Note that the `Current` value provides access to information about the currently executing request to the implementation of an operation in the server:

- `adapter`
The `adapter` member provides access to the object adapter via which the request is being dispatched. In turn, the adapter provides access to its communicator (via the `getCommunicator` operation).
- `con`
The `con` member provides information about the [connection](#) over which this request was received.
- `id`
The `id` member provides the [object identity](#) for the current request.
- `facet`
The `facet` member provides access to the [facet](#) for the request.
- `operation`
The `operation` member contains the name of the operation that is being invoked. Note that the operation name may indicate one of the [operations on `Ice::Object`](#), such as `ice_ping` or `ice_isA`. (`ice_isA` is invoked if a client performs a `checkedCast`.)
- `mode`
The `mode` member contains the invocation mode for the operation (`Normal` or `Idempotent`), which influences the [retry behavior](#) of the Ice run time.
- `ctx`
The `ctx` member contains the current [request context](#) for the invocation.
- `requestId`
The Ice [protocol](#) uses request IDs to associate replies with their corresponding requests. The `requestId` member provides this ID. For oneway requests (which do not have replies), the request ID is 0. For collocated requests (which do not use the Ice protocol), the request ID is -1.
- `encoding`
The [encoding](#) version used to encode the input and output parameters.

If you implement your server such that it uses a separate servant for each Ice object, the contents of `Current` are not particularly interesting. (You would most likely access `Current` to read the `adapter` member, for example, to activate or deactivate a servant.) However, as we will see in our discussion of [default servants](#) and [servant locators](#), the `Current` object is essential for more sophisticated (and more scalable) servant implementations.

Servant Locators

In a nutshell, a servant locator is a local object that you implement and attach to an [object adapter](#). Once an adapter has a servant locator, it consults its [active servant map \(ASM\)](#) to locate a servant for an incoming request as usual. If a servant for the request can be found in the ASM, the request is dispatched to that servant. However, if the ASM does not have an entry for the [object identity](#) of the request, the object adapter calls back into the servant locator to ask it to provide a servant for the request. The servant locator either:

- locates an existing servant or instantiates a new servant and passes it to the Ice run time, in which case the request is dispatched to that servant, or
- the servant locator indicates failure to locate a servant to the Ice run time, in which case the client receives an `ObjectNotExistException`.

This simple mechanism allows us to scale servers to provide access to an unlimited number of Ice objects. For example, instead of instantiating a separate servant for each and every Ice object in existence, the server can instantiate servants only for those Ice objects that are actually used by clients. Similar to a [Default Servant](#), the server can also instantiate only one single servant that the locator returns for a group of Ice objects with similar properties.

Servant locators are most commonly used by servers that provide access to databases: typically, the number of entries in the database is far larger than what the server can hold in memory. Servant locators allow the server to only instantiate servants for those Ice objects that are actually used by clients.

Another common use for servant locators is in servers that are used for process control or network management: in that case, there is no database but, instead, there is a potentially very large number of devices or network elements that must be controlled via the server. Otherwise, this scenario is the same as for large databases: the number of Ice objects exceeds the number of servants that the server can hold in memory and, therefore, requires an approach that allows the number of instantiated servants to be less than the number of Ice objects.

The ServantLocator Interface

A servant locator has the following interface:

Slice
<pre> module Ice { local interface ServantLocator { ["UserException"] Object locate(Current curr, out LocalObject cookie); ["UserException"] void finished(Current curr, Object servant, LocalObject cookie); void deactivate(string category); }; }; </pre>

Note that `ServantLocator` is a [local interface](#). To create an actual implementation of a servant locator, you must define a class that is derived from `Ice::ServantLocator` and provide implementations of the `locate`, `finished`, and `deactivate` operations. The Ice run time invokes the operations on your derived class as follows:

- `locate`

Whenever a request arrives for which no entry exists in the [active servant map \(ASM\)](#), the Ice run time calls `locate` and supplies the `Current` object for the request. The implementation of `locate` (which you provide as part of the derived class) is supposed to return a servant that can process the incoming request. Your implementation of `locate` can behave in three possible ways:

1. Locate an existing or instantiate a new servant, and return this servant for the current request. In this case, the Ice run time dispatches the request to this servant.
2. Return null. In this case, the Ice run time raises an `ObjectNotExistException` in the client.
3. Throw a run-time exception. In this case, the Ice run time propagates the thrown exception back to the client. Keep in mind that all run-time exceptions, apart from `ObjectNotExistException`, `OperationNotExistException`, and `FacetNotExistException`, are presented as `UnknownLocalException` to the client.

You can also throw user exceptions from `locate`. If the user exception is in the corresponding operation's exception specification, that user exception is returned to the client. User exceptions thrown by `locate` that are not listed in the exception specification of the corresponding operation are also returned to the client, and then thrown in the client as `UnknownUserException`. Non-Ice exceptions are returned to the client as `UnknownException`.

The `cookie` out-parameter to `locate` allows you to return a local object to the object adapter. The object adapter does not care about the contents of that object (and it is legal to return a null cookie). Instead, the Ice run time passes whatever cookie you return from `locate` back to you when it calls `finished`. This allows you to pass an arbitrary amount of state from `locate` to the corresponding call to `finished`.

- `finished`

If a call to `locate` has returned a servant to the Ice run time, the Ice run time dispatches the incoming request to the servant. Once the request is complete (that is, the operation being invoked has completed), the Ice run time calls `finished`, passing the servant whose operation has completed, the `Current` object for the request, and the cookie that was initially created by `locate`. This means that every call to `locate` is balanced by a corresponding call to `finished` (provided that `locate` actually returned a servant).

If you throw an exception from `finished`, the Ice run time propagates the thrown exception back to the client. As for `locate`, you can throw user exceptions from `finished`. If a user exception is in the corresponding operation's exception specification, that user exception is returned to the client. User exceptions that are not in the corresponding operation's exception specification are also returned to the client, and then thrown by the client as `UnknownUserException`.

`finished` can also throw [run-time exceptions](#). However, only `ObjectNotExistException`, `OperationNotExistException`,

and `FacetNotExistException` are propagated without change to the client; other run-time exceptions are returned to the client as `UnknownLocalException`.

Non-Ice exceptions thrown from `finished` are returned to the client as `UnknownException`.

If both the operation implementation and `finished` throw a user exception, the exception thrown by `finished` overrides the exception thrown by the operation.

- `deactivate`

The `deactivate` operation allows a servant locator to clean up once it is no longer needed. (For example, the locator might close a database connection.) The Ice run time passes the category of the servant locator being deactivated to the `deactivate` operation.

The run time calls `deactivate` when destroying the object adapter to which the servant locator is attached. More precisely, `deactivate` is called when you call `destroy` on the object adapter, or when you call `destroy` on the communicator (which implicitly calls `destroy` on the object adapter).

Once the run time has called `deactivate`, it is guaranteed that no further calls to `locate` or `finished` can happen, that is, `deactivate` is called exactly once, after all operations dispatched via this servant locator have completed.

This also explains why `deactivate` is not called as part of `ObjectAdapter::deactivate`: `ObjectAdapter::deactivate` initiates `deactivation` and returns immediately, so it cannot call `ServantLocator::deactivate` directly, because there might still be outstanding requests dispatched via this servant locator that have to complete first — in turn, this would mean that either `ObjectAdapter::deactivate` could block (which it must not do) or that a call to `ServantLocator::deactivate` could be followed by one or more calls to `finished` (which must not happen either).

It is important to realize that the Ice run time does not "remember" the servant that is returned by a particular call to `locate`. Instead, the Ice run time simply dispatches an incoming request to the servant returned by `locate` and, once the request is complete, calls `finished`. In particular, if two requests for the same servant arrive more or less simultaneously, the Ice run time calls `locate` and `finished` once for each request. In other words, `locate` establishes the association between an object identity and a servant; that association is valid only for a single request and is never used by the Ice run time to dispatch a different request.

Threading Guarantees for Servant Locators

The Ice run time guarantees that every operation invocation that involves a [servant locator](#) is bracketed by calls to `locate` and `finished`, that is, every call to `locate` is balanced by a corresponding call to `finished` (assuming that the call to `locate` actually returned a servant, of course).

In addition, the Ice run time guarantees that `locate`, the operation, and `finished` are called by the same thread. This guarantee is important because it allows you to use `locate` and `finished` to implement thread-specific pre- and post-processing around operation invocations. (For example, you can start a transaction in `locate` and commit or roll back that transaction in `finished`, or you can acquire a lock in `locate` and release the lock in `finished`.)

Both transactions and locks usually are thread-specific, that is, only the thread that started a transaction can commit it or roll it back, and only the thread that acquired a lock can release the lock.

If you are using [asynchronous method dispatch](#), the thread that starts a call is not necessarily the thread that finishes it. In that case, `finished` is called by whatever thread executes the operation implementation, which may be a different thread than the one that called `locate`.

The Ice run time also guarantees that `deactivate` is called when you destroy the object adapter to which the servant locator is attached. The `deactivate` call is made only once all operations that involved the servant locator are finished, that is, `deactivate` is guaranteed not to run concurrently with `locate` or `finished`, and is guaranteed to be the last call made to a servant locator.

Beyond this, the Ice run time provides no threading guarantees for servant locators. In particular, it is possible for invocations of:

- `locate` to proceed concurrently (for the same object identity or for different object identities).
- `finished` to proceed concurrently (for the same object identity or for different object identities).
- `locate` and `finished` to proceed concurrently (for the same object identity or for different object identities).

These semantics allow you to extract the maximum amount of parallelism from your application code (because the Ice run time does not serialize invocations when serialization may not be necessary). Of course, this means that you must [protect access to shared data](#) from `locate` and `finished` with mutual exclusion primitives as necessary.

Registering a Servant Locator

On this page:

- [Servant Locator Registration](#)
- [Call Dispatch Semantics for Servant Locators](#)

Servant Locator Registration

An [object adapter](#) does not automatically know when you create a [servant locator](#). Instead, you must explicitly register a servant locator with the object adapter:

Slice

```

module Ice {
    local interface ObjectAdapter {
        // ...

        void addServantLocator(ServantLocator locator, string category);

        ServantLocator removeServantLocator(string category);

        ServantLocator findServantLocator(string category);

        // ...
    };
};

```

As you can see, the object adapter allows you to add, remove, and find servant locators. Note that, when you register a servant locator, you must provide an argument for the `category` parameter. The value of the `category` parameter controls which [object identities](#) the servant locator is responsible for: only object identities with a matching `category` member trigger a corresponding call to `locate`. An incoming request for which no explicit entry exists in the [active servant map \(ASM\)](#) and with a category for which no servant locator is registered returns an `ObjectNotExistException` to the client.

`addServantLocator` has the following semantics:

- You can register exactly one servant locator for a specific category. Attempts to call `addServantLocator` for the same category more than once raise an `AlreadyRegisteredException`.
- You can register different servant locators for different categories, or you can register the same single servant locator multiple times (each time for a different category). In the former case, the category is implicit in the servant locator instance that is called by the Ice run time; in the latter case, the implementation of `locate` can find out which category the incoming request is for by examining the object identity member of the `Current` object that is passed to `locate`.
- It is legal to register a servant locator for the empty category. Such a servant locator is known as a *default servant locator*: if a request comes in for which no entry exists in the ASM, and whose category does not match the category of any other registered servant locator, the Ice run time calls `locate` on the default servant locator.

`removeServantLocator` removes and returns the servant locator for a specific category (including the empty category) with the following semantics:

- If no servant locator is registered for the specified category, the operation raises `NotRegisteredException`.
- Once a servant locator is successfully removed for the specified category, the Ice run time guarantees that no new incoming requests for that category are dispatched to the servant locator.
- A call to `removeServantLocator` returns immediately without waiting for the completion of any pending requests on that servant locator; such requests still complete normally by calling `finished` on the servant locator.
- Removing a servant locator does not cause Ice to invoke `deactivate` on that servant locator, as `deactivate` is only called when a registered servant locator's object adapter is destroyed.

`findServantLocator` allows you to retrieve the servant locator for a specific category (including the empty category). If no match is found, the operation returns null.

Call Dispatch Semantics for Servant Locators

The preceding rules may seem complicated, so here is a summary of the actions taken by the Ice run time to locate a servant for an incoming request.

Every incoming request implicitly identifies a specific object adapter for the request (because the request arrives at a specific transport endpoint and, therefore, identifies a particular object adapter). The incoming request carries an object identity that must be mapped to a servant. To locate a servant, the Ice run time goes through the following steps, in the order shown:

1. Look for the identity in the ASM. If the ASM contains an entry, dispatch the request to the corresponding servant.
2. If the category of the incoming object identity is non-empty, look for a [default servant](#) that is registered for that category. If such a default servant is registered, dispatch the request to that servant.
3. If the category of the incoming object identity is empty, or no default servant could be found for the category in step 2, look for a default servant that is registered for the empty category. If such a default servant is registered, dispatch the request to that servant.
4. If the category of the incoming object identity is non-empty and no servant could be found in the preceding steps, look for a servant locator that is registered for that category. If such a servant locator is registered, call `locate` on the servant locator and, if `locate` returns a servant, dispatch the request to that servant, followed by a call to `finished`; otherwise, if the call to `locate` returns null, raise `ObjectNotExistException` or `FacetNotExistException` in the client.
5. If the category of the incoming object identity is empty, or no servant locator could be found for the category in step 4, look for a default servant locator (that is, a servant locator that is registered for the empty category). If a default servant locator is registered, dispatch the request as for step 4.
6. Raise `ObjectNotExistException` or `FacetNotExistException` in the client. (`ObjectNotExistException` is raised if the ASM does not contain a servant with the given identity at all, `FacetNotExistException` is raised if the ASM contains a servant with a matching identity, but a non-matching [facet](#).)

It is important to keep these call dispatch semantics in mind because they enable a number of powerful implementation techniques. Each technique allows you to streamline your server implementation and to precisely control the trade-off between performance, memory consumption, and scalability. To illustrate the possibilities, we will outline a number of the most common implementation techniques.

- [Servant Locator Example](#)

Servant Locator Example

To illustrate the [servant locator](#) concepts outlined so far, let us examine a (very simple) implementation. Consider that we want to create an electronic phone book for the entire world's telephone system (which, clearly, involves a very large number of entries, certainly too many to hold the entire phone book in memory). The actual phone book entries are kept in a large database. Also assume that we have a search operation that returns the details of a phone book entry. The Slice definitions for this application might look something like the following:

Slice
<pre> struct Details { // Lots of details about the entry here... }; interface PhoneEntry { idempotent Details getDetails(); idempotent void updateDetails(Details d); // ... }; struct SearchCriteria { // Fields to permit searching... }; interface PhoneBook { idempotent PhoneEntry* search(SearchCriteria c); // ... }; </pre>

The details of the application do not really matter here; the important point to note is that each phone book entry is represented as an interface for which we need to create a servant eventually, but we cannot afford to keep servants for all entries permanently in memory.

Each entry in the phone database has a unique identifier. This identifier might be an internal database identifier, or a combination of field values, depending on exactly how the database is constructed. The important point is that we can use this database identifier to link the [proxy](#) for an Ice object to its persistent state: we simply use the database identifier as the [object identity](#). This means that each proxy contains the primary access key that is required to locate the persistent state of each Ice object and, therefore, instantiate a servant for that Ice object.

What follows is an outline implementation in C++. The class definition of our servant locator looks as follows:

C++

```

class MyServantLocator : public virtual Ice::ServantLocator {
public:

    virtual Ice::ObjectPtr locate(const Ice::Current& c,
Ice::LocalObjectPtr& cookie);

    virtual void finished(const Ice::Current& c,
const Ice::ObjectPtr& servant,
                        const Ice::LocalObjectPtr& cookie);

    virtual void deactivate(const std::string& category);
};

```

Note that `MyServantLocator` inherits from `Ice::ServantLocator` and implements the pure virtual functions that are generated by the `slice2cpp` compiler for the `Ice::ServantLocator` interface. Of course, as always, you can add additional member functions, such as a constructor and destructor, and you can add private data members as necessary to support your implementation.

In C++, you can implement the `locate` member function along the following lines:

C++

```

Ice::ObjectPtr
MyServantLocator::locate(const Ice::Current& c,
Ice::LocalObjectPtr& cookie)
{
    // Get the object identity. (We use the name member
    // as the database key.)
    //
    std::string name = c.id.name;

    // Use the identity to retrieve the state from the database.
    //
    ServantDetails d;
    try {
        d = DB_lookup(name);
    } catch (const DB_error&)
        return 0;
    }

    // We have the state, instantiate a servant and return it.
    //
    return new PhoneEntryI(d);
}

```

For the time being, the implementations of `finished` and `deactivate` are empty and do nothing.

The `DB_lookup` call in the preceding example is assumed to access the database. If the lookup fails (presumably, because no matching record could be found), `DB_lookup` throws a `DB_error` exception. The code catches that exception and returns zero instead; this raises `ObjectNotExistException` in the client to indicate that the client used a proxy to a *no-longer existent Ice object*.

Note that `locate` instantiates the servant on the heap and returns it to the Ice run time. This raises the question of when the servant will be destroyed. The answer is that the Ice run time holds onto the servant for as long as necessary, that is, long enough to invoke the operation on the returned servant and to call `finished` once the operation has completed. Thereafter, the servant is no longer needed and the Ice run time destroys the smart pointer that was returned by `locate`. In turn, because no other smart pointers exist for the same servant, this causes the destructor of the `PhoneEntryI` instance to be called, and the servant to be destroyed.

The upshot of this design is that, for every incoming request, we instantiate a servant and allow the Ice run time to destroy the servant once the request is complete. Depending on your application, this may be exactly what is needed, or it may be prohibitively expensive — we will explore designs that avoid creation and destruction of a servant for every request shortly.

In Java, the implementation of our servant locator looks very similar:

Java

```
public class MyServantLocator implements Ice.ServantLocator {

    public Ice.Object locate(Ice.Current c,
Ice.LocalObjectHolder cookie)
    {
        // Get the object identity. (We use the name member
        // as the database key.
        String name = c.id.name;

        // Use the identity to retrieve the state
        // from the database.
        //
        ServantDetails d;
        try {
            d = DB.lookup(name);
        } catch (DB.error e) {
            return null;
        }

        // We have the state, instantiate a servant and return it.
        //
        return new PhoneEntryI(d);
    }

    public void finished(Ice.Current c, Ice.Object servant,
java.lang.Object cookie)
    {
    }

    public void deactivate(String category)
    {
    }
}
```

The C# implementation is virtually identical to the Java implementation, so we do not show it here.

All implementations of `locate` follow the pattern illustrated by the previous pseudo-code:

1. Use the `id` member of the passed `Current` object to obtain the object identity. Typically, only the `name` member of the identity is used to retrieve servant state. The `category` member is normally used to select a servant locator. (We will explore [use of the category member](#) shortly.)
2. Retrieve the state of the Ice object from secondary storage (or the network) using the object identity as a key.
 - If the lookup succeeds, you have retrieved the state of the Ice object.
 - If the lookup fails, return null. In that case, the Ice object for the client's request truly does not exist, presumably, because that Ice object was deleted earlier, but the client still has a proxy to the now-deleted object.
3. Instantiate a servant and use the state retrieved from the database to initialize the servant. (In this example, we pass the retrieved state to the servant constructor.)
4. Return the servant.

Of course, before we can use our servant locator, we must inform the adapter of its existence prior to activating the adapter, for example (in Java or C#):

```
MyServantLocator sl = new MyServantLocator();
adapter.addServantLocator(sl, "");
```

Note that, in this example, we have installed the servant locator for the empty category. This means that `locate` on our servant locator will be called for invocations to any of our Ice objects (because the empty category acts as the default). In effect, with this design, we are not using the `category` member of the object identity. This is fine, as long as all our servants all have the same, single interface. However, if we need to support several different interfaces in the same server, this simple strategy is no longer sufficient.

See Also

- [Servant Locators](#)
- [Object Identity](#)
- [Object Life Cycle](#)
- [The Current Object](#)
- [Using Identity Categories with Servant Locators](#)

Using Identity Categories with Servant Locators

Our [simple example](#) always instantiates a servant of type `PhoneEntryI`. In other words, the servant locator implicitly is aware of the type of servant the incoming request is for. This is not a very realistic assumption for most servers because, usually, a server provides access to objects with several different interfaces. This poses a problem for our `locate` implementation: somehow, we need to decide inside `locate` what type of servant to instantiate. You have several options for solving this problem:

- Use a separate object adapter for each interface type and use a separate servant locator for each object adapter.

This technique works fine, but has the down-side that each object adapter requires a separate transport endpoint, which is wasteful.

