If a client sends a number of oneway or datagram invocations in succession, the client-side run time traps into the OS kernel for each message, which is expensive. In addition, each message is sent with its own **message header**, that is, for N messages, the bandwidth for N message headers is consumed. In situations where a client sends a number of oneway or datagram invocations, the additional overhead can be considerable.

To avoid the overhead of sending many small messages, you can send oneway and datagram invocations in a batch: instead of being sent as a separate message, a batch invocation is placed into a client-side buffer by the Ice run time. Successive batch invocations are added to the buffer and accumulated on the client side until they are flushed, either explicitly by the client or automatically by the Ice run time.

On this page:

- [Compressing Batched Invocations](#)
- [Active Connection Management and Batched Invocations](#)
- [Batched Invocation Interceptors](#)

Proxy Methods for Batched Invocations

Several **proxy methods** support the use of batched invocations. In Slice, these methods would look as follows:

Slice
<pre>Object* ice_batchOneway(); Object* ice_batchDatagram(); void ice_flushBatchRequests();</pre>

The `ice_batchOneway` and `ice_batchDatagram` methods create a new proxy configured for batch invocations. Once you obtain a batch proxy, messages sent via that proxy are buffered by the proxy instead of being sent immediately. Once the client has invoked one or more operations on a batch proxy, it can call `ice_flushBatchRequests` to explicitly flush the batched invocations. This causes the batched messages to be sent "in bulk", preceded by a single message header. On the server side, batched messages are dispatched by a single thread, in the order in which they were written into the batch. This means that messages from a single batch cannot appear to be reordered in the server. Moreover, either all messages in a batch are delivered or none of them. (This is true even for batched datagrams.)

Asynchronous versions of `ice_flushBatchRequests` are also available; see the relevant language mapping for more information.

As of Ice 3.6, batched invocations are queued by the proxy on which the request was invoked (this is true for all proxies except **fixed proxies**). It's important to be aware of this behavior for several reasons:

- Batched invocations queued on a proxy will be lost if that proxy is deallocated prior to being flushed
- Proxy instances maintain separate queues even if they refer to the same target object
- Using proxy **factory methods** may (or may not) create new proxy instances, which affects how batched invocations are queued. Consider this example:

C++

```
Ice::CommunicatorPtr comm = ...;
Ice::ObjectPrx batch =
comm->stringToProxy("...")->ice_batchOneway(); // Creates a batch
oneway proxy
Ice::ObjectPrx secureBatch = batch->ice_secure(); // Might create a
new proxy instance
batch->ice_ping();
secureBatch->ice_ping();
batch->ice_flushBatchRequests(); // Might also flush requests on
secureBatch
```

At run time, the `batch` and `secureBatch` variables might refer to the same proxy instance or two separate proxy instances, depending on the original stringified proxy's configuration. As a result, flushing requests using one variable may or may not flush the requests of the other.

Calling `ice_flushBatchRequests` on a proxy behaves like a oneway invocation in that **automatic retries** take place and an exception is raised if an error occurs while establishing a connection or sending the batch message.

Automatically Flushing Batched Invocations

The default behavior of the Ice run time, as governed by the configuration property `Ice.BatchAutoFlushSize`, automatically flushes batched invocations as soon as a batched request causes the accumulated message to exceed the specified limit. When this occurs, the Ice run time immediately flushes the existing batch of requests and begins a new batch with this latest request as its first element.

For batched oneway invocations, the value of `Ice.BatchAutoFlushSize` specifies the maximum message size in kilobytes; the default value is 1MB. In the case of batched datagram invocations, the maximum message size is the smaller of the system's maximum size for datagram packets and the value of `Ice.BatchAutoFlushSize`.

The receiver's setting for `Ice.MessageSizeMax` determines the maximum size that the Ice run time will accept for an incoming protocol message. The sender's setting for `Ice.BatchAutoFlushSize` must not exceed this limit, otherwise the receiver will silently discard the entire batch.

Automatic flushing is enabled by default as a convenience for clients to ensure a batch never exceeds the configured limit. A client can track batch request activity, and even implement its own auto-flush logic, by installing an **interceptor**.

Batched Invocations for Fixed Proxies

A *fixed proxy* is a special form of proxy that an application explicitly creates for use with a specific **bidirectional connection**. Batched invocations on a fixed proxy are not queued by the proxy, as is the case for regular proxies, but rather by the connection associated with the fixed proxy. Automatic flushing continues to work as usual for batched invocations on fixed proxies, and you have three options for manually flushing:

- Calling `ice_flushBatchRequests` on a fixed proxy flushes all batched requests queued by its connection; this includes batched requests from other fixed proxies that share the same connection
- Calling `Connection::flushBatchRequests` flushes all batched requests queued by the target connection
- Calling `Communicator::flushBatchRequests` flushes all batched requests on all connections associated with the target communicator

As of Ice 3.6, `Connection::flushBatchRequests` and `Communicator::flushBatchRequests` have no effect on batched requests queued by regular (non-fixed) proxies.