- Mangle a type identifier into the `name` component of the [object identity](#).

This technique uses part of the object identity to denote what type of object to instantiate. For example, in our file system application, we have directory and file objects. By convention, we could prepend a 'd' to the identity of every directory and prepend an 'f' to the identity of every file. The servant locator then can use the first letter of the identity to decide what type of servant to instantiate:

C++

```
Ice::ObjectPtr
MyServantLocator::locate(const Ice::Current& c,
Ice::LocalObjectPtr& cookie)
{
    // Get the object identity. (We use the name member
    // as the database key.)
    //
    std::string name = c.id.name;
    std::string realId = c.id.name.substr(1);
    try {
        if (name[0] == 'd') {
            // The request is for a directory.
            //
            DirectoryDetails d = DB_lookup(realId);
            return new DirectoryI(d);
        } else {
            // The request is for a file.
            //
            FileDetails d = DB_lookup(realId);
            return new FileI(d);
        }
    } catch (DatabaseNotFoundException&) {
        return 0;
    }
}
```

While this works, it is awkward: not only do we need to parse the `name` member to work out what type of object to instantiate, but we also need to modify the implementation of `locate` whenever we add a new type to our application.

- Use the `category` member of the object identity to denote the type of servant to instantiate.

This is the recommended approach: for every interface type, we assign a separate identifier as the value of the `category` member of the object identity. (For example, we can use 'd' for directories and 'f' for files.) Instead of registering a single servant locator, we create two different servant locator implementations, one for directories and one for files, and then register each locator for the appropriate category:

C++

```

class DirectoryLocator : public virtual Ice::ServantLocator {
public:

    virtual Ice::ObjectPtr locate(const Ice::Current& c,
Ice::LocalObjectPtr& cookie)
    {
        // Code to locate and instantiate a directory here...
    }

    virtual void finished(const Ice::Current& c,
const Ice::ObjectPtr& servant,
                        const Ice::LocalObjectPtr& cookie)
    {
    }

    virtual void deactivate(const std::string& category)
    {
    }
};

class FileLocator : public virtual Ice::ServantLocator {
public:

    virtual Ice::ObjectPtr locate(const Ice::Current& c, Ice::LocalObjectPtr& cookie)
    {
        // Code to locate and instantiate a file here...
    }

    virtual void finished(const Ice::Current& c,
const Ice::ObjectPtr& servant,
                        const Ice::LocalObjectPtr& cookie)
    {
    }

    virtual void deactivate(const std::string& category)
    {
    }
};

// ...

// Register two locators, one for directories and
// one for files.
//
adapter->addServantLocator(new DirectoryLocator(), "d");
adapter->addServantLocator(new FileLocator(), "f");

```

Yet another option is to use the `category` member of the object identity, but to use a single default servant locator (that is, a locator for the empty category). With this approach, all invocations go to the single default servant locator, and you can switch on the `category` value inside the implementation of the `locate` operation to determine which type of servant to instantiate. However, this approach is harder to maintain than the previous one; the `category` member of the Ice object identity exists specifically to support servant locators, so you might as well use it as intended.

- [Servant Locator Example](#)
- [Object Identity](#)

Using Cookies with Servant Locators

Occasionally, it can be useful for a [servant locator](#) to pass information between `locate` and `finished`. For example, the implementation of `locate` could choose among a number of alternative database backends, depending on load or availability and, to properly finalize state, the implementation of `finished` might need to know which database was used by `locate`. To support such scenarios, you can create a cookie in your `locate` implementation; the Ice run time passes the value of the cookie to `finished` after the operation invocation has completed. The cookie must derive from `Ice::LocalObject` and can contain whatever state and member functions are useful to your implementation:

C++

```
class MyCookie : public virtual Ice::LocalObject {
public:
    // Whatever is useful here...
};

typedef IceUtil::Handle<MyCookie> MyCookiePtr;

class MyServantLocator : public virtual Ice::ServantLocator {
public:

    virtual Ice::ObjectPtr locate(const Ice::Current& c,
Ice::LocalObjectPtr& cookie)
    {
        // Code as before...

        // Allocate and initialize a cookie.
        //
        cookie = new MyCookie(...);

        return new PhoneEntryI;
    }

    virtual void finished(const Ice::Current& c,
const Ice::ObjectPtr& servant,
                        const Ice::LocalObjectPtr& cookie)
    {
        // Down-cast cookie to actual type.
        //
        MyCookiePtr mc = MyCookiePtr::dynamicCast(cookie);

        // Use information in cookie to clean up...
        //
        // ...
    }

    virtual void deactivate(const std::string& category);
};

Overview of Default Servants

The *Active Servant Map* (ASM) is a simple lookup table that maintains a one-to-one mapping between object identities and servants. Although the ASM is easy to understand and offers efficient indexing, it does not scale well when the number of objects is very large. Scalability is a common problem with object-oriented middleware: servers frequently are used as front ends to large databases that are accessed remotely by clients. The server's job is to present an object-oriented view to clients of a very large number of records in the database. Typically, the number of records is far too large to instantiate servants for even a fraction of the database records.

A common technique for solving this problem is to use *default servants*. A default servant is a servant that, for each request, takes on the persona of a different Ice object. In other words, the servant changes its behavior according to the *object identity* that is accessed by a request, on a per-request basis. In this way, it is possible to allow clients access to an unlimited number of Ice objects with only a single servant in memory. A default servant is essentially a specialized version of a *servant locator* that satisfies the majority of use cases with a simpler API, whereas a servant locator provides more flexibility for those applications that require it.

Default servant implementations are attractive not only because of the memory savings they offer, but also because of the simplicity of implementation: in essence, a default servant is a facade [1] to the persistent state of an object in the database. This means that the programming required to implement a default servant is typically minimal: it simply consists of the code required to read and write the corresponding database records.

A default servant is a regular servant that you implement and register with an *object adapter*. For each incoming request, the object adapter first attempts to locate a servant in its ASM. If no servant is found, the object adapter dispatches the request to a default servant. With this design, a default servant is the object adapter's servant of last resort if no match was found in the ASM.

Implementing a default servant requires a somewhat different mindset than the typical "one servant per Ice object" strategy used in less advanced applications. The most important quality of a default servant is its statelessness: it must be prepared to dispatch multiple requests simultaneously for different objects. The price we have to pay for the unlimited scalability and reduced memory footprint is performance: default servants typically make a database access for every invoked operation, which is obviously slower than caching state in memory as part of a servant that has been added to the ASM. However, this does not mean that default servants carry an unacceptable performance penalty: databases often provide sophisticated caching, so even though the operation implementations read and write the database, as long as they access cached state, performance may be entirely acceptable.

Default Servant API

The default servant API consists of the following operations in the object adapter interface:

Slice

```

module Ice {
    local interface ObjectAdapter {
        void addDefaultServant(Object servant, string category);
        Object removeDefaultServant(string category);
        Object findDefaultServant(string category);

        // ...
    };
};

```

As you can see, the object adapter allows you to add, remove, and find default servants. Note that, when you register a default servant, you must provide an argument for the `category` parameter. The value of the `category` parameter controls which object identities the default servant is responsible for: only object identities with a matching `category` member trigger a dispatch to this default servant. An incoming request for which no explicit entry exists in the ASM and with a `category` for which no default servant is registered returns an `ObjectNotExistException` to the client.

`addDefaultServant` has the following semantics:

- You can register exactly one default servant for a specific category. Attempts to call `addDefaultServant` for the same category more than once raise an `AlreadyRegisteredException`.
- You can register different default servants for different categories, or you can register the same single default servant multiple times (each time for a different category). In the former case, the category is implicit in the default servant instance that is called by the Ice run time; in the latter case, the servant can find out which category the incoming request is for by examining the object identity member of the `Current` object that is passed to the dispatched operation.
- It is legal to register a default servant for the empty category. Such a servant is used if a request comes in for which no entry exists in the ASM, and whose category does not match the category of any other registered default servant.

`removeDefaultServant` removes the default servant for the specified category. Attempts to remove a non-existent default servant raise `NotRegisteredException`. The operation returns the removed default servant. Once a default servant is successfully removed for the specified category, the Ice run time guarantees that no new incoming requests for that category are dispatched to the servant.

The `findDefaultServant` operation allows you to retrieve the default servant for a specific category (including the empty category). If no default servant is registered for the specified category, `findDefaultServant` returns null.

Threading Guarantees for Default Servants

The threading semantics for a default servant are no different than for a servant registered in the ASM: operations may be dispatched on a default servant concurrently, for the same object identity or for different object identities. If you have configured the communicator with multiple `dispatch threads`, your default servant must protect access to shared data with appropriate locks.

Call Dispatch Semantics for Default Servants

This section summarizes the actions taken by the Ice run time to locate a servant for an incoming request.

Every incoming request implicitly identifies a specific object adapter for the request (because the request arrives at a specific `transport endpoint` and, therefore, identifies a particular object adapter). The incoming request carries an object identity that must be mapped to a servant. To locate a servant, the Ice run time goes through the following steps, in the order shown:

1. Look for the identity in the ASM. If the ASM contains an entry, dispatch the request to the corresponding servant.
2. If the category of the incoming object identity is non-empty, look for a default servant that is registered for that category. If such a default servant is registered, dispatch the request to that servant.
3. If the category of the incoming object identity is empty, or no default servant could be found for the category in step 2, look for a default servant that is registered for the empty category. If such a default servant is registered, dispatch the request to that servant.
4. If the category of the incoming object identity is non-empty and no servant could be found in the preceding steps, look for a `servant locator` that is registered for that category. If such a servant locator is registered, call `locate` on the servant locator and, if `locate` returns a servant, dispatch the request to that servant, followed by a call to `finished`; otherwise, if the call to `locate` returns null, raise `ObjectNotExistException` or `FacetNotExistException` in the client. (`ObjectNotExistException` is raised if the

ASM does not contain a servant with the given identity at all, `FacetNotExistException` is raised if the ASM contains a servant with a matching identity, but a non-matching facet.)

5. If the category of the incoming object identity is empty, or no servant locator could be found for the category in step 4, look for a default servant locator (that is, a servant locator that is registered for the empty category). If a default servant locator is registered, dispatch the request as for step 4.
6. Raise `ObjectNotExistException` or `FacetNotExistException` in the client. (`ObjectNotExistException` is raised if the ASM does not contain a servant with the given identity at all, `FacetNotExistException` is raised if the ASM contains a servant with a matching identity, but a non-matching facet.)

It is important to keep these call dispatch semantics in mind because they enable a number of powerful implementation techniques. Each technique allows you to streamline your server implementation and to precisely control the trade-off between performance, memory consumption, and scalability.

Guidelines for Implementing Default Servants

This section provides some guidelines to assist you in implementing default servants effectively.

Object Identity is the Key

When an incoming request is dispatched to the default servant, the target object identity is provided in the `Current` argument. The `name` field of the identity typically supplies everything the default servant requires in order to satisfy the request. For instance, it may serve as the key in a database query, or even hold an encoded structure in some proprietary format that your application uses to convey more than just a string.

Naturally, the client can also pass arguments to the operation that assist the default servant in retrieving whatever state it requires. However, this approach can easily introduce implementation artifacts into your `Slice` interfaces, and in most cases the client should not need to know that the server is implemented with a default servant. If at all possible, use only the object identity.

Minimize Contention

For better scalability, the default servant's implementation should strive to eliminate contention among the dispatch threads. As an example, when a database holds the default servant's state, each of the servant's operations usually begins with a query. Assuming that the database API is thread-safe, the servant needs to perform no explicit locking of its own. With a copy of the state in hand, the implementation can work with function-local data to satisfy the request.

Combine Strategies

The ASM still plays a useful role even in applications that are ideally suited for default servants. For example, there is no need to implement a singleton object as a default servant: if there can only be one instance of the object, implementing it as a default servant does nothing to improve your application's scalability.

Applications often install a handful of servants in the ASM while servicing the majority of requests in a default servant. For example, a database application might install a singleton query object in the ASM while using a default servant to process all invocations on the database records.

Categories Denote Interfaces

In general, all of the objects serviced by a default servant must have the same interface. If you only need a default servant for one interface, you can register the default servant with an empty category string. However, to implement several interfaces, you will need a default servant implementation for each one. Furthermore, you must take steps to ensure that the object adapter dispatches an incoming request to the appropriate default servant. The `category` field of the object identity is intended to serve this purpose.

For example, a process control system might have interfaces named `Sensor` and `Switch`. To direct requests to the proper default servant, the application uses the symbol `Sensor` or `Switch` as the category of each object's identity, and registers corresponding default servants having those same categories with the object adapter.

Plan for the Future

If you suspect that you might eventually need to implement more than one interface with default servants, we recommend using a non-empty category even if you start out having only one default servant. Adding another default servant later becomes much easier if the application is

already designed to operate correctly with categories.

Throw exceptions

If a request arrives for an object that no longer exists, it is the default servant's responsibility to raise `ObjectNotExistException` to properly manage [object life cycles](#).

Handle `ice_ping`

One issue you need to be aware of with default servants is the need to override `ice_ping`: the default implementation of `ice_ping` that the servant inherits from its skeleton class always succeeds. For servants that are registered with the ASM, this is exactly what we want; however, for default servants, `ice_ping` must fail if a client uses a proxy to an Ice object that [no longer exists](#). To avoid getting successful `ice_ping` invocations for non-existent Ice objects, you must override `ice_ping` in the default servant. The implementation must check whether the object identity for the request denotes a still-existing Ice object and, if not, raise `ObjectNotExistException`.

It is good practice to override `ice_ping` if you are using default servants. Because you cannot override operations on `Ice::Object` using a Java or C# tie servant (or an Objective-C delegate servant), you must implement default servants by deriving from the generated skeleton class if you choose to override `ice_ping`.

Consider Interceptors

A [dispatch interceptor](#) is often installed as a default servant.

Use a `BObject` Default Servant to Forward Messages

Message forwarding services, such as [Glacier2](#), can be implemented simply and efficiently with a `BObject` default servant. Such a servant simply chooses a destination to forward a request to, without decoding any of the parameters.

Dispatch Interceptors

A dispatch interceptor is a server-side mechanism that allows you to intercept incoming client requests before they are given to a servant. The interceptor can examine the incoming request; in particular, it can see whether the request dispatch is collocation-optimized and examine the [Current](#) information for the request.

A dispatch interceptor can dispatch a request to a servant and check whether the dispatch was successful; if not, the interceptor can choose to retry the dispatch. This functionality is useful to automatically retry requests that have failed due to a recoverable error condition, such as a database deadlock exception. (Freeze uses dispatch interceptors for this purpose in its [evictor implementations](#).)

- [Using a Dispatch Interceptor](#)

Dispatch Interceptor API

Dispatch interceptors are not defined in Slice, but are provided as an API that is specific to each programming language. The remainder of this section presents the interceptor API for C++; for Java and .NET, the API is analogous, so we do not show it here.

In C++, a dispatch interceptor has the following interface:

```

C++

namespace Ice {
    class DispatchInterceptor : public virtual Object {
    public:
        virtual DispatchStatus dispatch(Request&) = 0;
    };

    typedef IceInternal::Handle<DispatchInterceptor>
    DispatchInterceptorPtr;
}

```

Note that a `DispatchInterceptor` *is-a* `Object`, that is, you use a dispatch interceptor as a servant.

To create a dispatch interceptor, you must derive a class from `DispatchInterceptor` and provide an implementation of the pure virtual `dispatch` function. The job of `dispatch` is to pass the request to the servant and to return a dispatch status, defined as follows:

```

C++

namespace Ice {
    enum DispatchStatus {
        DispatchOK, DispatchUserException, DispatchAsync
    };
}

```

The enumerators indicate how the request was dispatched:

- `DispatchOK`
The request was dispatched synchronously and completed without an exception.
- `DispatchUserException`

The request was dispatched synchronously and raised a user exception.

- `DispatchAsync`
The request was dispatched successfully as an asynchronous request; the result of the request is not available to the interceptor because the result is delivered to the AMD callback when the request completes.

The Ice run time provides basic information about the request to the `dispatch` function in the form of a `Request` object:

```

C++

namespace Ice {
    class Request {
    public:
        virtual const Current& getCurrent();
    };
}
```

- `getCurrent` provides access to the `Current` object for the request, which provides access to information about the request, such as the object identity of the target object, the object adapter used to dispatch the request, and the operation name.

Note that `Request`, for performance reasons, is *not* thread-safe. This means that you must not concurrently dispatch from different threads using the same `Request` object. (Concurrent dispatch for different requests does not cause any problems.)

To use a dispatch interceptor, you instantiate your derived class and register it as a servant with the Ice run time in the usual way, such as by adding the interceptor to the [Active Servant Map \(ASM\)](#), or returning the interceptor as a servant from a call to `locate` on a [servant locator](#).

Objective-C Mapping for Dispatch Interceptors

The Objective-C mapping in Ice Touch does not support AMD, therefore the return type of the `dispatch` method is simplified to a boolean:

```

Objective-C

@protocol ICEDispatchInterceptor <ICEObject>
- (BOOL) dispatch:(id<ICERequest>)request;
@end
```

A return value of `YES` is equivalent to `DispatchOK` and indicates that the request completed without an exception. A return value of `NO` is equivalent to `DispatchUserException`.

Using a Dispatch Interceptor

Your implementation of the `dispatch` function must dispatch the request to the actual servant. Here is a very simple example implementation of an interceptor that dispatches the request to the servant passed to the interceptor's constructor:

C++

```

class InterceptorI : public Ice::DispatchInterceptor {
public:
    InterceptorI(const Ice::ObjectPtr& servant)
        : _servant(servant) {}

    virtual Ice::DispatchStatus dispatch(Ice::Request& request) {
        return _servant->ice_dispatch(request);
    }

    Ice::ObjectPtr _servant;
};

```

Note that our implementation of `dispatch` calls `ice_dispatch` on the target servant to dispatch the request. `ice_dispatch` does the work of actually (synchronously) invoking the operation.

Also note that `dispatch` returns whatever is returned by `ice_dispatch`. For synchronous dispatch, you should always implement your interceptor in this way and not change this return value.

We can use this interceptor to intercept requests to a servant of any type as follows:

C++

```

ExampleIPtr servant = new ExampleI;
Ice::DispatchInterceptorPtr interceptor = new InterceptorI(servant);
adapter->add(interceptor,
communicator->stringToIdentity("ExampleServant"));

```

Note that, because dispatch interceptor *is-a* servant, this means that the servant to which the interceptor dispatches need not be the actual servant. Instead, it could be another dispatch interceptor that ends up dispatching to the real servant. In other words, you can chain dispatch interceptors; each interceptor's `dispatch` function is called until, eventually, the last interceptor in the chain dispatches to the actual servant.

A more interesting use of a dispatch interceptor is to retry a call if it fails due to a recoverable error condition. Here is an example that retries a request if it raises a local exception defined in Slice as follows:

Slice

```

local exception DeadlockException { /* ... */ };

```

Note that this is a `local` exception. Local exceptions that are thrown by the servant propagate to `dispatch` and can be caught there. A database might throw such an exception if the database detects a locking conflict during an update. We can retry the request in response to this exception using the following `dispatch` implementation:

C++

```
virtual Ice::DispatchStatus dispatch(Ice::Request& request) {
    while (true) {
        try {
            return _servant->ice_dispatch(request);
        } catch (const DeadlockException&) {
            // Happens occasionally
        }
    }
}
```

Of course, a more robust implementation might limit the number of retries and possibly add a delay before retrying.

You can also retry an asynchronous dispatch. In this case, each asynchronous dispatch attempt creates a new AMD callback object.

- If the response for the retried request has been sent already, the interceptor receives a `ResponseSentException`. Your interceptor must either not handle this exception (or rethrow it) or return `DispatchAsync`.
- If the response for the request has not been sent yet, the Ice run time ignores any call to `ice_response` or `ice_exception` on the old AMD callback.

If an operation throws a user exception (as opposed to a local exception), the user exception cannot be caught by `dispatch` as an exception but, instead, is reported by the return value of `ice_dispatch`: a return value of `DispatchUserException` indicates that the operation raised a user exception. You can retry a request in response to a user exception as follows:

C++

```
virtual Ice::DispatchStatus dispatch(Ice::Request& request) {
    Ice::DispatchStatus d;
    do {
        d = _servant->ice_dispatch(request);
    } while (d == Ice::DispatchUserException);
    return d;
}
```

This is fine as far as it goes, but not particularly useful because the preceding code retries if *any* kind of user exception is thrown. However, typically, we want to retry a request only if a *specific* user exception is thrown. The problem here is that the `dispatch` function does not have direct access to the actual exception that was thrown — all it knows is that *some* user exception was thrown, but not which one.

To retry a request for a specific user exception, you need to implement your servants such that they leave some "footprint" behind if they throw the exception of interest. This allows your request interceptor to test whether the user exception should trigger a retry. There are various techniques you can use to achieve this. For example, you can use thread-specific storage to test a retry flag that is set by the servant if it throws the exception or, if you use transactions, you can attach the retry flag to the transaction context. However, doing so is more complex; the intended use case is to permit retry of requests in response to local exceptions, so we suggest you retry requests only for local exceptions.

The most common use case for a dispatch interceptor is as a **default servant**. Rather than having an explicit interceptor for individual servants, you can register a dispatch interceptor as default servant. You can then choose the "real" servant to which to dispatch the request inside `dispatch`, prior to calling `ice_dispatch`. This allows you to intercept and selectively retry requests based on their outcome, which cannot be done using a servant locator.

The Ice Threading Model

Ice is inherently a multi-threaded platform. There is no such thing as a single-threaded server in Ice. As a result, you must concern yourself with concurrency issues: if a thread reads a data structure while another thread updates the same data structure, havoc will ensue unless you protect the data structure with appropriate locks. In order to build Ice applications that behave correctly, it is important that you understand the threading semantics of the Ice run time. Here we discuss Ice's *thread pool* concurrency model and provide guidelines for writing thread-safe Ice applications.

Thread Pools

A thread pool is a collection of threads that the Ice run time draws upon to perform specific tasks.

On this page:

- [Introduction to Thread Pools](#)
- [Configuring Thread Pools](#)
- [Dynamic Thread Pools](#)

Introduction to Thread Pools

Each communicator creates two thread pools:

- The *client thread pool* services outgoing connections, which primarily involves handling the replies to outgoing requests and includes notifying AMI callback objects. If a connection is used in [bidirectional mode](#), the client thread pool also dispatches incoming callback requests.
- The *server thread pool* services incoming connections. It dispatches incoming requests and, for bidirectional connections, processes replies to outgoing requests.

By default, these two thread pools are shared by all of the communicator's [object adapters](#). If necessary, you can configure individual object adapters to use a [private thread pool](#) instead.

If a thread pool is exhausted because all threads are currently dispatching a request, additional incoming requests are transparently delayed until a request completes and relinquishes its thread; that thread is then used to dispatch the next pending request. Ice minimizes thread context switches in a thread pool by using a leader-follower implementation [1].

Configuring Thread Pools

Each thread pool has a unique name that serves as the prefix for its configuration properties:

- [name.Size](#)
This property specifies the initial size of the thread pool. If not defined, the default value is 1.
- [name.SizeMax](#)
This property specifies the maximum size of the thread pool. If not defined, the default value is 1. If the value of this property is less than that of [name.Size](#), this property is adjusted to be equal to [name.Size](#).
- [name.SizeWarn](#)
This property sets a high water mark; when the number of threads in a pool reaches this value, the Ice run time logs a warning message. If you see this warning message frequently, it could indicate that you need to increase the value of [name.SizeMax](#). The default value is 0, which disables the warning.
- [name.StackSize](#)
This property specifies the number of bytes to use as the stack size of threads in the thread pool. The operating system's default is used if this property is not defined or is set to 0.
- [name.Serialize](#)
Setting this property to a value greater than 0 forces the thread pool to serialize all messages received over a connection. It is unnecessary to enable serialization for a thread pool whose maximum size is 1 because such a thread pool is already limited to processing one message at a time. For thread pools with more than one thread, serialization can have a negative impact on latency and throughput. If not defined, the default value is 0. We discuss this feature in more detail in [Thread Pool Design Considerations](#).
- [name.ThreadIdleTime](#)
This property specifies the number of seconds that a thread in the thread pool must be idle before it terminates. The default value is 60 seconds if this property is not defined. Setting it to 0 disables the termination of idle threads.

For configuration purposes, the names of the client and server thread pools are `Ice.ThreadPool.Client` and `Ice.ThreadPool.Server`, respectively. As an example, the following properties establish the initial and maximum sizes for these thread pools:

```
Ice.ThreadPool.Client.Size=1
Ice.ThreadPool.Client.SizeMax=10
Ice.ThreadPool.Server.Size=1
Ice.ThreadPool.Server.SizeMax=10
```

To monitor the thread pool activities of the Ice run time, you can enable the `Ice.Trace.ThreadPool` property. Setting this property to a non-0 value causes the Ice run time to log a message when it creates a thread pool, as well as each time the size of a thread pool increases or decreases.

Dynamic Thread Pools

A *dynamic* thread pool can grow and shrink when necessary in response to changes in an application's work load. All thread pools have at least one thread, but a dynamic thread pool can grow as the demand for threads increases, up to the pool's maximum size. Threads may also be terminated automatically when they have been idle for some time.

The dynamic nature of a thread pool is determined by the configuration properties `name.Size`, `name.SizeMax`, and `name.ThreadIdleTime`. A thread pool is not dynamic in its default configuration because `name.Size` and `name.SizeMax` are both set to 1, meaning the pool can never grow to contain more than a single thread. To configure a dynamic thread pool, you must set at least one of `name.Size` or `name.SizeMax` to a value greater than 1. We can use several configuration scenarios to explore the semantics of dynamic thread pools in greater detail:

- `name.SizeMax=5`

This thread pool initially contains a single thread because `name.Size` has a default value of 1, and Ice can grow the pool up to the maximum of 5 threads. During periods of inactivity, idle threads terminate after 60 seconds (the default value for `name.ThreadIdleTime`) until the pool contains just 1 thread again.

- `name.Size=3`
`name.SizeMax=5`

This thread pool starts with 3 active threads but otherwise behaves the same as in the previous configuration. The pool can still shrink to a size of 1 as threads become idle.

- `name.Size=3`
`name.ThreadIdleTime=10`

This thread pool starts with 3 active threads and shrinks quickly to 1 thread during periods of inactivity. As demand increases again, the thread pool can return to its maximum size of 3 threads (`name.SizeMax` defaults to the value of `name.Size`).

- `name.SizeMax=5`
`name.ThreadIdleTime=0`

This thread pool can grow from its initial size of 1 thread to contain up to 5 threads, but it will never shrink because `name.ThreadIdleTime` is set to 0.

- `name.Size=5`
`name.ThreadIdleTime=0`

This thread pool starts with 5 threads and can neither grow nor shrink.

To summarize, the value of `name.ThreadIdleTime` determines whether (and how quickly) a thread pool can shrink to a size of 1. A thread pool that shrinks can also grow to its maximum size. Finally, setting `name.SizeMax` to a value larger than `name.Size` allows a thread pool to grow beyond its initial capacity.

Object Adapter Thread Pools

The default behavior of an [object adapter](#) is to share the [thread pools](#) of its communicator and, for many applications, this behavior is entirely sufficient. However, the ability to configure an object adapter with its own thread pool is useful in certain situations:

- When the concurrency requirements of an object adapter does not match those of its communicator. In a server with multiple object adapters, the configuration of the communicator's client and server thread pools may be a good match for some object adapters, but others may have different requirements. For example, the servants hosted by one object adapter may not support concurrent access, in which case limiting that object adapter to a single-threaded pool eliminates the need for synchronization in those servants. On the other hand, another object adapter might need a multi-threaded pool for better performance.
- To ensure that a minimum number of threads is available for dispatching requests to an adapter's servants. This is especially important for eliminating the possibility of deadlocks when using [nested invocations](#).

An object adapter's thread pool supports all of the properties described in [Configuring Thread Pools](#). For configuration purposes, the name of an adapter's thread pool is `adapter.ThreadPool`, where `adapter` is the name of the adapter.

An adapter creates its own thread pool when at least one of the following properties has a value greater than zero:

- `adapter.ThreadPool.Size`
- `adapter.ThreadPool.SizeMax`

These properties have the same semantics as those described earlier except they both have a default value of zero, meaning that an adapter uses the communicator's thread pools by default.

As an example, the properties shown below configure a thread pool for the object adapter named `PrinterAdapter`:

```
PrinterAdapter.ThreadPool.Size=3
PrinterAdapter.ThreadPool.SizeMax=15
PrinterAdapter.ThreadPool.SizeWarn=14
```

Thread Pool Design Considerations

Improper configuration of a [thread pool](#) can have a serious impact on the performance of your application. This page discusses some issues that you should consider when designing and configuring your applications.

On this page:

- [Single-Threaded Pool](#)
- [Multi-Threaded Pool](#)
- [Serializing Requests in a Multi-Threaded Pool](#)

Single-Threaded Pool

There are several implications of using a thread pool with a maximum size of one thread:

- **Only one message can be dispatched at a time.**

This can be convenient because it lets you avoid (or postpone) dealing with [thread-safety issues](#) in your application. However, it also eliminates the possibility of dispatching requests concurrently, which can be a bottleneck for applications running on multi-CPU systems or that perform blocking operations. Another option is to enable [serialization](#) in a multi-threaded pool.

- **Only one AMI reply can be processed at a time.**

An application must increase the size of the client thread pool in order to process multiple AMI callbacks in parallel.

- **Nested twoway invocations are limited.**

At most one level of [nested twoway invocations](#) is possible.

It is important to remember that a communicator's client and server thread pools have a default maximum size of one thread, therefore these limitations also apply to any object adapter that shares the communicator's thread pools.

Multi-Threaded Pool

Configuring a thread pool to support multiple threads implies that the application is prepared for the Ice run time to dispatch operation invocations or AMI callbacks concurrently. Although greater effort is required to design a thread-safe application, you are rewarded with the ability to improve the application's scalability and throughput.

Choosing an appropriate maximum size for a thread pool requires careful analysis of your application. For example, in compute-bound applications it is best to limit the number of threads to the number of physical processor cores or threads on the host machine; adding any more threads only increases context switches and reduces performance. Increasing the size of the pool beyond the number of cores can improve responsiveness when threads can become blocked while waiting for the operating system to complete a task, such as a network or file operation. On the other hand, a thread pool configured with too many threads can have the opposite effect and negatively impact performance. Testing your application in a realistic environment is the recommended way of determining the optimum size for a thread pool.

If your application uses [nested invocations](#), it is very important that you evaluate whether it is possible for thread starvation to cause a deadlock. Increasing the size of a thread pool can lessen the chance of a deadlock, but other design solutions are usually preferred.

Serializing Requests in a Multi-Threaded Pool

When using a multi-threaded pool, the nondeterministic nature of thread scheduling means that requests from the same connection may not be dispatched in the order they were received. Some applications cannot tolerate this behavior, such as a transaction processing server that must guarantee that requests are executed in order. There are two ways of satisfying this requirement:

1. Use a single-threaded pool.
2. [Configure a multi-threaded pool](#) to serialize requests using its `Serialize` property.

At first glance these two options may seem equivalent, but there is a significant difference: a single-threaded pool can only dispatch one request at a time and therefore serializes requests from *all* connections, whereas a multi-threaded pool configured for serialization can dispatch requests from different connections concurrently while serializing requests from the same connection.

For requests dispatched using [asynchronous method dispatch \(AMD\)](#), `Serialize` only serializes the dispatching, not the requests themselves. Ice will dispatch the next request once its dispatch its complete—it does not wait for the first request to provide a response or exception.

You can obtain a comparable behavior from a multi-threaded pool without enabling serialization, but only if you design the clients so that they do not send [requests from multiple threads](#), do not send requests over more than one connection, and only use synchronous twoway invocations. In general, however, it is better to avoid such tight coupling between the implementations of the client and server.

Enabling serialization can improve responsiveness and performance compared to a single-threaded pool, but there is an associated cost. The extra synchronization that the pool must perform to serialize requests can add significant overhead and result in higher latency and reduced throughput.

As you can see, thread pool serialization is not a feature that you should enable without analyzing whether the benefits are worthwhile. For example, it might be an inappropriate choice for a server with long-running operations when the client needs the ability to have several operations in progress simultaneously. If serialization was enabled in this situation, the client would be forced to work around it by [opening several connections](#) to the server, which again tightly couples the client and server implementations. If the server must keep track of the order of client requests, a better solution would be to use serialization in conjunction with [AMD](#) to queue the incoming requests for execution by other threads.

- [Nested Invocations](#)
- [Thread Safety](#)
- [Connection Establishment](#)

Concurrent Proxy Invocations

[Proxy objects](#) are fully thread safe, meaning a client can invoke on the same proxy object from multiple threads concurrently without the need for additional synchronization. However, Ice makes few guarantees about the order in which it sends proxy invocations over a connection.

To understand the ordering issue, it's important to first understand some fundamental proxy concepts:

- At any point in time, a proxy may or may not be [associated with a connection](#).
- A new proxy initially has no connection, and Ice does not attempt to associate it with a connection until its first invocation.
- If Ice needs to establish a new connection for a proxy, Ice queues all invocations on that proxy until the connection succeeds.
- After a proxy is associated with a connection, the proxy may or may not [cache that connection](#) for subsequent invocations.
- Proxies share connections by default, but an application can force proxies to use separate connections.

Ice (as of version 3.6) guarantees that ordering will be maintained for invocations on the same proxy object, but only if that proxy caches its connection. This guarantee also holds for invocations on two or more proxies that programmatically compare as equal, meaning the proxies have the same identity and other configuration settings, and furthermore these proxies must cache connections as well.

Ice does not guarantee the order of invocations for any other situation.

The order in which the Ice run time in a client sends invocations over a connection does not necessarily determine the order in which they will be executed in the server. See [Thread Pool Design Considerations](#) for information about ordering guarantees in servers.

Nested Invocations

A *nested invocation* is one that is made within the context of another Ice operation. For instance, the implementation of an operation in a servant might need to make a nested invocation on some other object, or an AMI callback object might invoke an operation in the course of processing a reply to an asynchronous request. It is also possible for one of these invocations to result in a nested callback to the originating process. The maximum depth of such invocations is determined by the size of the thread pools used by the communicating parties.

On this page:

- [Deadlocks with Nested Invocations](#)
- [Analyzing an Application for Nested Invocations](#)

Deadlocks with Nested Invocations

Applications that use nested invocations must be carefully designed to avoid the potential for deadlock, which can easily occur when invocations take a circular path. For example, this illustration presents a deadlock scenario when using the default thread pool configuration:

Nested invocation deadlock.

In this diagram, the implementation of `opA` makes a nested twoway invocation of `opB`, but the implementation of `opB` causes a deadlock when it tries to make a nested callback. As mentioned in [Thread Pools](#), the communicator's thread pools have a maximum size of one thread unless explicitly configured otherwise. In Server A, the only thread in the server thread pool is busy waiting for its invocation of `opB` to complete, and therefore no threads remain to handle the callback from Server B. The client is now blocked because Server A is blocked, and they remain blocked indefinitely unless timeouts are used.

There are several ways to avoid a deadlock in this scenario:

- **Increase the maximum size of the server thread pool in Server A.**

Configuring the server thread pool in Server A to support more than one thread allows the nested callback to proceed. This is the simplest solution, but it requires that you know in advance how deeply nested the invocations may occur, or that you set the maximum size to a sufficiently large value that exhausting the pool becomes unlikely. For example, setting the maximum size to two avoids a deadlock when a single client is involved, but a deadlock could easily occur again if multiple clients invoke `opA` simultaneously. Furthermore, setting the maximum size too large can cause its own [set of problems](#).

- **Use a oneway invocation.**

If Server A called `opB` using a [oneway invocation](#), it would no longer need to wait for a response and therefore `opA` could complete, making a thread available to handle the callback from Server B. However, we have made a significant change in the semantics of `opA` because now there is no guarantee that `opB` has completed before `opA` returns, and it is still possible for the oneway invocation of `opB` to block.

- **Create another object adapter for the callbacks.**

No deadlock occurs if the callback from Server B is directed to a different object adapter that is configured with its [own thread pool](#).

- **Implement `opA` using asynchronous dispatch and invocation.**

By declaring `opA` as an AMD operation and invoking `opB` using AMI, Server A can avoid blocking the thread pool's thread while it waits for `opB` to complete. This technique, known as *asynchronous request chaining*, is used extensively in Ice services such as IceGrid and Glacier2 to eliminate the possibility of deadlocks.

As another example, consider a client that makes a nested invocation from an AMI callback object using the default thread pool configuration. The (one and only) thread in the client thread pool receives the reply to the asynchronous request and invokes its callback object. If the callback object in turn makes a nested twoway invocation, a deadlock occurs because no more threads are available in the client thread pool to process the reply to the nested invocation. The solutions are similar to some of those presented in the above illustration: increase the maximum size of the client thread pool, use a oneway invocation, or call the nested invocation using AMI.

Analyzing an Application for Nested Invocations

A number of factors must be considered when evaluating whether an application is properly designed and configured for nested invocations:

- The thread pool configurations in use by all communicating parties have a significant impact on an application's ability to use nested invocations. While analyzing the path of circular invocations, you must pay careful attention to the threads involved to determine whether sufficient threads are available to avoid deadlock. This includes not just the threads that dispatch requests, but also the threads that make the requests and process the replies. Enabling the `Ice.Trace.ThreadPool` property can give you a better understanding of the thread pool behavior in your application.
- Bidirectional connections are another complication, since you must be aware of which threads are used on either end of the connection.
- Finally, the synchronization activities of the communicating parties must also be scrutinized. For example, a deadlock is much more likely when a lock is held while making an invocation.

As you can imagine, tracing the call flow of a distributed application to ensure there is no possibility of deadlock can quickly become a complex and tedious process. In general, it is best to avoid circular invocations if at all possible.

- [Oneway Invocations](#)

Thread Safety

The Ice run time itself is fully thread safe, meaning multiple application threads can safely call methods on objects such as communicators, object adapters, and proxies without synchronization problems. As a developer, you must also be concerned with thread safety because the Ice run time can dispatch multiple invocations concurrently in a server. In fact, it is possible for multiple requests to proceed in parallel within the same servant and within the same operation on that servant. It follows that, if the operation implementation manipulates non-stack storage (such as member variables of the servant or global or static data), you must interlock access to this data to avoid data corruption.

The need for thread safety in an application depends on its configuration. Using the default [thread pool](#) configuration typically makes synchronization unnecessary because at most one operation can be dispatched at a time. Thread safety becomes an issue once you increase the maximum size of a thread pool.

Ice uses the native synchronization and threading primitives of each platform. For C++ users, Ice provides a collection of convenient and portable [wrapper classes](#) for use by Ice applications.

On this page:

- [Threading Issues with Marshaling](#)
- [Thread Creation and Destruction Hooks](#)
- [Installing Thread Hooks with a Plug-in](#)

Threading Issues with Marshaling

The marshaling semantics of the Ice run time present a subtle thread safety issue that arises when an operation returns data by reference. In C++, the only relevant case is returning an instance of a Slice class, either directly or nested as a member of another type. In Java, .NET, and the scripting languages, Slice structures, sequences, and dictionaries are also affected.

The potential for corruption occurs whenever a servant returns data by reference, yet continues to hold a reference to that data. For example, consider the following Java implementation:

Java

```

public class GridI extends _GridDisp
{
    GridI()
    {
        _grid = // ...
    }

    public int[][]
    getGrid(Ice.Current curr)
    {
        return _grid;
    }

    public void
    setValue(int x, int y, int val, Ice.Current curr)
    {
        _grid[x][y] = val;
    }

    private int[][] _grid;
}

```

Suppose that a client invoked the `getGrid` operation. While the Ice run time marshals the returned array in preparation to send a reply

message, it is possible for another thread to dispatch the `setValue` operation on the same servant. This race condition can result in several unexpected outcomes, including a failure during marshaling or inconsistent data in the reply to `getGrid`. Synchronizing the `getGrid` and `setValue` operations would not fix the race condition because the Ice run time performs its marshaling outside of this synchronization.

One solution is to implement accessor operations, such as `getGrid`, so that they return copies of any data that might change. There are several drawbacks to this approach:

- Excessive copying can have an adverse affect on performance.
- The operations must return deep copies in order to avoid similar problems with nested values.
- The code to create deep copies is tedious and error-prone to write.

Another solution is to make copies of the affected data only when it is modified. In the revised code shown below, `setValue` replaces `_grid` with a copy that contains the new element, leaving the previous contents of `_grid` unchanged:

```

Java

```

public class GridI extends _GridDisp
{
 ...

 public synchronized int[][]
 getGrid(Ice.Current curr)
 {
 return _grid;
 }

 public synchronized void
 setValue(int x, int y, int val, Ice.Current curr)
 {
 int[][] newGrid = // shallow copy...
 newGrid[x][y] = val;
 _grid = newGrid;
 }

 ...
}

```

```

This allows the Ice run time to safely marshal the return value of `getGrid` because the array is never modified again. For applications where data is read more often than it is written, this solution is more efficient than the previous one because accessor operations do not need to make copies. Furthermore, intelligent use of shallow copying can minimize the overhead in mutating operations.

Finally, a third approach changes accessor operations to use AMD in order to regain control over marshaling. After annotating the `getGrid` operation with `amd` metadata, we can revise the servant as follows:

Java

```
public class GridI extends _GridDisp
{
    ...

    public synchronized void
    getGrid_async(AMD_Grid_getGrid cb, Ice.Current curr)
    {
        cb.ice_response(_grid);
    }

    public synchronized void
    setValue(int x, int y, int val, Ice.Current curr)
    {
        _grid[x][y] = val;
    }

    ...
}
```

Normally, AMD is used in situations where the servant needs to delay its response to the client without blocking the calling thread. For `getGrid`, that is not the goal; instead, as a side-effect, AMD provides the desired marshaling behavior. Specifically, the Ice run time marshals the reply to an asynchronous request at the time the servant invokes `ice_response` on the AMD callback object. Because `getGrid` and `setValue` are synchronized, this guarantees that the data remains in a consistent state during marshaling.

Thread Creation and Destruction Hooks

On occasion, it is necessary to intercept the creation and destruction of threads created by the Ice run time, for example, to interoperate with libraries that require applications to make thread-specific initialization and finalization calls (such as COM's `CoInitializeEx` and `CoUninitialize`). Ice provides callbacks to inform an application when each run-time thread is created and destroyed. For C++, the callback class looks as follows:

C++

```
class ThreadNotification : public IceUtil::Shared {
public:
    virtual void start() = 0;
    virtual void stop() = 0;
};
typedef IceUtil::Handle<ThreadNotification> ThreadNotificationPtr;
```

To receive notification of thread creation and destruction, you must derive a class from `ThreadNotification` and implement the `start` and `stop` member functions. These functions will be called by the Ice run by each thread as soon as it is created, and just before it exits. You must install your callback class in the Ice run time when you [create a communicator](#) by setting the `threadHook` member of the `InitializationData` structure.

For example, you could define a callback class and register it with the Ice run time as follows:

C++

```

class MyHook : public virtual Ice::ThreadNotification {
public:
    void start()
    {
        cout << "start: id = " << ThreadControl().id() << endl;
    }
    void stop()
    {
        cout << "stop: id = " << ThreadControl().id() << endl;
    }
};

int
main(int argc, char* argv[])
{
    // ...