The synchronous versions of `flushBatchRequests` block the calling thread until the batched requests have been successfully written to

the local transport. To avoid the risk of blocking, you must use the asynchronous versions instead (assuming they are supported by your chosen language mapping).

Note the following limitations in case a connection error occurs:

- Any requests queued by that connection are lost
- Automatic retries are not attempted
- The proxy method `ice_flushBatchRequests` and `Connection::flushBatchRequests` will raise an exception, but `Communicator::flushBatchRequests` ignores any errors

`Connection::flushBatchRequests` and `Communicator::flushBatchRequests` always send the batched requests without compression. To send a batch of fixed-proxies request with compression, you need to call `ice_flushBatchRequests` on a fixed proxy created with `ice_compress(true)`, for example:

```

C++
fixedPrx->ice_compress(true)->ice_flushBatchRequests();
```

Considerations for Batched Datagrams

For batched datagram invocations, you need to keep in mind that, if the data for the invocations in a batch substantially exceeds the PDU size of the network, it becomes increasingly likely for an individual UDP packet to get lost due to fragmentation. In turn, loss of even a single packet causes the entire batch to be lost. For this reason, batched datagram invocations are most suitable for simple interfaces with a number of operations that each set an attribute of the target object (or interfaces with similar semantics). Batched oneway invocations do not suffer from this risk because they are sent over stream-oriented transports, so individual packets cannot be lost.

If automatic flushing is enabled, Ice's default behavior uses the smaller of `Ice.BatchAutoFlushSize` and `Ice.UDP.SndSize` to determine the maximum size for a batch datagram message.

Compressing Batched Invocations

Batched invocations are more efficient if you also enable [compression](#) for the transport: many isolated and small messages are unlikely to compress well, whereas batched messages are likely to provide better compression because the compression algorithm has more data to work with.

Regardless of whether you used batched messages or not, you should enable compression only on lower-speed links. For high-speed LAN connections, the CPU time spent doing the compression and decompression is typically longer than the time it takes to just transmit the uncompressed data.

Active Connection Management and Batched Invocations

As for [oneway invocations](#), server-side [Active Connection Management \(ACM\)](#) can interfere with batched invocations over TCP or TCP-based transports (SSL, WebSocket, etc.). With server-side ACM enabled, it's possible for a server to close the connection at the wrong moment and not process a batch – with no indication being returned to the client that the batch was lost. We recommend that you either disable ACM for the server side, or enable ACM heartbeats in the client to ensure the connection remains active.

Batched Invocation Interceptors

Ice 3.6 added a batch interceptor API that allows you to implement your own auto-flush algorithm or receive notification when an auto-flush fails. We present the C++ API below (the API for other languages is very similar):

C++

```

namespace Ice {
class BatchRequest {
public:
    virtual void enqueue() const = 0;
    virtual int getSize() const = 0;
    virtual const std::string& getOperation() const = 0;
    virtual const Ice::ObjectPrx& getProxy() const = 0;
};

class BatchRequestInterceptor : public IceUtil::Shared {
public:
    virtual void enqueue(const BatchRequest& req, int count, int size) =
    0;
};
typedef IceUtil::Handle<BatchRequestInterceptor>
BatchRequestInterceptorPtr;

// C++11 only:
BatchRequestInterceptorPtr
newBatchRequestInterceptor(const std::function<void (const
BatchRequest&, int, int)>&);
}

```

You install an interceptor by setting the `batchRequestInterceptor` member of the `InitializationData` object that the application constructs when [initializing a new communicator](#):

C++

```

namespace Ice {
struct InitializationData {
    ...
    BatchRequestInterceptorPtr batchRequestInterceptor;
};
}

```

The Ice run time invokes the `enqueue` method on the interceptor for each batch request, passing the following arguments:

- `req` - An object representing the batch request being queued
- `count` - The number of requests currently in the queue
- `size` - The number of bytes consumed by the requests currently in the queue

The request represented by `req` is not included in the `count` and `size` figures.

A batch request is not queued until the interceptor calls `BatchRequest::enqueue`. The minimal interceptor implementation is therefore:

C++

```
class BatchRequestInterceptorI : public Ice::BatchRequestInterceptor {
public:
    virtual void enqueue(const BatchRequest& req, int count, int size)
    {
        req.enqueue();
    }
};
```

A more sophisticated implementation might use its own logic for automatically flushing queued requests:

C++

```
class BatchRequestInterceptorI : public Ice::BatchRequestInterceptor {
public:
    BatchRequestInterceptorI(const Ice::CommunicatorPtr& communicator)
    {
        _limit =
communicator->getProperties()->getPropertyAsIntWithDefault("Ice.BatchAutoFlushSize", 1024);
        _limit *= 1024; // Convert to bytes
    }

    virtual void enqueue(const BatchRequest& req, int count, int size)
    {
        if(size + req.getSize() > _limit)
            req.getProxy()->begin_ice_flushBatchRequests(
                [=](const Ice::Exception& ex) { /* Handle error */ },
                [=](bool sentSynchronously) { /* Sent callback */ });

        req.enqueue();
    }

private:
    int _limit;
};
```

In this example, the implementation consults the existing Ice property `Ice.BatchAutoFlushSize` to determine the limit that triggers an automatic flush. If a flush is necessary, the interceptor can obtain the relevant proxy by calling `getProxy` on the `BatchRequest` object.

Specifying your own exception handler when calling `begin_ice_flushBatchRequests` gives you the ability to take action if a failure occurs (Ice's default automatic flushing implementation ignores any errors). Aside from logging a message, your options are somewhat limited because it's not possible for the interceptor to force a retry.

For datagram proxies, we strongly recommend using a maximum queue size that is smaller than the network MTU to minimize the risk that datagram fragmentation could cause an entire batch to be lost.

Object Adapters

A communicator contains one or more object adapters. An object adapter sits at the boundary between the Ice run time and the server application code and has a number of responsibilities:

- Maps Ice objects to servants for incoming requests and dispatches the requests to the application code in each servant (that is, an object adapter implements an up-call interface that connects the Ice run time and the application code in the server).
- Assists in life cycle operations so Ice objects and servants can be created and existing destroyed without race conditions.
- Provides one or more transport endpoints. Clients access the Ice objects provided by the adapter via those endpoints. (It is also possible to create an object adapter without endpoints. In this case the adapter is used for [bidirectional callbacks](#).)

Each object adapter has one or more servants that incarnate Ice objects, as well as one or more transport endpoints. If an object adapter has more than one endpoint, all servants registered with that adapter respond to incoming requests on any of the endpoints. In other words, if an object adapter has multiple transport endpoints, those endpoints represent alternative communication paths to the same set of objects (for example, via different transports).

Each object adapter belongs to exactly one communicator (but a single communicator can have many object adapters). Each object adapter has a name that distinguishes it from all other object adapters in the same communicator.

Each object adapter can optionally have its own [thread pool](#), enabled via the `<adapter-name>.ThreadPool.Size` property. If so, client invocations for that adapter are dispatched in a thread taken from the adapter's thread pool instead of using a thread from the communicator's server thread pool.

[Servants](#) are the physical manifestation of an Ice object, that is, they are entities that are implemented in a concrete programming language and instantiated in the server's address space. Servants provide the server-side behavior for operation invocations sent by clients. The same servant can be registered with one or more object adapters.

The Active Servant Map

Each object adapter maintains a data structure known as the active servant map.

On this page:

- [Role of the Active Servant Map](#)
- [Design Considerations for the Active Servant Map](#)

Role of the Active Servant Map

The *active servant map* (or *ASM*, for short) is a lookup table that maps object identities to servants: for C++, the lookup value is a smart pointer to the corresponding servant's location in memory; for Java and C#, the lookup value is a reference to the servant. When a client sends an operation invocation to the server, the request is targeted at a specific transport endpoint. Implicitly, the transport endpoint identifies the object adapter that is the target of the request (because no two object adapters can be bound to the same endpoint). The proxy via which the client sends its request contains the [object identity](#) for the corresponding object, and the client-side run time sends this object identity over the wire with the invocation. In turn, the object adapter uses that object identity to look in its ASM for the correct servant to dispatch the call to, as shown below:

Binding a request to the correct servant.

The process of associating a request via a proxy to the correct servant is known as *binding*. The scenario depicted in the illustration shows direct binding, in which the transport endpoint is embedded in the proxy. Ice also supports an indirect binding mode, in which the correct transport endpoints are provided by a [location service](#).

If a client request contains an object identity for which there is no entry in the adapter's ASM, the adapter returns an `ObjectNotExistException` to the client (unless you use a [default servant](#) or [servant locator](#)).

Design Considerations for the Active Servant Map

Using an adapter's ASM to map Ice objects to servants has a number of design implications:

- Each Ice object is represented by a different servant.

It is possible to register a single servant with multiple identities. However, there is little point in doing so because a [default servant](#) achieves the same thing.

- All servants for all Ice objects are permanently in memory.

Using a separate servant for each Ice object in this fashion is common to many server implementations: the technique is simple to implement and provides a natural mapping from Ice objects to servants. Typically, on start-up, the server instantiates a separate servant for each Ice object, activates each servant, and then calls `activate` on the object adapter to start the flow of requests.

There is nothing wrong with the above design, provided that two criteria are met:

1. The server has sufficient memory available to keep a separate servant instantiated for each Ice object at all times.
2. The time required to initialize all the servants on start-up is acceptable.