    Ice::InitializationData id;
    id.threadHook = new MyHook;
    communicator = Ice::initialize(argc, argv, id);

    // ...
}

```

The implementation of your `start` and `stop` methods can make whatever thread-specific calls are required by your application.

For Java and C#, `Ice.ThreadNotification` is an interface:

```

public interface ThreadNotification {
    void start();
    void stop();
}

```

To receive the thread creation and destruction callbacks, you must derive a class from this interface that implements the `start` and `stop` methods, and register an instance of that class when you create the communicator. (The code to do this is analogous to the C++ version.)

For Python, the interface is:

Python

```
class ThreadNotification(object):
    def __init__(self):
        pass

    # def start():
    # def stop():
```

The Ice run time calls the `start` and `stop` methods of the class instance you provide to `Ice.initialize` when it creates and destroys threads.

Installing Thread Hooks with a Plug-in

The thread hook facility described [above](#) requires that you modify a program's source code in order to receive callbacks when threads in the Ice run time are created and destroyed. It is also possible to install thread hooks using the [Ice plug-in facility](#), which is useful for adding thread hooks to an existing program that you cannot (or prefer not to) modify.

Ice provides a base class named `ThreadHookPlugin` for C++, Java, and C# that supplies the necessary functionality. The C++ class definition is shown below:

C++

```
namespace Ice {
class ThreadHookPlugin : public Ice::Plugin {
public:

    ThreadHookPlugin(const CommunicatorPtr& communicator,
const ThreadNotificationPtr&);

    virtual void initialize();

    virtual void destroy();
};
}
```

The equivalent definitions for Java and C# are quite similar and therefore not presented here.

The `ThreadHookPlugin` constructor installs the given `ThreadNotification` object into the specified communicator. The `initialize` and `destroy` methods are empty, but you can subclass `ThreadHookPlugin` and override these methods if necessary.

In order to create a thread hook plug-in, you must do the following:

- Define and export a factory class (for Java and C#) or factory function (for C++) that returns an instance of `ThreadHookPlugin`, as described in the [plug-in API](#).
- Implement the `ThreadNotification` object that you will pass to the `ThreadHookPlugin` constructor.
- Package your code into a format that is suitable for dynamic loading, such as a shared library or DLL for C++ or an assembly for C#.

To install your plug-in, use a configuration property like the one shown below:

```
Ice.Plugin.MyThreadHookPlugin=MyHooks:createPlugin ...
```

The first component of the property value represents the plug-in's entry point. For C++, this value includes the abbreviated name of the shared library or DLL (`MyHooks`) and the name of a factory function (`createPlugin`).

If your property value is language-specific and the configuration file containing this property is shared by programs in multiple implementation languages, you can use an alternate syntax that is loaded only by the Ice run time for a certain language. For example, here is the C++-specific version:

```
Ice.Plugin.MyThreadHookPlugin.cpp=MyHooks:createPlugin ...
```

For more information, see [Ice.Plugin.*](#).

Dispatching Invocations to User Threads

By default, operation invocations and AMI callbacks are executed by a thread from a [thread pool](#). This behavior is simple and convenient for applications because they need not concern themselves with thread creation and destruction. However, there are situations where it is necessary to respond to operation invocations or AMI callbacks in a particular thread. For example, in a server, you might need to update a database that does not permit concurrent access from different threads or, in a client, you might need to update a user interface with the results of an invocation. (Many UI frameworks require all UI updates to be made by a specific thread.)

In Ice for C++, Java, .NET, and Objective-C, you can control which thread receives operation invocations and AMI callbacks, so you can ensure that all updates are made by a thread you choose. The implementation techniques vary slightly for each language and are explained in the sections that follow.

On this page:

- [C++ Dispatcher API](#)
 - [Dispatching with C++11 Lambda Functions](#)
- [Java Dispatcher API](#)
- [C# Dispatcher API](#)
- [Objective-C Dispatcher API](#)
- [Dispatcher Implementation Notes](#)

C++ Dispatcher API

To install a dispatcher, you must instantiate a class that derives from `Ice::Dispatcher` and [initialize a communicator](#) with that instance in the `InitializationData` structure. All invocations that arrive for this communicator are made via the specified dispatcher. For example:

C++

```

class MyDispatcher : public Ice::Dispatcher /*, ... */
    // ...
};

int
main(int argc, char* argv[])
{
    Ice::CommunicatorPtr communicator;

    try {
        Ice::InitializationData initData;
        initData.properties = Ice::createProperties(argc, argv);
        initData.dispatcher = new MyDispatcher();
        communicator = Ice::initialize(argc, argv, initData);

        // ...
    } catch (const Ice::Exception& ex) {
        // ...
    }

    // ...
}

```

The `Ice::Dispatcher` abstract base class has the following interface:

C++

```

class Dispatcher : virtual public IceUtil::Shared
{
public:
    virtual void dispatch(const DispatcherCallPtr&,
const ConnectionPtr&) = 0;
};

typedef IceUtil::Handle<Dispatcher> DispatcherPtr;

```

The Ice run time invokes the `dispatch` method whenever an operation invocation arrives or an AMI invocation completes, passing an instance of `DispatcherCall` and the connection via which the invocation arrived. The job of `dispatch` is to pass the incoming invocation to an operation implementation.

The connection parameter allows you to decide how to dispatch the operation based on the connection via which it was received. This value may be nil if no connection currently exists.

You can write `dispatch` such that it blocks and waits for completion of the invocation because `dispatch` is called by a thread in the server-side thread pool (for incoming operation invocations) or the client-side thread pool (for AMI callbacks).

The `DispatcherCall` instance encapsulates all the details of the incoming call. It is another abstract base class with the following interface:

C++

```

class DispatcherCall : virtual public IceUtil::Shared
{
public:
    virtual ~DispatcherCall() { }

    virtual void run() = 0;
};

typedef IceUtil::Handle<DispatcherCall> DispatcherCallPtr;

```

Your implementation of `dispatch` is expected to call `run` on the `DispatcherCall` instance (or, more commonly, to cause `run` to be called some time later). When you call `run`, the Ice run time processes the invocation in the thread that calls `run`.

A very simple way to implement `dispatch` would be as follows:

C++

```

class MyDispatcher : public Ice::Dispatcher
public:
    virtual void dispatch(const Ice::DispatcherCallPtr& d,
const Ice::ConnectionPtr&)
    {
        d->run(); // Does not throw, blocks until op completes.
    }
};

```

Whenever the Ice run time receives an incoming operation invocation or when an AMI invocation completes, it calls `dispatch` which, in turn, calls `run` on the `DispatcherCall` instance.

With this simple example, `dispatch` immediately calls `run`, and `run` does not return until the corresponding operation invocation is complete. As a result, this implementation ties up a thread in the thread pool for the duration of the call.

So far, we really have not gained anything because all we have is a callback method that is called by the Ice run time. However, this simple mechanism is sufficient to ensure that we can update a UI from the correct thread.

A common technique to avoid blocking is to use [asynchronous method invocation](#). In response to a UI event (such as the user pressing a "Submit" button), the application initiates an operation invocation from the corresponding UI callback by calling the operation's `begin_` method. This is guaranteed not to block the caller, so the UI remains responsive. Some time later, when the operation completes, the Ice run time invokes an AMI callback from one of the threads in its thread pool. That callback now has to update the UI, but that can only be done from the UI thread. By using a dispatcher, you can easily delegate the update to the correct thread. For example, here is how you can arrange for AMI callbacks to be passed to the UI thread with MFC:

C++

```

class MyDialog : public CDialog { ... };

class MyDispatcher : public Ice::Dispatcher {
public:
    MyDispatcher(MyDialog* dialog) : _dialog(dialog)
    {
    }

    virtual void
    dispatch(const Ice::DispatcherCallPtr& call,
const Ice::ConnectionPtr&)
    {
        _dialog->PostMessage(WM_AMI_CALLBACK, 0,
reinterpret_cast<LPARAM>(new Ice::DispatcherCallPtr(call)));
    }

private:
    MyDialog* _dialog;
};

```

The `MyDispatcher` class simply stores the `CDialog` handle for the UI and calls `PostMessage`, passing the `DispatcherCall` instance. In turn, this causes the UI thread to receive an event and invoke the UI callback method that was registered to respond to `WM_AMI_CALLBACK` events.

In turn, the implementation of the callback method calls `run`:

```
C++
```

```

LRESULT
MyDialog::OnAMICallback(WPARAM, LPARAM lParam)
{
    try {
        Ice::DispatcherCallPtr* call =
reinterpret_cast<Ice::DispatcherCallPtr*>(lParam);
        (*call)->run();
        delete call;
    } catch (const Ice::Exception& ex) {
        // ...
    }
    return 0;
}

```

The Ice run time calls `dispatch` once the asynchronous operation invocation is complete. In turn, this causes the `OnAMICallback` to trigger, which calls `run`. Because the operation has completed already, `run` does not block, so the UI remains responsive.

Please see the MFC demo in your Ice distribution for a fully-functional UI client that uses this technique.

Dispatching with C++11 Lambda Functions

With a suitable C++ compiler and an Ice installation that was built with C++11 features enabled, you can use lambda functions instead of defining a callback class. The dispatcher API includes the following helper function:

```
C++
```

```

namespace Ice {
inline DispatcherPtr
newDispatcher(const std::function<void (const Ice::DispatcherCallPtr&,
const Ice::ConnectionPtr)>& cb)
{
    return ...;
}
}

```

The return value of `newDispatcher` is a `Dispatcher` object that delegates to your lambda function. You can invoke `newDispatcher` as shown below:

C++

```
Ice::DispatcherPtr disp = Ice::newDispatcher([](const
Ice::DispatcherCallPtr& d,
                                                    const
Ice::ConnectionPtr&) {
    d->run();
});
initData.dispatcher = disp;
communicator = Ice::initialize(...);
```

Java Dispatcher API

To install a dispatcher, you must instantiate a class that implements `Ice.Dispatcher` and [initialize a communicator](#) with that instance in the `InitializationData` structure. All invocations that arrive for this communicator are made via the specified dispatcher. For example:

Java

```

public class MyDispatcher implements Ice.Dispatcher
{
    // ...
}

public class Server
{
    public static void
    main(String[] args)
    {
        Ice.Communicator communicator;

        try {
            Ice.InitializationData initData =
new Ice.InitializationData();
            initData.properties = Ice.Util.createProperties(args);
            initData.dispatcher = new MyDispatcher();
            communicator = Ice.Util.initialize(args, initData);

            // ...
        } catch (Ice.LocalException & ex) { {
            // ...
        }

        // ...
    }

    // ...
}

```

The `Ice.Dispatcher` interface looks as follows:

Java

```

public interface Dispatcher
{
    void dispatch(Runnable runnable, Ice.Connection con);
}

```

The Ice run time invokes the `dispatch` method whenever an operation invocation arrives, passing a `Runnable` and the connection via which the invocation arrived. The job of `dispatch` is to pass the incoming invocation to an operation implementation.

The connection parameter allows you to decide how to dispatch the operation based on the connection via which it was received. This value may be null if no connection currently exists.

You can write `dispatch` such that it blocks and waits for completion of the invocation because `dispatch` is called by a thread in the

server-side thread pool (for incoming operation invocations) or the client-side thread pool (for AMI callbacks).

Your implementation of `dispatch` is expected to call `run` on the `Runnable` instance (or, more commonly, to cause `run` to be called some time later). When you call `run`, the Ice run time processes the invocation in the thread that calls `run`.

A very simple way to implement `dispatch` would be as follows:

```

Java

```

public class MyDispatcher implements Ice.Dispatcher
{
 public void
 dispatch(Runnable runnable, Ice.Connection connection)
 {
 // Does not throw, blocks until op completes.
 runnable.run();
 }
}

```

```

Whenever the Ice run time receives an incoming operation invocation or when an AMI invocation completes, it calls `dispatch` which, in turn, calls `run` on the `Runnable` instance.

With this simple example, `dispatch` immediately calls `run`, and `run` does not return until the corresponding operation invocation is complete. As a result, this implementation ties up a thread in the thread pool for the duration of the call.

So far, we really have not gained anything because all we have is a callback method that is called by the Ice run time. However, this simple mechanism is sufficient to ensure that we can update a UI from the correct thread.

A common technique to avoid blocking is to use [asynchronous method invocation](#). In response to a UI event (such as the user pressing a "Submit" button), the application initiates an operation invocation from the corresponding UI callback by calling the operation's `begin_` method. This is guaranteed not to block the caller, so the UI remains responsive. Some time later, when the operation completes, the Ice run time invokes an AMI `response` callback from one of the threads in its thread pool. That callback now has to update the UI, but that can only be done from the UI thread. By using a dispatcher, you can easily delegate the update to the correct thread. For example, here is how you can arrange for AMI callbacks to be passed to the UI thread with Swing:

```

Java

```

```

public class Client extends JFrame
{
    public static void main(final String[] args)
    {
        SwingUtilities.invokeLater(new Runnable()
        {
            public void run()
            {
                try {
                    new Client(args);
                } catch (Ice.LocalException e) {
                    JOptionPane.showMessageDialog(
                        null, e.toString(),
                        "Initialization failed",
                        JOptionPane.ERROR_MESSAGE);
                }
            }
        });
    }

    Client(String[] args)
    {
        Ice.Communicator communicator;

        try {
            Ice.InitializationData initData =
new Ice.InitializationData();
            initData.dispatcher = new Ice.Dispatcher()
            {
                public void
                dispatch(Runnable runnable, Ice.Connection connection)
                {
                    SwingUtilities.invokeLater(runnable);
                }
            };
            communicator = Ice.Util.initialize(args, initData);
        }
        catch(Throwable ex)
        {
            // ...
        }
        // ...
    }
}

```

The dispatch method simply delays the call to run by calling `invokeLater`, passing it the `Runnable` that is provided by the Ice run time. This causes the Swing UI thread to eventually make the call to run. Because the Ice run time does not call `dispatch` until the

asynchronous invocation is complete, that call to `run` does not block and the UI remains responsive.

Please see the `swing` demo in your Ice distribution for a fully-functional UI client that uses this technique.

C# Dispatcher API

To install a dispatcher, you must [initialize a communicator](#) with a delegate of type `Ice.Dispatcher` in the `InitializationData` structure. All invocations that arrive for this communicator are made via the specified dispatcher. For example:

```

C#

public class Server
{
    public static void Main(string[] args)
    {
        Ice.Communicator communicator = null;

        try {
            Ice.InitializationData initData =
new Ice.InitializationData();
            initData.dispatcher = new MyDispatcher().dispatch;
            communicator = Ice.Util.initialize(ref args, initData);
            // ...
        } catch (System.Exception ex) {
            // ...
        }

        // ...
    }

    // ...
}

```

The `Ice.Dispatcher` delegate is defined as follows:

```

C#

public delegate void Dispatcher(System.Action call, Connection con);

```

The Ice run time calls your delegate whenever an operation invocation arrives, passing a `System.Action` delegate and the connection via which the invocation arrived. The job of your delegate is to pass the incoming invocation to an operation implementation.

The connection parameter allows you to decide how to dispatch the operation based on the connection via which it was received. This value may be null if no connection currently exists.

In this example, the delegate calls a method `dispatch` on an instance of a `MyDispatcher` class. You can write `dispatch` such that it blocks and waits for completion of the invocation because `dispatch` is called by a thread in the server-side thread pool (for incoming operation invocations) or the client-side thread pool (for AMI callbacks).

Your implementation of `dispatch` is expected to invoke the `call` delegate (or, more commonly, to cause it to be invoked some time later). When you invoke the `call` delegate, the Ice run time processes the invocation in the thread that invokes the delegate.

A very simple way to implement `dispatch` would be as follows:

```

C#

```
public class MyDispatcher
{
 public void
 dispatch(System.Action call, Ice.Connection con)
 {
 // Does not throw, blocks until op completes.
 call();
 }
};
```

```

Whenever the Ice run time receives an incoming operation invocation or when an AMI invocation completes, it calls `dispatch` which, in turn, invokes the `call` delegate.

With this simple example, `dispatch` immediately invokes the delegate, and that call does not return until the corresponding operation invocation is complete. As a result, this implementation ties up a thread in the thread pool for the duration of the call.

So far, we really have not gained anything because all we have is a callback method that is called by the Ice run time. However, this simple mechanism is sufficient to ensure that we can update a UI from the correct thread.

A common technique to avoid blocking is to use [asynchronous method invocation](#). In response to a UI event (such as the user pressing a "Submit" button), the application initiates an operation invocation from the corresponding UI callback by calling the operation's `begin_` method. This is guaranteed not to block the caller, so the UI remains responsive. Some time later, when the operation completes, the Ice run time invokes an AMI callback from one of the threads in its thread pool. That callback now has to update the UI, but that can only be done from the UI thread. By using a dispatcher, you can easily delegate the update to the correct thread. For example, here is how you can arrange for AMI callbacks to be passed to the UI thread with WPF:

C#

```

public partial class MyWindow : Window
{
    private void Window_Loaded(object sender, EventArgs e)
    {
        Ice.Communicator communicator = null;

        try
        {
            Ice.InitializationData initData =
new Ice.InitializationData();
            initData.dispatcher =
                delegate(System.Action action,
Ice.Connection connection)
                {
                    Dispatcher.BeginInvoke(DispatcherPriority.Normal, actio
n);
                };
            communicator = Ice.Util.initialize(initData);
        }
        catch(Ice.LocalException ex)
        {
            // ...
        }
    }

    // ...
}

```

The delegate calls `Dispatcher.BeginInvoke` on the action delegate. This causes WPF to queue the actual asynchronous invocation of `action` for later execution by the UI thread. Because the Ice run time does not invoke your delegate until an asynchronous operation invocation is complete, when the UI thread executes the corresponding call to the `EndInvoke` method, that call does not block and the UI remains responsive.

The net effect is that you can invoke an operation asynchronously from a UI callback method without the risk of blocking the UI thread. For example:

C#

```

public partial class MyWindow : Window
{
    private void someOp_Click(object sender, RoutedEventArgs e)
    {
        MyIntfPrx p = ...;

        // Call remote operation asynchronously.
        // Response is processed in UI thread.
        p.begin_someOp().whenCompleted(this.opResponse,
this.opException);
    }

    public void opResponse()
    {
        // Update UI...
    }

    public void opException(Ice.Exception ex)
    {
        // Update UI...
    }
}

```

Please see the `wpf` demo in your Ice distribution for a fully-functional UI client that uses this technique.

Objective-C Dispatcher API

To install a dispatcher, you must [initialize a communicator](#) with a callback (as an Objective-C block) in the `ICEInitializationData` structure. All invocations that arrive for this communicator are made via the specified callback. For example:

Objective-C

```

int
main(int argc, char* argv[])
{
    objc_startCollectorThread();
    id<ICECommunicator> communicator = nil;
    @try
    {
        ICEInitializationData* initData = [ICEInitializationData
initializationData];
        initData.dispatcher =
            ^(id<ICEDispatcherCall> call, id<ICEConnection> con)
            {
                // ...
            };
        communicator = [ICEUtil createCommunicator:&argc argv:argv
initData:initData];
        // ...
    }
    @catch(ICELocalException* ex)
    {
        // ...
    }

    // ...
}

```

The type of the dispatcher callback must match the following block signature:

Objective-C

```
void(^)(id<ICEDispatcherCall> call, id<ICEConnection> connection)
```

The Ice run time invokes the dispatcher callback whenever an operation invocation arrives, passing an object implementing the `ICEDispatcherCall` protocol and the connection via which the invocation arrived. The job of your callback implementation is to execute the given call.

The connection parameter allows you to decide how to dispatch the operation based on the connection via which it was received. This value may be `nil` if no connection currently exists.

You can write the callback such that it blocks and waits for completion of the invocation because the callback is called by a thread in the server-side thread pool (for incoming operation invocations) or the client-side thread pool (for AMI callbacks).

The `ICEDispatcherCall` protocol defines how to execute the incoming call:

Objective-C

```
@protocol ICEDispatcherCall <NSObject>
-(void) run;
@end
```

Your callback is expected to call `run` on the `ICEDispatcherCall` instance (or, more commonly, to cause `run` to be called some time later). When you call `run`, the Ice run time processes the invocation in the thread that calls `run`.

A very simple way to implement the dispatcher callback would be as follows:

Objective-C

```
void(^myDispatcher)(id<ICEDispatcherCall>, id<ICEConnection>) =
^(id<ICEDispatcherCall> call, id<ICEConnection> con)
{
    // Does not throw, blocks until op completes.
    [call run];
};
```

Whenever the Ice run time receives an incoming operation invocation or when an AMI invocation completes, it calls the dispatcher callback which, in turn, invokes the `run` method on the call.

With this simple example, the dispatcher callback immediately invokes `run`, and `run` does not return until the corresponding operation invocation is complete. As a result, this implementation ties up a thread in the thread pool for the duration of the call.

So far, we really have not gained anything because all we have is a callback method that is called by the Ice run time. However, this simple mechanism is sufficient to ensure that we can update a UI from the correct thread.

A common technique to avoid blocking is to use [asynchronous method invocation](#). In response to a UI event (such as the user pressing a "Submit" button), the application initiates an operation invocation from the corresponding UI callback by calling the operation's `begin_` method. This is guaranteed not to block the caller, so the UI remains responsive. Some time later, when the operation completes, the Ice run time invokes an AMI callback from one of the threads in its thread pool. That callback now has to update the UI, but that can only be done from the UI thread. By using a dispatcher, you can easily delegate the update to the correct thread. For example, here is how you can arrange for AMI callbacks to be passed to Cocoa or Cocoa Touch main thread:

Objective-C

```

-(void)viewDidLoad
{
    ICEInitializationData* initData = [ICEInitializationData
initializationData];
    initData.dispatcher =
        ^(id<ICEDispatcherCall> call, id<ICEConnection> con)
        {
            dispatch_sync(dispatch_get_main_queue(), ^ { [call run]; });
        };

    communicator = [[ICEUtil createCommunicator:initData] retain];

    // ....
}

```

The dispatcher callback calls `dispatch_sync` on the main queue. This queues the actual call for later execution by the main thread. Because the Ice run time does not invoke the dispatcher callback until an asynchronous operation invocation is complete, when the UI thread executes the corresponding call, that call does not block and the UI remains responsive.

The net effect is that you can invoke an operation asynchronously from a UI callback method without the risk of blocking the UI thread. For example:

Objective-C

```

-(void)someOp:(id)sender
{
    id<MyIntfPrx> p = ...;
    [p begin_someOp:^( [self response]; }
        exception:^(ICEException* ex) { [self exception:ex]; }];
}

-(void) response
{
    // Update UI...
}

-(void) exception:(ICEException* ex)
{
    // Update UI...
}

```

Please see the Cocoa or iPhone demos in your Ice Touch distribution for fully-functional UI clients that use this technique.

Dispatcher Implementation Notes

An application that uses a custom dispatcher must adhere to the following rules to avoid a deadlock:

- Dispatcher implementations must ensure that all requests are dispatched. Failing to dispatch all requests will cause `Communicator::destroy` to hang indefinitely. If a dispatcher has resources that must be reclaimed (e.g., joining with a helper thread), it can safely do so after `Communicator::destroy` has completed.
- Never make a blocking invocation from the dispatch thread, such as a synchronous proxy operation or a proxy method that can potentially block, such as `ice_getConnection`. These invocations depend on the dispatcher for their own completion, therefore blocking the dispatch thread will inevitably lead to deadlock.

Blocking API Calls

This page lists the Ice APIs that can potentially block the calling thread. Graphical applications should normally avoid calling these APIs from the "event loop" thread.

The JavaScript mapping does not have any blocking APIs.

All synchronous remote invocations can block, including the built-in proxy operations `ice_ping`, `ice_isA`, `ice_id` and `ice_ids`. Since `checkedCast` internally calls `ice_isA`, it too can block.

For asynchronous remote invocations, the `begin_` method never blocks but the `end_` method can block.

Ice also has a number of local APIs that can block, either because they wait indefinitely for a condition to become true, or because their implementations may make remote invocations:

- AsyncResult
 - `waitForCompleted`
 - `waitForSent`
- Communicator
 - `createAdmin`
 - `createObjectAdapter`
 - `createObjectAdapterWithEndpoints`
 - `createObjectAdapterWithRouter`
 - `destroy`
 - `end_flushBatchRequests`
 - `flushBatchRequests`
 - `getAdmin`
 - `waitForShutdown`
- Connection
 - `close`
 - `end_flushBatchRequests`
 - `flushBatchRequests`
 - `waitUntilHolding`
- ObjectPrx
 - `ice_getConnection`
- ObjectAdapter
 - `activate`
 - `deactivate`
 - `destroy`
 - `waitForDeactivate`
 - `waitForHold`

The Java mapping allows you to [interrupt](#) threads blocked in these APIs.

Connection Management

The Ice run time establishes connections automatically and transparently as a side effect of using proxies. There are well-defined rules that determine when a [new connection is established](#). If necessary, you can influence [connection management activities](#).

Connection management becomes increasingly important as network environments grow more complex. In particular, if you need to make callbacks from a server to a client through a firewall, you must use a [bidirectional connection](#). In most cases, you can use a [Glacier2 router](#) to automatically take advantage of bidirectional connections. However, the Ice run time also provides direct access to connections, allowing you to explicitly control establishment and closure of both unidirectional and bidirectional connections.

Most Ice applications benefit from [active connection management](#) and transparent connection establishment and thus need not concern themselves with the details of connections. Not all Ice applications can be so fortunate, and for those applications Ice provides convenient [access to connections](#) that enables developers to address the realities of today's deployment environments.

The discussion that follows assumes that you are familiar with [proxies](#) and [endpoints](#).

Topics

- [Connection Establishment](#)
- [Active Connection Management](#)
- [Using Connections](#)
- [Connection Closure](#)
- [Bidirectional Connections](#)

Connection Establishment

Connections are established as a side effect of using proxies. The first invocation on a proxy causes the Ice run time to search for an existing connection to one of the [proxy's endpoints](#); only if no suitable connection exists does the Ice run time establish a new connection to one of the proxy's endpoints.

This page describes how and when Ice establishes a new connection.

On this page:

 - [Connection Reuse for Proxies with Multiple Endpoints](#)
 - [Protocol Compression and Connection Reuse](#)
 - [Influencing Connection Reuse](#)
- [Connection Caching](#)
- [Timeouts and Connection Establishment](#)

Endpoint Selection for New Connections

A proxy performs a number of operations on its endpoints before it asks the Ice run time to supply a connection. These operations produce a list of zero or more endpoints that satisfy the proxy's configuration. If the resulting list is empty, the application receives `NoEndpointException` to indicate that no suitable endpoints could be found. For example, this situation can arise when a twoway proxy contains only a UDP endpoint; the UDP endpoint is eliminated from consideration because it cannot be used for twoway invocations.

The proxy performs the following steps to derive its endpoint list:

1. Remove the endpoints of unknown transports. For instance, SSL endpoints are removed if the [SSL plug-in](#) is not installed.
2. Remove endpoints that are not suitable for the proxy's invocation mode. For example, datagram endpoints are removed for twoway, oneway and batch oneway proxies. Similarly, non-datagram endpoints are removed for datagram and batch datagram proxies.
3. Perform DNS queries to convert host names into IP addresses, if necessary. For a multi-homed host name, the proxy adds a new endpoint for each address returned by the DNS query.
4. Sort the endpoints according to the configured selection type, which is established using the `ice_endpointSelection` proxy method. The default value is `Random`, meaning the endpoints are randomly shuffled. Alternatively, the value `Ordered` maintains the existing order of the endpoints.
5. Satisfy the proxy's security requirements:
 - If `Ice.Override.Secure` is defined, remove all non-secure endpoints.
 - Otherwise, if the proxy is configured to prefer secure endpoints (e.g., by calling the `ice_preferSecure` proxy method), move all secure endpoints to the beginning of the list. Note that this setting still allows non-secure endpoints to be included.
 - Otherwise, move all non-secure endpoints to the beginning of the list.

If [connection caching](#) is enabled and the Ice run time [already has a compatible connection](#), it reuses the cached connection. Otherwise, the run time attempts to connect to each endpoint in the list until it succeeds or exhausts the list; the order in which endpoints are selected for connection attempts depends on the endpoint selection policy. This policy can be set using a default property (`Ice.Default.EndpointSelection`), using a proxy property (`name.EndpointSelection`), and using the `ice_endpointSelection` proxy method.

Interface Selection for New Connections

If a new outgoing connection must be established, Ice's default behavior allows the operating system to select the network interface to be used for the connection. You can force Ice to use a specific network interface for outgoing connections by configuring a [source address](#). There are two ways to do this:

- Define the `Ice.Default.SourceAddress` property to establish a default source address for all outgoing connections created by a communicator
- Include a `--sourceAddress` option in proxy endpoints, which overrides any setting for `Ice.Default.SourceAddress`

The value in each case must be an IP address associated with the desired network interface.

Error Semantics for Failed Connections

If a failure occurs during a connection attempt, the Ice run time tries to connect to all of the proxy's remaining endpoints until either a connection is successfully established or all attempts have failed. At that point, the Ice run time may attempt [automatic retries](#) depending on the value of the `Ice.RetryIntervals` configuration property. The default value of this property is 0, which causes the Ice run time to try connecting to all of the endpoints one more time.

Tip

Define the property `Ice.Trace.Retry=2` to monitor these attempts.

If no connection can be established on this second attempt, the Ice run time raises an exception that indicates the reason for the final failed attempt (typically `ConnectFailedException`). Similarly, if a connection was lost during a request and could not be reestablished (assuming the request can be retried), the Ice run time raises an exception that indicates the reason for the final failed attempt.

Reusing an Existing Connection

When establishing a connection for a proxy, the Ice run time reuses an existing connection under the following conditions:

- The remote endpoint matches one of the proxy's endpoints.
- The connection was established by the communicator that created the proxy.
- The connection matches the proxy's configuration. [Timeout values](#) play an important role here, as an existing connection is only reused if its timeout value (i.e., the timeout used when the connection was established) matches the endpoint timeout in the new proxy. Similarly, a proxy configured with a [connection ID](#) only reuses a connection if it was established by a proxy with the same connection ID.

Connection Reuse for Proxies with Multiple Endpoints

Applications must exercise caution when using proxies containing multiple endpoints, especially endpoints using different transports. For example, suppose a proxy has multiple endpoints, such as one each for TCP, SSL, and UDP. When establishing a connection for this proxy, the Ice run time will open a new connection only if it cannot reuse an existing connection to any of the endpoints (that is, if [connection caching](#) is enabled). Furthermore, the proxy in its default (that is, non-secure) configuration gives higher priority to non-secure endpoints. If you want to ensure that a particular transport is used by a proxy, you must configure the proxy appropriately, such as by calling the [proxy methods](#) `ice_secure` or `ice_datagram` as necessary.

Protocol Compression and Connection Reuse

The Ice run time does not consider [compression](#) settings when searching for existing connections to reuse; proxies whose compression settings differ can share the same connection (assuming all other selection criteria are satisfied).

Influencing Connection Reuse

The default behavior of the Ice run time, which reuses connections whenever possible, is appropriate for many applications because it conserves resources and typically has little or no impact on performance. However, when a server implementation attaches semantics to a connection, the client often must be designed to cooperate, despite the tighter coupling it causes. For example, a server might use a serialized [thread pool](#) to preserve the order of requests received over each connection. If the client wants to execute several requests simultaneously, it must be able to force the Ice run time to establish new connections at will.

For those situations that require more control over connection reuse, the Ice run time allows you to form arbitrary groups of proxies that share a connection by configuring them with the same connection identifier. The [proxy method](#) `ice_connectionId` returns a new proxy configured with the given connection ID. Once configured, the Ice run time ensures that the proxy only reuses a connection that was established by a proxy with the same connection ID (assuming all other criteria for connection reuse are also satisfied). A new connection is created if none with a matching ID is found, which means each proxy could conceivably have its own connection if each were assigned a unique connection ID.

As an example, consider the following code fragment:

C++

```

Ice::ObjectPrx prx = comm->stringToProxy("ident:tcp -p 10000");
Ice::ObjectPrx g1 = prx->ice_connectionId("group1");
Ice::ObjectPrx g2 = prx->ice_connectionId("group2");
prx->ice_ping(); // Opens a new connection
g1->ice_ping(); // Opens a new connection
g2->ice_ping(); // Opens a new connection
MyInterfacePrx i1 = MyInterfacePrx::checkedCast(g1);
i1->ice_ping(); // Reuses g1's connection
MyInterfacePrx i2 =
MyInterfacePrx::checkedCast(prx->ice_connectionId("group2"));
i2->ice_ping(); // Reuses g2's connection

```

A total of three connections are established by this example:

1. The proxy `prx` establishes a new connection. This proxy has the default connection ID (an empty string).
2. The proxy `g1` establishes a new connection because the only existing connection, the one established by `prx`, has a different connection ID.
3. Similarly, the proxy `g2` establishes a new connection because none of the existing connections have a matching connection ID.

The proxy `i1` inherits its connection ID from `g1`, and therefore shares the connection for `group1`; `i2` explicitly configured its connection ID and shares the `group2` connection with proxy `g2`.

Connection Caching

When we refer to a proxy's connection, we actually mean the connection that the proxy is *currently* using. This connection can change over time, such that a proxy might use several connections during its lifetime. For example, an idle connection may be [closed automatically](#) and then transparently replaced by a new connection when activity resumes.

After establishing a connection in response to proxy activities, the Ice run time adds the connection to an internal pool for subsequent [reuse](#) by other proxies. The Ice run time manages the lifetime of the connection and eventually [closes](#) it. The connection is not affected by the life cycle of the proxies that use it, except that the lack of activity may prompt the Ice run time to close the connection after a while.

Once a proxy has been associated with a connection, the proxy's default behavior is to continue using that connection for all subsequent requests. In effect, the proxy caches the connection and attempts to use it for as long as possible in order to minimize the overhead of creating new connections. If the connection is later closed and the proxy is used again, the proxy repeats the connection-establishment procedure described [earlier](#).

There are situations in which this default caching behavior is undesirable, such as when a client has a proxy with multiple endpoints and wishes to balance the load among the servers at those endpoints. The client can disable connection caching by passing an argument of `false` to the proxy method `ice_connectionCached`. The new proxy returned by this method repeats the connection-establishment procedure before each request, thereby achieving request load balancing at the expense of potentially higher latency.

This type of load balancing is performed solely by the client using whatever endpoints are contained in the proxy. More sophisticated forms of load balancing are also possible, such as when using [IceGrid](#).

Timeouts and Connection Establishment

As of Ice 3.6, the default timeout for all connections is 60 seconds, as determined by the `Ice.Default.Timeout` property. The [connection timeout](#) value applies to all network operations. If a connection cannot be established within the allotted time, Ice raises `ConnectTimeoutException`.

You can set a timeout on a proxy using the `ice_timeout` proxy method. To use the same timeout period for all proxies, you can define the `Ice.Override.Timeout` property; in this case, Ice ignores any timeout established using the `ice_timeout` proxy method or the `Ice.Default.Timeout` property. Finally, if you want to specify a [separate timeout](#) value that affects only connection establishment and takes precedence over a proxy's configured timeout value, you can define the `Ice.Override.ConnectTimeout` property.

Connection timeout values affect [connection reuse](#). For example, if the endpoint in proxy A is identical to the endpoint in proxy B except their timeout values differ, the proxies cannot share the same connection.

The timeout in effect when a connection is established is bound to that connection and cannot be changed. If a network operation times out, all outstanding requests on that connection receive a `TimeoutException` and the connection is [closed forcefully](#). The Ice run time automatically retries these requests on a new connection, assuming that [automatic retries](#) are enabled and would not violate at-most-once semantics.

Invocation timeouts are a separate feature added in Ice 3.6 and do not affect connection reuse.

Active Connection Management

Active Connection Management (ACM) is enabled by default and helps to improve scalability and conserve application resources by closing idle connections.

On this page:

- [Configuring Active Connection Management](#)
- [ACM Timeout Semantics](#)
- [Creating a Connection Management Policy](#)
 - [Bidirectional Connections](#)
 - [Managing Sessions](#)
 - [Detecting Peer Problems](#)
 - [Disabling ACM](#)

Configuring Active Connection Management

There are three components to an ACM configuration:

- **Close**
Determines the situations in which Ice closes a connection
- **Heartbeat**
Determines the situations in which Ice sends "heartbeat" messages to keep a connection alive
- **Timeout**
Defines the time interval in which the Close and Heartbeat actions occur

You can configure these components using [ACM properties](#) that affect all of the connections created by a communicator or modify a single connection directly in your code:

- `Ice.ACM.Close`
`Ice.ACM.Heartbeat`
`Ice.ACM.Timeout`
These properties establish the default settings for a communicator and affect both client (outgoing) and server (incoming) connections.
- `Ice.ACM.Client.Close`
`Ice.ACM.Client.Heartbeat`
`Ice.ACM.Client.Timeout`
These properties override the default properties above for client (outgoing) connections.
- `Ice.ACM.Server.Close`
`Ice.ACM.Server.Heartbeat`
`Ice.ACM.Server.Timeout`
These properties override the default properties above for server (incoming) connections.
- `adapter.ACM.Close`
`adapter.ACM.Heartbeat`
`adapter.ACM.Timeout`
These properties override the `Ice.ACM.Server` properties above for connections to a particular object adapter.
- Programmatically by calling `setACM` on a [connection object](#). These settings override all ACM property configurations for that connection.

ACM Timeout Semantics

That the Close and Heartbeat behaviors share a single Timeout setting may seem surprising at first glance. For instance, it's possible for a program to configure certain combinations of Close and Heartbeat settings such that the heartbeats prevent a connection from ever becoming eligible for closure. In general, however, one peer will configure Close and Timeout settings while the other peer will configure Heartbeat and Timeout settings, in a coordinated effort to meet the application's requirements for connection management.

For each connection configured for ACM, Ice checks its status approximately every $(\text{Timeout} / 2)$ seconds. If heartbeats are configured for the connection, Ice also sends a heartbeat during every status check. If two peers use the same Timeout value, this strategy ensures that heartbeat messages are sent well before the connection would be considered idle by the other peer.

Creating a Connection Management Policy

The ACM settings give you a lot of flexibility for developing a connection management policy that meets the needs of your application. As application requirements can vary greatly, we provide recommendations for several common use cases in the subsections below. You should also take the following general guidelines into consideration when developing your policy:

- **Connection semantics**
Is your application dependent on a connection remaining open? For example, there may be semantics attached to a connection, as in the case of a session in which a peer's identity, or some allocated resources, are valid only as long as the peer's connection remains active. [Glacier2 sessions](#) work this way. In this case you'd want to enable heartbeats and configure the timeout so that it is compatible with the session's expiration timeout.
- **Network traversal issues**
Depending on your network topology, security requirements, and other application considerations, a connection may be a valuable resource that is expensive or time-consuming to construct and you may not want Ice to discard it lightly. If sending heartbeats is too costly, you may need to disable automatic closure altogether.
- **Aggressiveness**
ACM's combination of heartbeats and connection closure options allows your application to detect when something has gone wrong with a peer. Furthermore, the connection closure options provide varying levels of response, from conservative to aggressive. Your application requirements will dictate the necessary behavior.
- **Local networks**
When operating in a purely local network in which there are no firewalls to traverse and none of the other considerations listed above are a concern, you can usually allow Ice to open and close connections transparently. In fact, the default configuration is a reasonable starting point.
- **Two sides to every connection**
It's important to consider the requirements of both clients *and* servers when designing your connection management policy. For example, if a client and server are using significantly different settings for their ACM timeouts, it can result in surprising and usually undesirable behavior.

To verify that the policy you've configured is behaving as expected, set `Ice.Trace.Network=2` and monitor your log output for connection-related activity.

Bidirectional Connections

A [bidirectional connection](#) allows a server to make callback invocations on a client, offering a simple solution to work around the limitations enforced by network firewalls in which the server would otherwise be prevented from establishing a separate connection back to the client. Given that the client's connection to the server represents the server's only path to that client, this connection must remain open as long as the client needs it.

In versions prior to Ice 3.6, our recommendation was to disable ACM completely in both client and server when using bidirectional connections to prevent unintended closure. As of Ice 3.6, there's no harm in enabling ACM connection closure as long as you also enable client-side heartbeats to prevent the connection from becoming idle during periods of inactivity. Consider the following settings:

```
# Client
Ice.ACM.Close=0      # CloseOff
Ice.ACM.Heartbeat=3 # HeartbeatAlways
Ice.ACM.Timeout=30

# Server
Ice.ACM.Close=4      # CloseOnIdleForceful
Ice.ACM.Heartbeat=0 # HeartbeatOff
Ice.ACM.Timeout=30
```

Here the client will always send heartbeats at regular intervals to keep connections alive. There's no need for the server to send heartbeats because the client has disabled automatic connection closure. If a connection does become idle, which most likely would be due to a serious problem with the client, the server forcefully closes the connection regardless of whether any incoming or outgoing requests are pending at

the time.

If your application manually configures bidirectional connections (as opposed to the automatic setup provided by Glacier2 connections, for instance), it's not much extra work to configure the ACM settings individually on the connection object if your requirements for bidirectional connections differ from the communicator-wide settings defined by the ACM properties. As an example, an application may not always need to use a connection for bidirectional purposes. As long as a connection is unidirectional, the application might consider it safe to be closed automatically by ACM. Once it transitions to a bidirectional connection, the program that initiated the connection should modify its ACM configuration similar to the client settings shown above.

Managing Sessions

The notion of a session is a common and very useful solution for managing resources associated with a particular client. Briefly, the idea is that a client creates a session, which usually includes an authentication process, and then allocates some resources. The server associates those resources with the client's session and requires the client to keep the session active, using an expiration timer to reclaim a session and its resources if a client abandons the session without formally terminating it. The strategy represents good defensive programming for a server; without such a solution, ill-behaved clients could continue allocating resources indefinitely.

In versions prior to Ice 3.6, we recommended that the client create a background thread that periodically "pinged" the server using an interval based on the server's session expiration time. The thread is no longer necessary as of Ice 3.6, since the ACM heartbeat functionality serves the same purpose. Note however that there are still a couple of considerations:

- The client needs to determine the server's session expiration time. An application might configure this statically, or the value may only be available at run time by calling an Ice operation. In the latter case, the client would need to transfer this value to a corresponding ACM timeout setting, most likely by calling `setACM` on the connection object.
- Using ACM heartbeats to keep a session alive is convenient for clients but presents a problem for server implementations: How does a server know that the connection is still alive? The solution is for the server to call `setCallback` on each connection to register a callback that Ice invokes each time a heartbeat is received, and when the connection is eventually closed.

The following configuration settings should get you started:

```
# Client
Ice.ACM.Close=0      # CloseOff
Ice.ACM.Heartbeat=3  # HeartbeatAlways
Ice.ACM.Timeout=30

# Server
Ice.ACM.Close=4      # CloseOnIdleForceful
Ice.ACM.Heartbeat=0  # HeartbeatOff
Ice.ACM.Timeout=30
```

These settings assume that the application configures the ACM timeout statically. (For example, perhaps the ACM timeout also serves directly as the session expiration timeout.) The server's setting for ACM connection closure represents a design decision that assists the implementation: When Ice detects that a connection has become idle, likely due to a serious problem with the client, it forcefully closes the connection. This process involves calling the callback that the server previously set on the connection; presumably the server interprets this notification as an indication that the session can be destroyed. Without the connection callback, the server would have to implement some other strategy for periodically reaping expired sessions.

Detecting Peer Problems

ACM is an effective tool for detecting and recovering from catastrophic problems with a peer. Let's suppose that it's safe to enable ACM connection closure in an application for both the client and the server. Furthermore, in this application, the server can take a significant amount of time to dispatch a client invocation. The client is willing to wait as long as it takes for the invocation to complete, however, as a defensive measure, the client also wants the ability to recover in case the server becomes unresponsive. Consider these settings:

```

# Client
Ice.ACM.Close=3      # CloseOnInvocationAndIdle
Ice.ACM.Heartbeat=0 # HeartbeatOff
Ice.ACM.Timeout=30

# Server
Ice.ACM.Close=1      # CloseOnIdle
Ice.ACM.Heartbeat=1 # HeartbeatOnInvocation
Ice.ACM.Timeout=30

```

The server configuration causes it to close connections when they become idle. Since the client doesn't send heartbeats, this means the client hasn't actively used the connection during the timeout period. The server configuration also sends heartbeats to the client, but only while the server is dispatching invocations. As a result, no matter how long it takes to dispatch the invocations, the Ice run time in the server will continue sending heartbeat messages as an indicator to the client that the server is still "healthy". If the Ice run time in the client determines that a connection has become idle, it either means the connection is no longer being used, or if outgoing invocations are still pending, it means that the server has stopped sending heartbeats for some reason. In the former case, the connection is transparently closed without affecting the client. In the latter case, Ice forcefully closes the connection. Assuming the subsequent [automatic retry](#) behavior fails, all pending client invocations on that connection will terminate with an exception.

Don't use ACM timeouts as a mechanism for aborting long-running invocations. Ice provides [invocation timeouts](#) for that purpose.

Disabling ACM

An application may be interested in preventing ACM from closing connections. For example, [oneway requests](#) can be silently discarded when a server closes a connection. One solution is to set the following property in the server:

```
Ice.ACM.Server.Close=0
```

This setting prevents the server from closing an incoming connection regardless of how long the connection has been idle.

Another solution is to enable heartbeats in the client so that the connection remains idle and never becomes eligible for closure while the client process is operating normally. If the client should terminate unexpectedly, the server will still be able to close the connection within a reasonable amount of time without waiting for a low-level notification from the network layer.

Using Connections

Applications can gain access to an Ice object representing an established connection.

On this page:

- [The Connection Interface](#)
 - [Flushing Batch Requests for a Connection](#)
- [The Endpoint Interface](#)
 - [Opaque Endpoints](#)
- [Client-Side Connection Usage](#)
- [Server-Side Connection Usage](#)
- [Closing a Connection](#)
 - [Graceful Closure](#)
 - [Forceful Closure](#)

The Connection Interface

The Slice definition of the Connection interface is shown below:

Slice
<pre> module Ice { local class ConnectionInfo { bool incoming; string adapterName; string connectionId; }; local interface ConnectionCallback { void heartbeat(Connection con); void closed(Connection con); }; local enum ACMClose { CloseOff, CloseOnIdle, CloseOnInvocation, CloseOnInvocationAndIdle, CloseOnIdleForceful }; local enum ACMHeartbeat { HeartbeatOff, HeartbeatOnInvocation, HeartbeatOnIdle, HeartbeatAlways }; local struct ACM { int timeout; ACMClose close; }; </pre>

```

    ACMHeartbeat heartbeat;
};

local interface Connection {
    void close(bool force);
    Object* createProxy(Identity id);
    void setAdapter(ObjectAdapter adapter);
    ObjectAdapter getAdapter();
    Endpoint getEndpoint();
    void flushBatchRequests();
    void setCallback(ConnectionCallback callback);
    void setACM(optional(1) int timeout, optional(2) ACMClose close,
optional(3) ACMHeartbeat heartbeat);
    ACM getACM();
    string type();
    int timeout();
    string toString();
    ConnectionInfo getInfo();
};

local class IPConnectionInfo extends ConnectionInfo {
    string localAddress;
    int localPort;
    string remoteAddress;
    int remotePort;
};

local class TCPConnectionInfo extends IPConnectionInfo {};

local class UDPConnectionInfo extends IPConnectionInfo {
    string mcastAddress;
    int mcastPort;
};

local class WSConnectionInfo extends IPConnectionInfo {};
};

module IceSSL {
    local class ConnectionInfo extends Ice::IPConnectionInfo {
        string cipher;
        Ice::StringSeq certs;
    };
};

```

```

    };
};

```

As indicated in the Slice definition, a connection is a [local interface](#), similar to a communicator or an object adapter. A connection therefore is only usable within the process and cannot be accessed remotely.

The `Connection` interface supports the following operations:

- `void close(bool force)`
Explicitly [closes the connection](#). The connection is closed gracefully if `force` is false, otherwise the connection is closed forcefully.
- `Object* createProxy(Identity id)`
Creates a special proxy that only uses this connection. This operation is primarily used for [bidirectional connections](#).
- `void setAdapter(ObjectAdapter adapter)`
Associates this connection with an object adapter to enable a [bidirectional connection](#).
- `ObjectAdapter getAdapter()`
Returns the object adapter associated with this connection, or nil if no association has been made.
- `Endpoint getEndpoint()`
Returns an [Endpoint object](#).
- `void flushBatchRequests()`
Flushes any pending [batch requests](#) for this connection.
- `void setCallback(ConnectionCallback callback)`
Associates a callback with this connection that is invoked whenever the connection receives a heartbeat message or is closed. Passing a nil value clears the current callback.
- `void setACM(optional(1) int timeout, optional(2) ACMClose close, optional(3) ACMHeartbeat heartbeat)`
Configures [Active Connection Management](#) settings for this connection. All arguments are optional, therefore you can change some of the settings while leaving the others unaffected. Refer to your language mapping for more details on optional parameters.
- `ACM getACM()`
Returns the connection's current settings for [Active Connection Management](#).
- `string type()`
Returns the connection type as a string, such as "tcp".
- `int timeout()`
Returns the [timeout](#) value used when the connection was established.
- `string toString()`
Returns a readable description of the connection.
- `ConnectionInfo getInfo()`
This operation returns a `ConnectionInfo` class defined as follows:

Slice

```

local class ConnectionInfo {
    bool incoming;
    string adapterName;
};

```

The `incoming` member is true if the connection is an incoming connection and false, otherwise. If `incoming` is true, `adapterName` provides the name of the object adapter that accepted the connection. Note that the object returned by `getInfo` implements a more derived interface, depending on the connection type. You can down-cast the returned class instance and access the connection-specific information according to the type of the connection.

Flushing Batch Requests for a Connection

The `flushBatchRequests` operation blocks the calling thread until any batch requests that are queued for a connection have been successfully written to the local transport. To avoid the risk of blocking, you can also invoke this operation asynchronously using the `begin_flushBatchRequests` method (in those language mappings that support it).

Since batch requests are inherently oneway invocations, the `begin_flushBatchRequests` method does not support a request callback. However, you can use the exception callback to handle any errors that might occur while flushing, and the sent callback to receive notification that the batch request has been flushed successfully.

For example, the code below demonstrates how to flush batch requests asynchronously in C++:

C++

```

class FlushCallback : public IceUtil::Shared
{
public:

    void exception(const Ice::Exception& ex)
    {
        cout << "Flush failed: " << ex << endl;
    }

    void sent(bool sentSynchronously)
    {
        cout << "Batch sent!" << endl;
    }
};
typedef IceUtil::Handle<FlushCallback> FlushCallbackPtr;

void flushConnection(const Ice::ConnectionPtr& conn)
{
    FlushCallbackPtr f = new FlushCallback;
    Ice::Callback_Connection_flushBatchRequestsPtr cb =
        Ice::newCallback_Connection_flushBatchRequests(
            f, &FlushCallback::exception, &FlushCallback::sent);
    conn->begin_flushBatchRequests(cb);
}

```

For more information on asynchronous invocations, please see the relevant language mapping chapter.

The Endpoint Interface

The `Connection::getEndpoint` operation returns an interface of type `Endpoint`:

Slice

```

module Ice {
    const short TCPEndpointType = 1;
    const short UDPEndpointType = 3;

    local class EndpointInfo {
        int timeout;
        bool compress;
        short type();
        bool datagram();
        bool secure();
    };

    local interface Endpoint {
        EndpointInfo getInfo();
        string toString();
    };

    local class IPEndpointInfo extends EndpointInfo {
        string host;
        int port;
        string sourceAddress;
    };

    local class TCPEndpointInfo extends IPEndpointInfo {};

    local class UDPEndpointInfo extends IPEndpointInfo {
        byte protocolMajor;
        byte protocolMinor;
        byte encodingMajor;
        byte encodingMinor;
        string mcastInterface;
        int mcastTtl;
    };

    local class WSEndpointInfo extends IPEndpointInfo {
        string resource;
    };

    local class OpaqueEndpointInfo extends EndpointInfo {
        Ice::EncodingVersion rawEncoding;
        Ice::ByteSeq rawBytes;
    };
};

module IceSSL {
    const short EndpointType = 2;

    local class EndpointInfo extends Ice::IPEndpointInfo {};
};

```

The `getInfo` operation returns an `EndpointInfo` instance. Note that the object returned by `getInfo` implements a more derived interface, depending on the endpoint type. You can down-cast the returned class instance and access the endpoint-specific information according to the type of the endpoint, as returned by the `type` operation.

The `timeout` member provides the `timeout` in milliseconds. The `compress` member is true if the endpoint uses `compression` (if available). The `datagram` operation returns true if the endpoint is for a `datagram` transport, and the `secure` operation returns true if the endpoint uses `SSL`.

The derived classes provide further detail about the endpoint according to its type.

Opaque Endpoints

An application may receive a proxy that contains an endpoint whose type is unrecognized by the Ice run time. In this situation, Ice preserves the endpoint in its encoded (*opaque*) form so that the proxy remains intact, but Ice ignores the endpoint for all connection-related activities. Preserving the endpoint allows an application to later forward that proxy with all of its original endpoints to a different program that might support the endpoint type in question.

Although a connection will never return an opaque endpoint, it is possible for a program to encounter an opaque endpoint when iterating over the endpoints returned by the proxy method `ice_getEndpoints`.

As a practical example, consider a program for which the `IceSSL` plug-in is not configured. If this program receives a proxy containing an `SSL` endpoint, Ice treats it as an opaque endpoint such that calling `getInfo` on the endpoint object returns an instance of `OpaqueEndpointInfo`.

Note that the `type` operation of the `OpaqueEndpointInfo` object returns the *actual* type of the endpoint. For example, the operation returns the value 2 if the object encodes an `SSL` endpoint. As a result, your program cannot assume that an `EndpointInfo` object whose type is 2 can be safely down-cast to `IceSSL::EndpointInfo`; if the `IceSSL` plug-in is not configured, such a down-cast will fail because the object is actually an instance of `OpaqueEndpointInfo`.

Client-Side Connection Usage

Clients obtain a connection by using one of the proxy methods `ice_getConnection` or `ice_getCachedConnection`. If the proxy does not yet have a connection, the `ice_getConnection` method immediately attempts to establish one. As a result, the caller must be prepared for this method to block and raise `connection failure` exceptions. (Use the asynchronous version of this method to avoid blocking.) If the proxy denotes a `collocated object` and collocation optimization is enabled, calling `ice_getConnection` returns null.

If you wish to obtain the proxy's connection without the potential for triggering connection establishment, call `ice_getCachedConnection`; this method returns null if the proxy is not currently associated with a connection or if connection caching is disabled for the proxy.

As an example, the C++ code below illustrates how to obtain a connection from a proxy and print its type:

C++

```

Ice::ObjectPrx proxy = ...
try
{
    Ice::ConnectionPtr conn = proxy->ice_getConnection();
    if(conn)
    {
        cout << conn->type() << endl;
    }
    else
    {
        cout << "collocated" << endl;
    }
}
catch(const Ice::LocalException& ex)
{
    cout << ex << endl;
}

```

Server-Side Connection Usage

Servers can access a connection via the `con` member of the `Ice::Current` parameter passed to every operation. For collocated invocations, `con` has a nil value.

For example, this Java code shows how to invoke `toString` on the connection:

Java

```

public int add(int a, int b, Ice.Current curr)
{
    if (curr.con != null)
    {
        System.out.println("Request received on connection:\n" +
curr.con.toString());
    }
    else
    {
        System.out.println("collocated invocation");
    }
    return a + b;
}

```

Although the mapping for the Slice operation `toString` results in a Java method named `_toString`, the Ice run time implements `toString` to return the same value.

Closing a Connection

Applications should rarely need to close a connection explicitly, but those that do must be aware of its implications. Since there are two ways to close a connection, we discuss them separately.

Graceful Closure

Passing an argument of `false` to the `close` operation initiates graceful connection closure, as discussed in [Connection Closure](#). The operation blocks until all pending outgoing requests on the connection have completed.

Forceful Closure

A forceful closure is initiated by passing an argument of `true` to the `close` operation, causing the peer to receive a `ConnectionLostException`.

A client must use caution when forcefully closing a connection. Any outgoing requests that are pending on the connection when `close` is invoked will fail with a `ForcedCloseConnectionException`. Furthermore, requests that fail with this exception are not automatically retried.

In a server context, forceful closure can be useful as a defense against hostile clients.

The Ice run time interprets a `CloseConnectionException` to mean that it is safe to [retry](#) the request without violating at-most-once semantics. If automatic retries are enabled, a client must only initiate a graceful close when it knows that there are no outgoing requests in progress on that connection, or that any pending requests can be safely retried.

- [Automatic Retries](#)
- [Connection Establishment](#)
- [Connection Closure](#)
- [Bidirectional Connections](#)
- [IceSSL](#)

Connection Closure

The Ice run time may close a connection for many reasons, including the situations listed below:

- When deactivating an object adapter or shutting down a communicator
- As required by [active connection management](#)
- When initiated by [an application](#)
- After a [network operation times out](#)
- In response to an exception, such as a socket failure or protocol error

In most cases, the Ice run time closes a connection gracefully as required by the [Ice protocol](#). The Ice run time only closes a connection forcefully when a timeout or protocol error occurs, or when the application explicitly requests it.

On this page:

- [Graceful Connection Closure](#)
- [Connection Closure and Oneway Invocations](#)

Graceful Connection Closure

Gracefully closing a connection occurs in stages:

- In the process that initiates closure, incoming and outgoing requests that are in progress are allowed to complete, and then a close connection message is sent to the peer. Any incoming requests received after closure is initiated are silently discarded (but may be retried, as discussed in the next bullet). An attempt to make a new outgoing request on the connection results in a `CloseConnectionException` and an automatic retry (if enabled).
- Upon receipt of a close connection message, the Ice run time in the peer closes its end of the connection. Any outgoing requests still pending on that connection fail with a `CloseConnectionException`. This exception indicates to the Ice run time that it is safe to retry those requests without violating at-most-once semantics, assuming [automatic retries](#) have not been disabled.
- After detecting that the peer has closed the connection, the initiating Ice run time closes the connection.

Connection Closure and Oneway Invocations

[Oneway invocations](#) are generally considered reliable because they are sent over a stream-oriented transport. However, it is quite possible for oneway requests to be silently discarded if a server has initiated [graceful connection closure](#). Whereas graceful closure causes a discarded twoway request to receive a `CloseConnectionException` and eventually be retried, the sender receives no notice about a discarded oneway request.

If an application makes assumptions about the reliability of oneway requests, it may be necessary to control the events surrounding connection closure as much as possible, for example by [disabling active connection management](#) and avoiding explicit connection closures.

Bidirectional Connections

On this page:

- [Use Cases for Bidirectional Connections](#)
- [Configuring a Client for Bidirectional Connections](#)
 - [Active Connection Management Considerations](#)
- [Configuring a Server for Bidirectional Connections](#)
- [Fixed Proxies](#)
- [Limitations of Bidirectional Connections](#)
- [Threading Considerations for Bidirectional Connections](#)

Use Cases for Bidirectional Connections

An Ice connection normally allows requests to flow in only one direction. If an application's design requires the server to make callbacks to a client, the server usually establishes a new connection to that client in order to send callback requests, as shown below:

Callbacks in an open network.

Unfortunately, network restrictions often prevent a server from being able to create a separate connection to the client, such as when the client resides behind a firewall as shown here:

Callbacks with a firewall.

In this scenario, the firewall blocks any attempt to establish a connection directly to the client.

For situations such as these, a bidirectional connection offers a solution. Requests may flow in both directions over a bidirectional connection, enabling a server to send callback requests to a client over the client's existing connection to the server.

There are two ways to make use of a bidirectional connection. First, you can use a [Glacier2 router](#), in which case bidirectional connections are used automatically. If you do not require the functionality offered by Glacier2 or you do not want an intermediary service between clients and servers, you can configure bidirectional connections manually.

The remainder of this section discusses manual configuration of bidirectional connections. An example that demonstrates how to configure a bidirectional connection is provided in the directory `demo/Ice/bidir` of your Ice distribution.

Configuring a Client for Bidirectional Connections

A client needs to perform the following steps in order to configure a bidirectional connection:

1. [Create an object adapter](#) to receive callback requests. This adapter does not require a name or endpoints if its only purpose is to receive callbacks over bidirectional connections.
2. [Register the callback object](#) with the object adapter.
3. Activate the object adapter.
4. [Obtain a connection](#) object by calling `ice_getConnection` on the proxy.
5. Invoke `setAdapter` on the connection, passing the callback object adapter. This associates an object adapter with the connection and enables callback requests to be dispatched.
6. Pass the [identity](#) of the callback object to the server.

The C++ code below illustrates these steps:

C++