For many servers, neither criterion presents a problem: provided that the number of servants is small enough and that the servants can be initialized quickly, this is a perfectly acceptable design. However, the design does not scale well: the memory requirements of the server grow linearly with the number of Ice objects so, if the number of objects gets too large (or if each servant stores too much state), the server runs out of memory.

Ice offers two APIs that help you scale servers to larger numbers of objects: *servant locators* and *default servants*. A *default servant* is essentially a simplified version of a *servant locator* that satisfies the majority of use cases, whereas a servant locator provides more flexibility for those applications that require it.

Creating an Object Adapter

An object adapter is an instance of the local interface `ObjectAdapter`. You create an object adapter by calling one of several operations on a communicator:

Slice

```

module Ice {
    local interface ObjectAdapter {
        string getName();
        Communicator getCommunicator();

        // ...
    };

    local interface Communicator {
        ObjectAdapter createObjectAdapter(string name);
        ObjectAdapter createObjectAdapterWithEndpoints(string name,
string endpoints);
        ObjectAdapter createObjectAdapterWithRouter(string name, Router*
rtr);

        // ...
    };
};

```

The `ObjectAdapter` operations behave as follows:

- The `getName` operation returns the name of the adapter as passed to one of the [communicator operations](#) `createObjectAdapter`, `createObjectAdapterWithEndpoints`, or `createObjectAdapterWithRouter`.
- The `getCommunicator` operation returns the communicator that was used to create the adapter.

Note that there are other operations in the `ObjectAdapter` interface; we will explore these throughout the remainder of this discussion.

An application normally needs to configure an object adapter with [endpoints](#) or a [router](#). Calling `createObjectAdapter` with a non-empty value for `name` means the new object adapter will check the communicator's configuration for [properties](#), including:

- `name.Endpoints` - defines one or more object adapter endpoints
- `name.Router` - specifies the stringified proxy of a router

`createObjectAdapter` raises an exception if neither is defined. Passing an empty value for `name` to `createObjectAdapter` creates an object adapter that can only be used for [collocated invocations](#).

The `createObjectAdapterWithEndpoints` operation allows you to specify the object adapter's endpoints directly, overriding any setting for `name.Endpoints`. Similarly, `createObjectAdapterWithRouter` accepts a router proxy and overrides `name.Router`.

Servant Activation and Deactivation

The term *servant activation* refers to making the presence of a servant for a particular Ice object known to the Ice run time. Activating a servant adds an entry to the [Active Servant Map](#) (ASM). Another way of looking at servant activation is to think of it as creating a link between the *identity* of an Ice object and the corresponding programming-language servant that handles requests for that Ice object. Once the Ice run time has knowledge of this link, it can dispatch incoming requests to the correct servant. Without this link, that is, without a corresponding entry in the ASM, an incoming request for the identity results in an `ObjectNotExistException`. While a servant is activated, it is said to *incarnate* the corresponding Ice object.

The inverse operation is known as *servant deactivation*. Deactivating a servant removes an entry for a particular identity from the ASM. Thereafter, incoming requests for that identity are no longer dispatched to the servant and result in an `ObjectNotExistException`.

The object adapter offers a number of operations for managing servant activation and deactivation:

Slice

```

module Ice {
    local interface ObjectAdapter {
        // ...

        Object* add(Object servant, Identity id);
        Object* addWithUUID(Object servant);
        Object  remove(Identity id);
        Object  find(Identity id);
        Object  findByProxy(Object* proxy);

        // ...
    };
};

```

The operations behave as follows:

- `add`

The `add` operation adds a servant with the given identity to the ASM. Requests are dispatched to that servant as soon as `add` is called. The return value is the proxy for the Ice object incarnated by that servant. The proxy embeds the identity passed to `add`.

You cannot call `add` with the same identity more than once: attempts to add an already existing identity to the ASM result in an `AlreadyRegisteredException`. (It does not make sense to add two servants with the same identity because that would make it ambiguous as to which servant should handle incoming requests for that identity.)

Note that it is possible to activate the same servant multiple times with different identities. In that case, the same single servant incarnates multiple Ice objects. We explore the ramifications of this in more detail in our discussion of [server implementation techniques](#).

- `addWithUUID`

The `addWithUUID` operation behaves the same way as the `add` operation but does not require you to supply an identity for the servant. Instead, `addWithUUID` generates a UUID as the identity for the corresponding Ice object. You can retrieve the generated identity by calling the `ice_getIdentity` operation on the returned proxy. `addWithUUID` is useful to create identities for temporary objects, such as short-lived session objects. (You can also use `addWithUUID` for persistent objects that do not have a natural identity, as we have done for the file system application.)

- `remove`

The `remove` operation breaks the association between an identity and its servant by removing the corresponding entry from the ASM; it returns a reference to the removed servant.