```
Ice::ObjectAdapterPtr adapter = communicator->createObjectAdapter( "");
Ice::Identity ident;
ident.name = IceUtil::generateUUID();
ident.category = "";
CallbackPtr cb = new CallbackI;
adapter->add(cb, ident);
adapter->activate();
proxy->ice_getConnection()->setAdapter(adapter);
proxy->addClient(ident);
```

The last step may seem unusual because a client would typically pass a proxy to the server, not just an identity. For example, you might be tempted to give the proxy returned by the adapter operation `add` to the server, but this would not have the desired effect: if the callback object adapter is configured with endpoints, the server would attempt to establish a separate connection to one of those endpoints, which defeats the purpose of a bidirectional connection. It is just as likely that the callback object adapter has no endpoints, in which case the proxy is of no use to the server.

Similarly, you might try invoking `createProxy` on the connection to obtain a proxy that the server can use for callbacks. This too would fail, because the proxy returned by the connection is for local use only and cannot be used by another process.

As you will see below, the server must create its own callback proxy.

Active Connection Management Considerations

[Active Connection Management \(ACM\)](#) automatically and transparently closes idle connections. As far as the Ice run time is concerned, an outgoing connection is a client connection regardless of whether it's also used as a bidirectional connection, therefore the client-side [ACM properties](#) govern the ACM behavior for bidirectional connections in a client. Also note that the client's outgoing connection is the only channel on which the server can send callback invocations to the client, therefore prematurely closing the connection (such as allowing the ACM facility to close it automatically) introduces the risk that the client might unknowingly fail to receive callbacks.

As of Ice 3.6, it's not necessary to disable client-side ACM when using bidirectional connections. If you leave ACM enabled, you simply need to ensure that the connection remains active to prevent the ACM facility from closing it. The easiest way to accomplish this is to enable connection heartbeats:

```
Ice.ACM.Client.Heartbeat=Always
```

Alternatively, you can enable heartbeats on a bidirectional connection by calling `setACM`:

C++

```
proxy->ice_getCachedConnection()->setACM(IceUtil::None, IceUtil::None,
Ice::HeartbeatAlways);
```

The server's ACM configuration also plays an important role here. For more information, refer to our discussion of [ACM configurations for bidirectional connections](#).

Configuring a Server for Bidirectional Connections

A server needs to take the following steps in order to make callbacks over a bidirectional connection:

1. Obtain the identity of the callback object, which is typically supplied by the client.

2. **Create a proxy** for the callback object by calling `createProxy` on the connection. The connection object is accessible as a member of the `Ice::Current` parameter to an operation implementation.

These steps are illustrated in the C++ code below:

```

C++

void addClient(const Ice::Identity& ident, const Ice::Current& curr)
{
    CallbackPrx client =
    CallbackPrx::uncheckedCast(curr.con->createProxy(ident));
    client->notify();
}

```

Fixed Proxies

The proxy returned by a connection's `createProxy` operation is called a *fixed proxy*. It can only be used in the server process and cannot be marshaled or stringified by `proxyToString`; attempts to do so raise `FixedProxyException`.

A fixed proxy is bound to the connection that created it, and ceases to work once that connection is closed. If the connection is closed prematurely, either by [active connection management](#) (ACM) or by explicit action on the part of the application, the server can no longer make callback requests using that proxy. Any attempt to use the proxy again usually results in a `CloseConnectionException`.

Many aspects of a fixed proxy cannot be changed. For example, it is not possible to change the proxy's endpoints or timeout. Attempting to invoke a method such as `ice_timeout` on a fixed proxy raises `FixedProxyException`.

Limitations of Bidirectional Connections

Bidirectional connections have certain limitations:

- They can only be configured for connection-oriented transports such as TCP and SSL.
- Most proxy [factory methods](#) are not relevant for a proxy created by a connection's `createProxy` operation. The proxy is bound to an existing connection, therefore the proxy reflects the connection's configuration. Attempting to change settings such as the proxy's timeout value causes the Ice run time to raise `FixedProxyException`. Note however that it is legal to configure a fixed proxy for using oneway or twoway invocations. You may also invoke `ice_secure` on a fixed proxy if its security configuration is important; a fixed proxy configured for secure communication raises `NoEndpointException` on the first invocation if the connection is not secure.
- A connection established from a Glacier2 router to a server is not configured for bidirectional use. Only the connection from a client to the router is bidirectional. However, the client must not attempt to manually configure a bidirectional connection to a router, as this is handled internally by the Ice run time.

Threading Considerations for Bidirectional Connections

The Ice run time normally creates two [thread pools](#) for processing network traffic on connections: the client thread pool manages outgoing connections and the server thread pool manages incoming connections. All of the object adapters in a server share the same thread pool by default, but an object adapter can also be configured to have [its own thread pool](#). The default size of the client and server thread pools is one.

The client thread pool processes replies to pending requests. When a client configures an outgoing connection for bidirectional requests, the client thread pool also becomes responsible for dispatching callback requests received over that connection.

Similarly, the server thread pool normally dispatches requests from clients. If a server uses a bidirectional connection to send callback requests, then the server thread pool must also process the replies to those requests.

You must increase the size of the appropriate thread pool if you need the ability to dispatch multiple requests in parallel, or if you need to make [nested twoway invocations](#). For example, a client that receives a callback request over a bidirectional connection and makes nested invocations must increase the size of the *client* thread pool.

Connection Timeouts

On this page:

- [Overview of Connection Timeouts](#)
- [Configuring Connection Timeouts](#)
- [Connection Timeout Failures](#)
- [ACM and Timeouts](#)
- [Connection Reuse and Timeouts](#)

Overview of Connection Timeouts

As of Ice 3.6, connection timeouts only affect network operations. Use `invocation timeouts` to limit the amount of time a client waits for an operation to complete.

Connection timeouts allow applications to detect low-level network problems in a reasonable period of time. Ice enforces connection timeouts when performing network operations such as establishing a connection, reading and writing to a connection, and closing a connection. Disabling connection timeouts means an application may not discover a network issue until much later (if at all) when low-level network protocols finally detect and report the problem, therefore Ice enables connection timeouts by default and we strongly encourage you to use them.

You should normally choose your connection timeouts based on the speed of the network on which the connections take place. For example, the connection timeout for a local gigabit network will usually be much smaller than the timeout for a 56kbps connection.

Finally, note that timeouts in Ice are "soft" timeouts, in the sense that they are not precise, real-time timeouts. (The precision is limited by the capabilities of the underlying operating system.)

Configuring Connection Timeouts

Ice supports several configuration properties that you can use to control connection timeouts:

- `Ice.Default.Timeout`
Added in Ice 3.6, this property specifies the default timeout in milliseconds for all connections. This property's default value of 60000 means connection timeouts are enabled by default with a timeout of 60 seconds.
- `Ice.Override.ConnectTimeout`
This setting overrides any existing connection timeout, but only applies while Ice establishes a connection.
- `Ice.Override.CloseTimeout`
This setting overrides any existing connection timeout, but only applies while Ice closes a connection.
- `Ice.Override.Timeout`
This setting overrides any existing connection timeout. It applies to all network operations unless superseded by `Ice.Override.ConnectTimeout` or `Ice.Override.CloseTimeout`.

You can also configure connection timeouts individually for the endpoints of a proxy. Consider this example:

```
MyProxy=hello:tcp -h 10.0.0.1 -t 1000:tcp -h 205.125.53.4 -t 5000
```

This stringified proxy contains two TCP endpoints. The first endpoint refers to a host in a local network and its `-t` option specifies a connection timeout of one second. The second endpoint refers to a host on the internet and uses a connection timeout of five seconds. If a proxy's endpoints don't include timeouts, the endpoints inherit the communicator's default timeout set by `Ice.Default.Timeout`. The various `Ice.Override` properties take precedence over any endpoint timeouts.

Finally, the proxy method `ice_timeout` returns a new proxy in which all of its endpoints have the specified timeout:

C++

```
Ice::ObjectPrx p = communicator->stringToProxy("hello:tcp -h 10.0.0.1 -t
1000:tcp -h 205.125.53.4 -t 5000");

cout << p->ice_toString() << endl; // Output: hello:tcp -h 10.0.0.1 -t
1000:tcp -h 205.125.53.4 -t 5000
p = p->ice_timeout(1500);
cout << p->ice_toString() << endl; // Output: hello:tcp -h 10.0.0.1 -t
1500:tcp -h 205.125.53.4 -t 1500
```

The `Ice.Override` properties also take precedence over any timeouts configured via `ice_timeout`.

Connection Timeout Failures

Ice considers a connection timeout to indicate a serious error with the underlying network connection, causing Ice to immediately close the connection and report a `TimeoutException`, or one of its subclasses `ConnectTimeoutException` or `CloseTimeoutException` if appropriate, for all of the invocations pending on that connection.

The application may not receive an exception immediately after a connection timeout occurs, as Ice may attempt the invocation again if [automatic retries](#) are enabled and the invocation qualifies for retry. Since its default configuration allows Ice to perform one retry without a delay, it will appear to the application as if the timeout takes twice as long as expected to be reported.

In most cases you won't need to handle a timeout as a special case and can use the typical exception clauses:

C++

```
Filesystem::FilePrx myFile = ...;
myFile = myFile->ice_timeout(2500);

try {
    Lines text = myFile->read();
} catch (const Filesystem::GenericError & ex) {
    cerr << ex.reason << endl;
} catch (const Ice::LocalException & ex) {
    cerr << "failed: " << ex << endl;
}
```

If your application needs to treat timeouts differently, you can catch them as follows:

C++

```

Filesystem::FilePrx myFile = ...;
myFile = myFile->ice_timeout(2500);

try {
    Lines text = myFile->read();
} catch (const Filesystem::GenericError & ex) {
    cerr << ex.reason << endl;
} catch (const Ice::ConnectTimeoutException &) {
    cerr << "connect timed out!" << endl;
} catch (const Ice::CloseTimeoutException &) {
    cerr << "close timed out!" << endl;
} catch (const Ice::TimeoutException &) {
    cerr << "timed out!" << endl;
} catch (const Ice::LocalException & ex) {
    cerr << "failed: " << ex << endl;
}

```

ACM and Timeouts

The new [Active Connection Management](#) features in Ice 3.6 can also help your application in detecting and dealing with connectivity issues and complement the connection timeout behavior. For example, connection timeouts only have an effect when the Ice run time is actively performing network operations, but it's also possible for problems to arise during periods of inactivity. These problems may not be noticed for some time.

The ACM heartbeat facility can optionally be configured to send heartbeat messages at regular intervals when a connection would otherwise be idle. Doing so makes it more likely that the Ice run time will detect a connectivity issue in a timely manner.

Connection Reuse and Timeouts

Ice tries to reuse existing connections as much as possible unless the application indicates otherwise. When an application makes its first invocation on a proxy, Ice searches its list of open connections to see if any of them match any of the proxy's endpoints. Determining whether an existing connection is "compatible" with a proxy endpoint, and therefore suitable for reuse, involves several criteria. One attribute that Ice considers is the timeout: the endpoint's timeout and the connection's timeout must match for the connection to be considered eligible for reuse.

If you encounter a situation where Ice is opening a new connection when you expect it to use an existing connection, your timeout configuration may be the reason.

See [Connection Establishment](#) for more information on how Ice decides whether to open a new connection or reuse an existing one.

Collocated Invocation and Dispatch

On this page:

- [Overview](#)
- [Collocated Invocations](#)
- [Creating an Object Adapter for Collocated Invocations](#)

Overview

One of the useful features of the Ice run time is that it is *location transparent*: the client does not need to know where the implementation of an Ice object resides; an invocation on an object automatically is directed to the correct target, whether the object is implemented in the local address space, in another address space on the same machine, or in another address space on a remote machine. Location transparency is important because it allows us to change the location of an object implementation without breaking client programs and, by using a location service such as [IceDiscovery](#) or [IceGrid](#), addressing information such as host names and port numbers can be externalized so they do not appear in stringified proxies.

Collocated Invocations

For invocations that cross address space boundaries (or more accurately, cross communicator boundaries), the Ice run time dispatches requests via the appropriate transport. However, for a proxy invocation in which the proxy and the servant that processes the invocation share the same communicator (so-called *collocated* invocations), the Ice run time, by default, does not send the invocation via the transport specified in the proxy. Instead, collocated invocations take a short-cut inside the Ice run time and are dispatched more efficiently.

Note that if the proxy and the servant do not use the same communicator, the invocation is *not* collocated, even though caller and callee are in the same address space.

The reason for this is if collocated invocations were sent via TCP/IP, for example, invocations would still be sent via the operating system kernel (using the back plane instead of a network) and would incur the full cost of creating TCP/IP connections, trapping in and out of the kernel, and so on. By optimizing collocated requests, much of this overhead can be avoided.

For efficiency reasons, collocated invocations are not completely location transparent, that is, a collocated call has semantics that differ in some ways from calls that cross address-space boundaries. Specifically, collocated invocations differ from ordinary invocations in the following respects:

- Most collocated invocations are dispatched in the server-side thread pool just like regular invocations; the only exceptions are synchronous twoway collocated invocations with no invocation timeout, which are dispatched in the calling thread.
- The object adapter holding state is ignored: collocated invocations proceed normally even if the target object's adapter is in the holding state.
- AMI callbacks for asynchronous collocated invocations are dispatched from the servant's calling thread and not from the client-side thread pool unless AMD is used for the servant dispatch. In this case, the AMI callback is called from the client-side thread pool.
- Invocation timeouts work as usual, but connection timeouts are ignored.

In practice, these differences rarely matter. The most likely cause of surprises with collocated invocations is dispatch in the calling thread, that is, a collocated invocation behaves like a local, synchronous procedure call. This can cause problems if, for example, the calling thread acquires a lock that an operation implementation tries to acquire as well: unless you use [recursive mutexes](#), this will cause deadlock.

The Ice run time uses the following semantics to determine whether a proxy is eligible for the collocated optimization:

- For an indirect proxy, collocation optimization is used if the proxy's adapter ID matches the adapter ID or replica group ID of an object adapter in the same communicator.
- For a [well-known proxy](#), the Ice run time queries each object adapter Active Servant Map to determine if the servant is local.
- For a direct proxy, the Ice run time performs an endpoint search using the proxy's endpoints.

When an endpoint search is required, the Ice run time compares each of the proxy's endpoints against the endpoints of the communicator's object adapters. Only the transport, address and port are considered; other attributes of an endpoint, such as timeout settings, are not considered during this search. If a match is found, the invocation is dispatched using collocation optimization. Normally this search is executed only once, during the proxy's first invocation, although the proxy's [connection caching](#) setting influences this behavior.

Collocation optimization is enabled by default, but you can disable it for all proxies by setting the property `Ice.Default.CollocationOptimized=0`. You can also disable the optimization for an individual proxy using the factory method `ice_collocationOptimized(false)`. Finally, for proxies created from a property using `propertyToProxy`, the property `name.CollocationOptimized` configures the default setting for the proxy.

Creating an Object Adapter for Collocated Invocations

An object adapter requires no endpoints if its only purpose is to dispatch collocated requests. You can create a "collocated-only" object adapter by calling `createObjectAdapter` with an empty name:

C++