Once the servant is deactivated, new incoming requests for the removed identity cause the client to receive an `ObjectNotExistE`

`exception`. Requests that are executing inside the servant at the time `remove` is called are allowed to complete normally. Once the last request for the servant is complete, the object adapter drops its reference (or smart pointer, for C++) to the servant. At that point, the servant becomes available for garbage collection (or is destroyed, for C++), provided there are no other references or smart pointers to the servant. The net effect is that a deactivated servant is destroyed once it becomes idle.

Deactivating an [object adapter](#) implicitly calls `remove` on its active servants.

- `find`

The `find` operation performs a lookup in the ASM and returns the servant for the specified object identity. If no servant with that identity is registered, the operation returns null. Note that `find` does not consult any [servant locators](#) or [default servants](#).

- `findByProxy`

The `findByProxy` operation performs a lookup in the ASM and returns the servant with the object identity and facet that are embedded in the proxy. If no such servant is registered, the operation returns null. Note that `findByProxy` does not consult any [servant locators](#) or [default servants](#).

Object Adapter States

On this page:

- [Object Adapter State Transitions](#)
- [Changing Object Adapter States](#)

Object Adapter State Transitions

An object adapter has a number of processing states:

- **Holding**

In this state, any incoming requests for the adapter are held, that is, not dispatched to servants.

For TCP/IP (and other stream-oriented protocols), the server-side run time stops reading from the corresponding transport endpoint while the adapter is in the holding state. In addition, it also does not accept incoming connection requests from clients. This means that if a client sends a request to an adapter that is in the holding state, the client eventually receives a `TimeoutException` or `ConnectTimeoutException` (unless the adapter is placed into the active state before the timer expires).

For UDP, client requests that arrive at an adapter that is in the holding state are thrown away.

Immediately after creation of an adapter, the adapter is in the holding state. This means that requests are not dispatched until you place the adapter into the active state.

Note that [bidirectional adapters](#) cannot be placed into the holding state. If you call `hold` on a bidirectional adapter, the call does nothing.

- **Active**

In this state, the adapter accepts incoming requests and dispatches them to servants. A newly-created adapter is initially in the holding state. The adapter begins dispatching requests as soon as you place it into the active state.

You can transition between the active and the holding state as many times as you wish.

Note that [bidirectional adapters](#) need not be activated. Further, calls to collocated servants (that is, to servants that are activated in the communicator that created the proxy) succeed even if the adapter is not activated, unless you have disabled [collocation optimization](#).

- **Inactive**

In this state, the adapter has conceptually been destroyed (or is in the process of being destroyed). Deactivating an adapter destroys all transport endpoints that are associated with the adapter. Requests that are executing at the time the adapter is placed into the inactive state are allowed to complete, but no new requests are accepted. (New requests are rejected with an exception). Any attempt to use a deactivated object adapter results in an `ObjectAdapterDeactivatedException`.

Changing Object Adapter States

The `ObjectAdapter` interface offers operations that allow you to change the adapter state, as well as to wait for a state change to be complete:

Slice

```

module Ice {
    local interface ObjectAdapter {
        // ...

        void activate();
        void hold();
        void waitForHold();
        void deactivate();
        void waitForDeactivate();
        void isDeactivated();
        void destroy();

        // ...
    };
};

```

The operations behave as follows:

- `activate`

The `activate` operation places the adapter into the `active` state. Activating an adapter that is already active has no effect. The Ice run time starts dispatching requests to servants for the adapter as soon as `activate` is called.

- `hold`

The `hold` operation places the adapter into the `holding` state. Requests that arrive after calling `hold` are held as described above. Requests that are in progress at the time `hold` is called are allowed to complete normally. Note that `hold` returns immediately without waiting for currently executing requests to complete.

- `waitForHold`

The `waitForHold` operation suspends the calling thread until the adapter has completed its transition to the holding state, that is, until all currently executing requests have finished. You can call `waitForHold` from multiple threads, and you can call `waitForHold` while the adapter is in the active state. If you call `waitForHold` on an adapter that is already in the holding state, `waitForHold` returns immediately.

- `deactivate`

The `deactivate` operation initiates deactivation of the adapter: requests that arrive after calling `deactivate` are rejected, but currently executing requests are allowed to complete. Once all requests have completed, the adapter enters the `inactive` state. Note that `deactivate` returns immediately without waiting for the currently executing requests to complete. A deactivated adapter cannot be reactivated; you can create a new adapter with the same name, but only after calling `destroy` on the existing adapter. Any attempt to use a deactivated object adapter results in an `ObjectAdapterDeactivatedException`.

- `waitForDeactivate`

The `waitForDeactivate` operation suspends the calling thread until the adapter has completed its transition to the `inactive` state, that is, until all currently executing requests have completed. You can call `waitForDeactivate` from multiple threads, and you can call `waitForDeactivate` while the adapter is in the active or holding state. Calling `waitForDeactivate` on an adapter that is in the inactive state does nothing and returns immediately.

- `isDeactivated`

The `isDeactivated` operation returns true if `deactivate` has been invoked on the adapter. A return value of true does not necessarily indicate that the adapter has fully transitioned to the inactive state, only that it has begun this transition. Applications that need to know when deactivation is completed can use `waitForDeactivate`.

- `destroy`

The `destroy` operation deactivates the adapter and releases all of its resources. Internally, `destroy` invokes `deactivate` followed by `waitForDeactivate`, therefore the operation blocks until all currently executing requests have completed. Furthermore, any servants associated with the adapter are destroyed, all transport endpoints are closed, and the adapter's name becomes available for reuse.

Destroying a communicator implicitly destroys all of its object adapters. Invoking `destroy` on an adapter is only necessary when you need to ensure that its resources are released prior to the destruction of its communicator.

Placing an adapter into the holding state is useful, for example, if you need to make state changes in the server that require the server (or a group of servants) to be idle. For example, you could place the implementation of your servants into a dynamic library and upgrade the implementation by loading a newer version of the library at run time without having to shut down the server.

Similarly, waiting for an adapter to complete its transition to the inactive state is useful if your server needs to perform some final clean-up work that cannot be carried out until all executing requests have completed.

Note that you can create an object adapter with the same name as a previous object adapter, but only once `destroy` on the previous adapter has completed.

- [Bidirectional Connections](#)

Object Adapter Endpoints

An object adapter maintains two sets of transport endpoints. One set identifies the network interfaces on which the adapter listens for new connections, and the other set is embedded in proxies created by the adapter and used by clients to communicate with it. We will refer to these sets of endpoints as the *physical endpoints* and the *published endpoints*, respectively. In most cases these sets are identical, but there are situations when they must be configured independently.

On this page:

- [Physical Object Adapter Endpoints](#)
- [Published Object Adapter Endpoints](#)
- [Refreshing Object Adapter Endpoints](#)
- [Timeouts in Object Adapter Endpoints](#)
- [Discovering Object Adapter Endpoints](#)
- [A Router's Effect on Object Adapter Endpoints](#)

Physical Object Adapter Endpoints

An object adapter's physical endpoints identify the network interfaces on which it receives requests from clients. These endpoints are configured via the `name.Endpoints` property, or they can be specified explicitly when [creating an adapter](#) using the operation `createObjectAdapterWithEndpoints`. The [endpoint syntax](#) generally consists of a transport protocol followed by an optional host name and port.

If a host name is specified, the object adapter listens only on the network interface associated with that host name. If no host name is specified but the property `Ice.Default.Host` is defined, the object adapter uses the property's value as the host name. Finally, if a host name is not specified, and the property `Ice.Default.Host` is undefined, the object adapter listens on all available network interfaces, including the loopback interface. You may also force the object adapter to listen on all interfaces by using one of the host names `0.0.0.0` or `*`. The adapter does *not* expand the list of interfaces when it is initialized. Instead, if no host is specified, or you use `-h *` or `-h 0.0.0.0`, the adapter binds to `INADDR_ANY` to listen for incoming requests.

If the host name refers to a DNS name which is configured with multiple addresses, the object adapter will listen on the first address returned by the DNS resolver.

If you want an adapter to accept requests on certain network interfaces, you must specify a separate endpoint for each interface. For example, the following property configures a single endpoint for the adapter named `MyAdapter`:

```
MyAdapter.Endpoints=tcp -h 10.0.1.1 -p 9999
```

This endpoint causes the adapter to accept requests on the network interface associated with the IP address `10.0.1.1` at port `9999`. Note however that this adapter configuration does not accept requests on the loopback interface (the one associated with address `127.0.0.1`). If both addresses must be supported, then both must be specified explicitly, as shown below:

```
MyAdapter.Endpoints=tcp -h 10.0.1.1 -p 9999:tcp -h 127.0.0.1 -p 9999
```

If these are the only two network interfaces available on the host, then a simpler configuration omits the host name altogether, causing the object adapter to listen on both interfaces automatically:

```
MyAdapter.Endpoints=tcp -p 9999
```

If you want to make your configuration more explicit, you can use one of the special host names mentioned earlier:

```
MyAdapter.Endpoints=tcp -h * -p 9999
```

One advantage of this last example is that it ensures the object adapter *always* listens on all interfaces, even if a definition for `Ice.Default.Host` is later added to your configuration. Without an explicit host name, the addition of `Ice.Default.Host` could potentially change the interfaces on which the adapter is listening. For diagnostic purposes, you can determine the set of local addresses that Ice substitutes for the

wildcard address by setting the property `Ice.Trace.Network=3` and reviewing the server's log output.

Careful consideration must also be given to the selection of a port for an endpoint. If no port is specified, the adapter uses a port that is selected (essentially at random) by the operating system, meaning the adapter will likely be using a different port each time the server is restarted. Whether that behavior is desirable depends on the application, but in many applications a client has a proxy containing the adapter's endpoint and expects that proxy to remain valid indefinitely. Therefore, an endpoint generally should contain a fixed port to ensure that the adapter is always listening at the same port.

However, there are certain situations where a fixed port is not required. For example, an adapter whose servants are transient does not need a fixed port, because the proxies for those objects are not expected to remain valid past the lifetime of the server process. Similarly, a server using indirect binding via `IceGrid` does not need a fixed port because its port is never published.

Published Object Adapter Endpoints

An object adapter publishes its endpoints in the proxies it creates, but it is not always appropriate to publish the adapter's physical endpoints in a proxy. For example, suppose a server is running on a host in a private network, protected from the public network by a firewall that can forward network traffic to the server. The adapter's physical endpoints must use the private network's address scheme, but a client in the public network would be unable to use those endpoints if they were published in a proxy. In this scenario, the adapter must publish endpoints in its proxies that direct the client to the firewall instead.

The published endpoints are configured using the adapter property `name.PublishedEndpoints`. If this property is not defined, the adapter publishes its physical endpoints by default, with one exception: endpoints for the loopback address (`127.0.0.1`) are not published unless the loopback interface is the only interface, or `127.0.0.1` (or `loopback`) is explicitly listed as an endpoint with the `-h` option. Otherwise, to force the inclusion of loopback endpoints when they would normally be excluded, you must define `name.PublishedEndpoints` explicitly.

As an example, the properties below configure the adapter named `MyAdapter` with physical and published endpoints:

```
MyAdapter.Endpoints=tcp -h 10.0.1.1 -p 9999
MyAdapter.PublishedEndpoints=tcp -h corpfw -p 25000
```

This example assumes that clients connecting to host `corpfw` at port 25000 are forwarded to the adapter's endpoint in the private network.

Another use case of published endpoints is for replicated servers. Suppose we have two instances of a stateless server running on separate hosts in order to distribute the load between them. We can supply the client with a bootstrap proxy containing the endpoints of both servers, and the Ice run time in the client will select one of the servers at random when a connection is established. However, should the client invoke an operation on a server that returns a proxy for another object, that proxy would normally contain only the endpoint of the server that created it. Invocations on the new proxy would always be directed at the same server, reducing the opportunity for load balancing.

We can alleviate this situation by configuring the adapters to publish the endpoints of both servers. For example, here is a configuration for the server on host `Sun1`:

```
MyAdapter.Endpoints=tcp -h Sun1 -p 9999
MyAdapter.PublishedEndpoints=tcp -h Sun1 -p 9999:tcp -h Sun2 -p 9999
```

Similarly, the configuration for host `Sun2` retains the same published endpoints:

```
MyAdapter.Endpoints=tcp -h Sun2 -p 9999
MyAdapter.PublishedEndpoints=tcp -h Sun1 -p 9999:tcp -h Sun2 -p 9999
```

For troubleshooting purposes, you can examine the published endpoints for an object adapter by setting the property `Ice.Trace.Network=3`. Note however that this setting generates significant trace information about the Ice run time's network activity, therefore you may not want to use this setting by default.

Refreshing Object Adapter Endpoints

A host's network interfaces may change over time, for example, if a laptop moves in and out of range of a wireless network. The object adapter provides an operation to refresh its list of interfaces:

```

Slice

local interface ObjectAdapter {
    void refreshPublishedEndpoints();
    // ...
};
```

Calling `refreshPublishedEndpoints` causes the object adapter to update its internal list of available network interfaces and to use this updated information in the `name.PublishedEndpoints` property. This allows you to react to changing network interfaces while an object adapter is in use, but your application code is responsible for determining when it is necessary to call this operation.

Note that `refreshPublishedEndpoints` takes effect only for object adapters that specify published endpoints without a host, or that set the published endpoints to `-h *` or `-h 0.0.0.0`.

Timeouts in Object Adapter Endpoints

As a defense against hostile clients, we recommend that you specify a `timeout` for your physical object adapter endpoints. The timeout value you select affects tasks that the Ice run time normally does not expect to block for any significant amount of time, such as writing a reply message to a socket or waiting for SSL negotiation to complete. If you don't specify a timeout for an endpoint, the Ice run time uses the value of the `Ice.Default.Timeout` property. You can also specify the value `infinite` in an endpoint to wait indefinitely, but be aware that this could allow malicious or misbehaving clients to consume excessive resources such as file descriptors.

Specifying a timeout in an object adapter endpoint is done exactly as in a proxy endpoint, using the `-t` option:

```
MyAdapter.Endpoints=tcp -p 9999 -t 5000
```

In this example, we specify a timeout of five seconds.

Unless overridden by `published endpoints`, the timeout specified in your object adapter endpoint also appears in the endpoints of any proxies created by that object adapter. This feature allows you to provide a default timeout value for clients that use your object adapter, although the client's code or configuration can cause it to use a different timeout in practice.

Discovering Object Adapter Endpoints

The object adapter provides operations for retrieving the physical and published endpoints:

Slice

```
module Ice {
  local interface ObjectAdapter {
    // ...

    EndpointSeq getEndpoints();
    EndpointSeq getPublishedEndpoints();

    // ...
  };
};
```

The sequences that are returned contain [Endpoint](#) objects representing the adapter's physical and published endpoints, respectively.

A Router's Effect on Object Adapter Endpoints

If an object adapter is configured with a router, the adapter's published endpoints are augmented to reflect the router. See [Glacier2](#) for more information on configuring an adapter with a router.

Creating Proxies with an Object Adapter

Proxies are created as a side-effect of using the [servant activation operations](#), but the [life cycle](#) of proxies is completely independent from that of servants. The `ObjectAdapter` interface provides several operations for creating a proxy for an object, regardless of whether a servant is currently activated for that object's identity:

Slice

```

module Ice {
  local interface ObjectAdapter {
    // ...

    Object* createProxy(Identity id);
    Object* createDirectProxy(Identity id);
    Object* createIndirectProxy(Identity id);

    // ...
  };
};

```

These operations are described below:

- `createProxy`

The `createProxy` operation returns a new proxy for the object with the given identity. The adapter's configuration determines whether the return value is a [direct proxy](#) or an [indirect proxy](#). If the adapter is configured with an [adapter ID](#), the operation returns an indirect proxy that refers to the adapter ID. If the adapter is also configured with a [replica group ID](#), the operation returns an indirect proxy that refers to the replica group ID. Otherwise, if an adapter ID is not defined, `createProxy` returns a direct proxy containing the adapter's [published endpoints](#).

- `createDirectProxy`

The `createDirectProxy` operation returns a direct proxy containing the adapter's [published endpoints](#).

- `createIndirectProxy`

The `createIndirectProxy` operation returns an [indirect proxy](#). If the adapter is configured with an [adapter ID](#), the returned proxy refers to that adapter ID. Otherwise, the proxy refers only to the object's identity.

In contrast to `createProxy`, `createIndirectProxy` does not use the replica group ID. Therefore, the returned proxy always refers to a specific replica.

After using one of the operations discussed above to create a proxy, you will receive a proxy that is configured by default for twoway invocations. If you require the proxy to have a different configuration, you can use the [proxy factory methods](#) to create a new proxy with the desired configuration. As an example, the code below demonstrates how to configure the proxy for oneway invocations:

C++

```

Ice::ObjectAdapterPtr adapter = ...;
Ice::Identity id = ...;
Ice::ObjectPrx proxy = adapter->createProxy(id)->ice_oneway();

```

You can also instruct the object adapter to use a different default proxy configuration by setting the property `name.ProxyOptions`. For example, the following property causes the object adapter to return proxies that are configured for oneway invocations by default:

```
MyAdapter.ProxyOptions=-o
```

Using Multiple Object Adapters

A typical server rarely needs to use more than one object adapter. If you are considering using multiple object adapters, we suggest that you check whether any of the considerations in the list below apply to your situation:

- You need fine-grained control over which objects are accessible. For example, you could have an object adapter with only secure endpoints to restrict access to some administrative objects, and another object adapter with non-secure endpoints for other objects. Because an object adapter is associated with one or more transport endpoints, you can firewall a particular port, so objects associated with the corresponding endpoint cannot be reached unless the firewall rules are satisfied.
- You need control over the number of threads in the pools for different sets of objects in your application. For example, you may not need concurrency on the objects connected to a particular object adapter, and multiple object adapters, each with its own [thread pool](#), can be useful to solve [deadlocks](#).
- You want to be able to temporarily disable processing new requests for a set of objects. This can be accomplished by placing an object adapter in the [holding state](#).
- You want to set up different request routing when using an Ice router with [Glacier2](#).

If none of the preceding items apply, chances are that you do not need more than one object adapter.

The Current Object

Up to now, we have tacitly ignored the trailing parameter of type `Ice::Current` that is passed to each skeleton operation on the server side. The `Current` structure is defined as follows:

Slice

```

module Ice {
    local dictionary<string, string> Context;

    enum OperationMode { Normal, \Idempotent };

    local struct Current {
        ObjectAdapter    adapter;
        Connection        con;
        Identity          id;
        string            facet;
        string            operation;
        OperationMode    mode;
        Context           ctx;
        int               requestId;
        EncodingVersion  encoding;
    };
};

```