```
Ice::ObjectAdapterPtr collocAdapter =  
communicator->createObjectAdapter( " " );
```

Normally Ice requires an object adapter to either have endpoints or be configured with a router, but Ice relaxes this restriction when the name is empty. Note however that this means collocated-only object adapters cannot be configured using properties.

Proxies created by a collocated-only object adapter contain no endpoints, which essentially makes them well-known proxies. When the program makes its initial invocation on such a proxy, Ice searches every local object adapter for a servant with an identity matching that of the proxy. For Ice to successfully find the collocated servant, it must be present in the object adapter's [active servant map](#). Servant locators and default servants are not queried in this situation.

Locators

In [Terminology](#), we described briefly how the Ice run time uses an intermediary, known as a *location service*, to convert the symbolic information in an indirect proxy into an endpoint that it can use to communicate with a server. This section expands on that introduction to explain in more detail how the Ice run time interacts with a location service. You can create your own location service or you can use [IceDiscovery](#) or [IceGrid](#), which are both implementations of a location service. Describing how to implement a location service is outside the scope of this manual.

A *locator* is an Ice object that is implemented by a location service. A locator object must support the Slice interface `Ice::Locator`, which defines operations that satisfy the location requirements of the Ice run time. Applications do not normally use these operations directly, but the locator object may support an implementation-specific interface derived from `Ice::Locator` that provides additional functionality. For example, IceGrid's locator object provides access to an `IceGrid::Query` object so that applications can perform [more sophisticated queries](#).

Locator Semantics for Clients

On this page:

- [Invocations with an Indirect Proxy](#)
- [Replication with a Locator](#)
- [Locator Cache](#)
- [Locator Cache Timeout](#)
- [Load Balancing with a Locator](#)

Invocations with an Indirect Proxy

On the first use of an indirect proxy in an application, the Ice run time may issue a remote invocation on the locator object. This activity is transparent to the application, as shown below:

Locating an object.

1. The client invokes the operation `initialOp` on an indirect proxy.
2. The Ice run time checks an internal cache (called the *locator cache*) to determine whether a query has already been issued for the symbolic information in the proxy. If so, the cached endpoint is used and an invocation on the locator object is avoided. Otherwise, the Ice run time issues a locate request to the locator.
3. If the object is successfully located, the locator returns its current endpoints. The Ice run time in the client caches this information, [establishes a connection](#) to one of the endpoints, and proceeds to send the invocation as usual.
4. If the object's endpoints cannot be determined, the client receives an exception. `NotRegisteredException` is raised when an identity, object adapter identifier or replica group identifier is not known. A client may also receive `NoEndpointException` if the location service failed to determine the current endpoints.

As far as the Ice run time is concerned, the locator simply converts the information in an indirect proxy into usable endpoints. Whether the locator's implementation is more sophisticated than a simple lookup table is irrelevant to the Ice run time. However, the act of performing this conversion may have additional semantics that the application must be prepared to accept.

For example, when using IceGrid as your location service, the target server may be launched automatically if it is not currently running, and the locate request does not complete until that server is started and ready to receive requests. As a result, the initial request on an indirect proxy may incur additional overhead as all of this activity occurs.

Replication with a Locator

An indirect proxy may substitute a [replica group](#) identifier in place of the object adapter identifier. In fact, the Ice run time does not distinguish between these two cases and considers a replica group identifier as equivalent to an object adapter identifier for the purposes of resolving the proxy. The location service implementation must be able to distinguish between replica groups and object adapters using only this identifier.

The location service may return multiple endpoints in response to a locate request for an adapter or replica group identifier. These endpoints might all correspond to a single object adapter that is available at several addresses, or to multiple object adapters each listening at a single address, or some combination thereof. The Ice run time attaches no semantics to the collection of endpoints, but the application can make assumptions based on its knowledge of the location service's behavior.

When a location service returns more than one endpoint, the Ice run time behaves exactly as if the proxy had contained several endpoints. As always, the goal of the Ice run time is to [establish a connection](#) to one of the endpoints and deliver the client's request. By default, all requests made via the proxy that initiated the connection are sent to the same server until that connection is closed.

After the connection is closed, such as by [Active Connection Management \(ACM\)](#), subsequent use of the proxy causes the Ice run time to obtain another connection. Whether that connection uses a different endpoint than previous connections depends on a number of factors, but it is possible for the client to connect to a different server than for previous requests.

Locator Cache

After successfully resolving an indirect proxy, the location service must return at least one endpoint. How the service derives the list of endpoints that corresponds to the proxy is entirely implementation dependent. For example, IceGrid's location service can be configured to respond in a variety of ways; one possibility uses a simple round-robin scheme, while another selects endpoints based on the system load of the target hosts.

A locate request has the potential to significantly increase the latency of the application's invocation with a proxy, and this is especially true if the locate request triggers additional implicit actions such as starting a new server process. Fortunately, this overhead is normally incurred only during the application's initial invocation on the proxy, but this impact is influenced by the Ice run time's caching behavior.

To minimize the number of locate requests, the Ice run time caches the results of previous requests. By default, the results are cached indefinitely, so that once the Ice run time has obtained the endpoints associated with an indirect proxy, it never issues another locate request for that proxy. Furthermore, the default behavior of a proxy is to [cache its connection](#), that is, once a proxy has obtained a connection, it continues to use that connection indefinitely.

Taken together, these two caching characteristics represent the Ice run time's best efforts to optimize an application's use of a location service: after a proxy is associated with a connection, all future invocations on that proxy are sent on the same connection without any need for cache lookups, locate requests, or new connections.

If a proxy's connection is closed, the next invocation on the proxy prompts the Ice run time to consult its locator cache to obtain the endpoints from the prior locate request. Next, the Ice run time searches for an [existing connection](#) to any of those endpoints and uses that if possible, otherwise it attempts to establish a new connection to each of the endpoints until one succeeds. Only if that process fails does the Ice run time clear the entry from its cache and issue a new locate request with the expectation that a usable endpoint is returned.

The Ice run time's default behavior is optimized for applications that require minimal interaction with the location service, but some applications can benefit from more frequent locate requests. Normally this is desirable when implementing a load-balancing strategy, as we discuss in more detail below. In order to increase the frequency of locate requests, an application must configure a timeout for the locator cache and manipulate the connections of its proxies.

Locator Cache Timeout

An application can define a timeout to control the lifetime of entries in the locator cache. This timeout can be specified globally using the `Ice.Default.LocatorCacheTimeout` property and for individual proxies using the `proxy method ice_locatorCacheTimeout`. The Ice run time's default behavior is equivalent to a timeout value of `-1`, meaning the cache entries never expire. Using a timeout value greater than zero causes the cache entries to expire after the specified number of seconds. Finally, a timeout value of zero disables the locator cache altogether.

The previous section explained the circumstances in which the Ice run time consults the locator cache. Briefly, this occurs only when the application has invoked an operation on a proxy and the proxy is not currently associated with a connection. If the timeout is set to zero, the Ice run time issues a new locate request immediately. Otherwise, for a non-zero timeout, the Ice run time examines the locator cache to determine whether the endpoints from the previous locate request have expired. If so, the Ice run time discards them and issues a new locate request.

Given this behavior, if your goal is to force a proxy invocation to issue locate requests more frequently, you can do so only when the proxy is not associated with a connection. You can accomplish that in several ways:

- create a new proxy, which is inherently not connected by default
- [explicitly close](#) the proxy's existing connection
- disabling the proxy's [connection caching](#) behavior

Of these choices, the last is the most common.

Load Balancing with a Locator

Ice supports [proxy-based load balancing](#) whose behavior is driven solely by a proxy's configuration settings. A disadvantage of relying solely on this form of load balancing is that the client cannot make any intelligent decisions based on the status of the servers. If you want to distribute your requests in a more sophisticated way, you must either modify your clients to query the servers directly, or use a location service that can transparently direct a client to an appropriate server. For example, the IceGrid location service can monitor the system load on each server host and use that information when responding to locate requests.

The location service may return only one endpoint, which presumably represents the best server (at that moment) for the client to use. With only one endpoint available, changing the proxy's endpoint selection type makes no difference. However, by disabling connection caching and modifying the locator cache timeout, the application can force the Ice run time to periodically retrieve an updated endpoint from the location service. For example, an application can set a locator cache timeout of thirty seconds and communicate with the selected server for that period. After the timeout has expired, the next invocation prompts the Ice run time to issue a new locate request, at which point the client might be directed to a different server.

If the location service returns multiple endpoints, the application must be designed with knowledge of how to interpret them. For instance, the location service may attach semantics to the order of the endpoints (such as least-loaded to most-loaded) and intend that the application use the endpoints in the order provided. Alternatively, the client may be free to select any of the endpoints. As a result, the application and the location service must cooperate to achieve the desired results.

You can combine the simple form of load balancing described in the previous section with an intelligent location service to gain even more flexibility. For example, suppose an application expects to receive multiple endpoints from the location service and has configured its proxy to disable connection caching and set a locator cache timeout. For each invocation, Ice run time selects one of the endpoints provided by the location service. When the timeout expires, the Ice run time issues a new locate request and obtains a fresh set of endpoints from which to choose.

Locator Configuration for a Client

An Ice client application must supply a proxy for the `locator` object, which it can do in several ways:

- by explicitly configuring an indirect proxy using the `ice_locator` [proxy method](#)
- by calling `setDefaultLocator` on a communicator, after which all new proxies use the given locator by default
- by defining the `Ice.Default.Locator` configuration property, which causes all proxies to use the given locator by default

The Ice run time's efforts to resolve an indirect proxy can be traced by setting the following configuration properties:

```
Ice.Trace.Network=2
Ice.Trace.Protocol=1
Ice.Trace.Locator=2
```

See `Ice.Trace.*` for more information on these properties.

See Also

- [Locator Semantics for Clients](#)
- [Proxy Methods](#)
- [Ice.Default.*](#)
- [Ice.Trace.*](#)

Locator Semantics for Servers

A location service must know the endpoints of any [object adapter](#) whose identifier can be used in an indirect proxy. For example, suppose a client uses the following proxy:

```
Object1@PublicAdapter
```

The Ice run time in the client includes the identifier `PublicAdapter` in its [locate request](#) and expects to receive the associated endpoints. The only way the location service can know these endpoints is if it is given them. When you consider that an object adapter's endpoints may not specify fixed ports, and therefore the endpoint addresses may change each time the object adapter is activated, it is clear that the best source of endpoint information is the object adapter itself. As a result, an object adapter that is [properly configured](#) contacts the locator during activation to supply its identifier and current endpoints. More specifically, the object adapter registers itself with an object implementing the `Ice::LocatorRegistry` interface, whose proxy the object adapter obtains from the locator.

A location service may require that all object adapters be pre-registered via some implementation-specific mechanism. ([IceGrid](#) behaves this way by default.) This implies that activation can fail if the object adapter supplies an identifier that is unknown to the location service. In such a situation, the object adapter's `activate` operation raises `NotRegisteredException`.

In a similar manner, an object adapter that participates in a [replica group](#) includes the group's identifier in the locator request that is sent during activation. If the location service requires replica group members to be configured in advance, `activate` raises `NotRegisteredException` if the object adapter's identifier is not one of the group's [registered participants](#).

Locator Configuration for a Server

On this page:

- [Configuring an Object Adapter with a Locator](#)
- [Registering a Process with a Locator](#)

Configuring an Object Adapter with a Locator

An **object adapter** must be able to obtain a **locator proxy** in order to register itself with a location service. Each object adapter can be configured with its own locator proxy by defining its `Locator` property, as shown in the example below for the object adapter named `SampleAdapter`:

```
SampleAdapter.Locator=IceGrid/Locator:tcp -h locatorhost -p 10000
```

Alternatively, a server may call `setLocator` on the object adapter prior to activation. If the object adapter is not explicitly configured with a locator proxy, it uses the **default locator** as provided by its communicator.

Two other configuration properties influence an object adapter's interactions with a location service during activation:

- `AdapterId`
Configuring a non-empty identifier for the `AdapterId` property causes the object adapter to register itself with the location service. A locator proxy must also be configured.
- `ReplicaGroupId`
Configuring a non-empty identifier for the `ReplicaGroupId` property indicates that the object adapter is a member of a **replica group**. For this property to have an effect, `AdapterId` must also be configured with a non-empty value.

We can use these properties as shown below:

```
SampleAdapter.AdapterId=SampleAdapterId
SampleAdapter.ReplicaGroupId=SampleGroupId
SampleAdapter.Locator=IceGrid/Locator:tcp -h locatorhost -p 10000
```

Note that a location service may enforce [pre-registration requirements](#).

Registering a Process with a Locator

An activation service, such as an `IceGrid` node, needs a reliable way to gracefully deactivate a server. One approach is to use a platform-specific mechanism, such as POSIX signals. This works well on POSIX platforms when the server is prepared to [intercept signals](#) and react appropriately. On Windows platforms, it works less reliably for C++ servers, and not at all for Java servers. For these reasons, Ice provides an alternative that is both portable and reliable:

```

Slice
module Ice {
  interface Process {
    void shutdown();
    void writeMessage(string message, int fd);
  };
};

```

The Slice interface `Process` allows an activation service to request a graceful shutdown of the server. When `shutdown` is invoked, the object implementing this interface is expected to initiate the termination of its server process. The activation service may expect the server to

terminate within a certain period of time, after which it may terminate the server abruptly.

One of the benefits of the Ice [administrative facility](#) is that it creates an implementation of `Process` and makes it available via an administrative object adapter, or your own object adapter. Furthermore, IceGrid automatically enables this facility on the servers that it activates.

Distinguishing Objects and Servants

The term *Ice object* refers to a conceptual entity that is incarnated by a programming language object called a servant. An Ice object typically implements a Slice [interface](#), but could implement a Slice [class with operations](#) instead.

In addition, applications can transfer instances of Slice classes *by value*, using classes as just another type in the data model, along with other Slice types such as structures and sequences. We refer to this usage as transferring *objects by value*, to distinguish it from the formal concept of *Ice objects*.

As a refresher on Slice syntax, consider the following definitions:

Slice

```

class ClassWithOperations
{
    int cost;

    void updateCost();
};

interface Remote
{
    ClassWithOperations getByValue();
    ClassWithOperations* getByProxy();
};

```

As its name implies, the operation `getByValue` returns a `ClassWithOperations` object by value, whereas the `getByProxy` operation returns a proxy to a remote Ice object that implements `ClassWithOperations`. Although their syntax is quite similar, the semantics of these two operations are very different. Calling `getByValue`, a client receives a *local* instance of `ClassWithOperations` on which it can access the `cost` member and call the `updateCost` method. With `getByProxy`, a client can use the returned proxy to call `updateCost` as a remote invocation but cannot access the `cost` member, which is local state for the remote servant.

Design Considerations for Exceptions

Using exceptions to report error conditions is a generally accepted idiom, given its wide support in programming languages and its convenience in simplifying a developer's error-handling responsibilities. The alternatives, such as using numeric error codes, can be unwieldy in practice and lack the flexibility that a well-designed exception hierarchy provides. Slice does not impose any particular error-handling style on developers, but if you choose to use Slice exceptions, you should understand their advantages and limitations.

Slice exception types support single inheritance, which allows you to compose hierarchies of related error conditions. Furthermore, exceptions may have any number of data members, meaning your errors can convey as little or as much detail as you like. One limitation of exceptions is that they are treated differently than other Slice data types: exceptions cannot be passed as parameters, and cannot be used

as data members. The sole purpose of an exception type is to appear in the `throws` clause of an operation.

As an Ice developer, you are not expected to know the intricacies of how Ice transfers exceptions from server to client. However, it can be very useful for you to understand that [exceptions are composed of slices](#), that [multiple encoding formats](#) are available, and that [passing exceptions through intermediaries](#) may require additional effort.

Design Considerations for Objects

The motivation for using objects by value is not as simple as for exceptions. If you wish to use the exception idiom, you have no choice but to use the Slice exception model. However, an application is not forced to use objects by value. Other user-defined Slice types, such as sequences, dictionaries, and structures, may satisfy the data model requirements of many applications. Classes and structures may seem similar at first glance because they can both be used as data containers, but there are also some [significant differences](#) between them. Be sure you understand the [architectural implications of classes](#) before using them in your application. Granted, if your data model requires the use of inheritance, polymorphism, or self-referential capabilities, you really have no other choice but to use classes.

One aspect of using objects by value that must not be overlooked is overhead, both in terms of the processing effort required to encode and decode them, as well as the space consumed in messages that use them. In Ice 3.4 and earlier, objects by value were relatively expensive, likely causing many developers to use structures when classes might have been the more convenient choice. In Ice 3.5 and later, the new [compact format](#) makes objects by value much more competitive with structures. Ice 3.5 and later also make it possible to [forward objects of unknown types](#) for situations where flexibility takes precedence over compactness.

Composition using Slices

The data encoding rules for [classes](#) and [exceptions](#) rely on the concept of *slices* in which each slice corresponds to a level in the type hierarchy and contains the encoded data members defined at that level. The low-level details of the encoding rules are not relevant here, but having a basic understanding of how Ice marshals and unmarshals classes and exceptions can help you with your design decisions. Consider this example:

Slice	
<pre>class A { int i; }; class B extends A { float f; }; class C extends B { string s; };</pre>	

The encoded form of an instance of class `C` is summarized below:

Slice	Contents
C	string s
B	float f
A	int i

Notice that the instance is encoded in order from most-derived to least-derived. For the sake of simplicity, we have omitted many of the

encoding details. For instance, we have not shown that the initial (most-derived) slice includes a type ID string such as `"::MyModule::C"` that identifies the object's type.

Although we used a class hierarchy in the example above, the behavior for exceptions is very similar.

Let's add the following interface to our discussion:

```

Slice
interface I
{
    B getObject();
};

```

Now suppose a client invokes `getObject`. Let's also suppose that the servant actually returns an instance of class `C`, which is perfectly legal given that `C` derives from `B`. The Ice run time in the client knows that the formal return type of the `getObject` operation is `B` and unmarshals the object as follows:

1. Extract the type ID of the initial slice (`"::MyModule::C"`).
2. If this type is known to the client, instantiate the object, decode the state for each of its slices, and return the object.
3. If type `C` is *not* known to the client, which can occur when client and server are using different versions of the `Slice` definitions, the Ice run time discards the encoded data for slice `C` (also known as *slicing* the object), reads the type ID of the next slice, and repeats step 2.
4. If type `B` is also not known to the client then we have a problem. First, from a logical standpoint, the client *must* know type `B` because it is the statically-declared return type of the operation that the client just invoked. Second, we cannot slice this object any further because it would no longer be compatible with the formal signature of the operation; the returned object must at least be an instance of `B`, so we could not return an instance of `A`. In either case, the Ice run time would raise an exception.

Generally speaking, to unmarshal an instance of a class or exception, the Ice run time discards the slices of unknown types until it finds a type that it recognizes, exhausts all slices, or can no longer satisfy the formal type signature of the operation. This slicing feature allows the receiver, whose `Slice` definitions may be limited or outdated, to continue to function properly even when it does not recognize the most-derived type.

With this knowledge, we can now discuss new features introduced in Ice 3.5 that affect the run time's encoding rules for classes and exceptions. Namely, a choice of [encoding formats](#) and the ability to [preserve the slices](#) of unknown types. First, however, you should understand the need for object factories.

The Factory Requirement

For `Slice` classes that define data members but no operations, receiving an object by value is straightforward: the Ice run time examines the [type ID](#) encoded with the object, translates that (in a language-specific manner) into the corresponding generated class, and creates an instance of that class to represent the object. This happens without any help from the application. However, things get more complicated when a [class defines operations](#). By definition, such a class is abstract, therefore Ice cannot allocate an instance of the generated abstract class. Only the application knows which derived class implements an abstract `Slice` class, so Ice requires the application to supply factories for translating type IDs into their programming language equivalent objects.

Ice does not require or support user-supplied factories for exceptions because exceptions cannot define operations.

The encoding for classes does not inform the receiver whether an object is abstract. As Ice processes each slice of an object, it first attempts to locate the corresponding generated class. If Ice cannot find the class, or finds the class but determines that it is abstract, the run time looks for a factory registered by the application for that type ID. If no factory is found to create the object, Ice may discard the slice as described above.

Here is some sample code to demonstrate the implementation and registration of a factory:

Java

```
private static class CWOFactory implements Ice.ObjectFactory
{
    public Ice.Object create(String typeId)
    {
        assert(typeId.equals(ClassWithOperations.ice_staticId()));
        return new ClassWithOperationsImpl();
    }

    public void destroy()
    {
    }
}

private static class ClassWithOperationsImpl extends ClassWithOperations
{
    public void updateCost()
    {
        // ...
    }
}

Ice.Communicator communicator = ...;
communicator.addObjectFactory(new CWOFactory(),
ClassWithOperations.ice_staticId());
```

Our factory is only intended to create instances of the `ClassWithOperations` type we defined earlier, which is the reason for the assertion. In your own application, you can partition the factory responsibilities however you wish. For example, you can define a separate factory class for each Slice class, or use a single factory class that knows how to create multiple types. Whatever you decide, you must register a factory for each abstract class that the program has the potential to receive, and the registrations must occur before any remote invocations are made that might return one of these types.

You can also register a factory for a concrete Slice class if you wish to substitute a derived type, or simply because you want more control over the allocation of that type.

Slice Formats

Version 1.0 of the Ice encoding, which is used by all versions of Ice through 3.4, supports a single format for encoding the slices of classes and exceptions. The primary design goal for this format was the ability to support *slicing* at the expense of a somewhat larger encoding. The fact that the encoding embeds the *type IDs* of each type in an instance's type hierarchy means the size of the encoded data is affected by the symbol names and nesting depth of the Slice definitions. Consider this example:

Slice

```

module TopLevelModule
{
    module IntermediateModule
    {
        class Account { ... };
        class SubcontractorAccount extends Account { ... };
    };
};

```

The encoding for an instance of `SubcontractorAccount` includes the following type ID strings:

- `::TopLevelModule::IntermediateModule::SubcontractorAccount`
- `::TopLevelModule::IntermediateModule::Account`
- `::Ice::Object`

The last ID serves as a terminator to indicate the last slice and reflects the fact that all object types ultimately derive from the base `Object` type.

As you can see, there is a non-trivial amount of overhead for passing objects by value. Note however that the encoding includes a lookup table for type IDs to minimize this overhead as much as possible, meaning each unique type ID is only encoded once per message. While sending a single instance of `SubcontractorAccount` might be relatively expensive, sending a collection of `SubcontractorAccount` objects amortizes this cost over a number of instances. We can contrive situations where a message contains many instances of unrelated types, in which case the encoded type IDs would have a greater impact on the size of the resulting message, but those scenarios are less common.

The slice format for classes and exceptions is nearly identical. The main difference is that, for an exception, there is no need for a type ID lookup table because there can never be more than one instance of an exception in a message.

With version 1.1 of the encoding introduced in Ice 3.5, you now have two slice formats to choose from: *compact* and *sliced*.

Compact Format

The compact format in version 1.1 of the encoding sacrifices the [slicing](#) feature of classes and exceptions to reduce the encoded size of these types. The format still encodes the type ID of the most-derived type, and continues to use a lookup table to prevent duplication of type IDs in a message, but omits the type IDs for any intermediate types. Version 1.1 of the encoding also eliminates the need to encode the type ID for the base `Object` type of class instances and, together with other optimizations, makes the encoded size of classes in the compact format much more competitive with that of structures.

Ice 3.5 and later use the compact format by default. Existing applications that rely on the slicing feature may begin receiving `NoObjectFactoryException` errors after migrating to Ice 3.5 or later, an indication that the run time does not recognize the most-derived type and cannot slice to a less-derived type because the compact format omits the necessary type information. These applications must use the [sliced format](#) instead, which behaves similarly to the format in version 1.0 of the encoding.

Using our previous example, an instance of `SubcontractorAccount` still includes the type ID string `"::TopLevelModule::IntermediateModule::SubcontractorAccount"` in the compact format, but omits the type ID strings for `Account` and `Object`. Clearly we could reduce this overhead even further by using shorter symbol names and eliminating the nested module, or we could omit the type ID string altogether by using a [compact type ID](#).

Sliced Format

The sliced format in version 1.1 of the encoding retains the [slicing](#) behavior of version 1.0: a receiver discards the slices of unknown types until it finds a type that it recognizes, exhausts all available slices, or slices so far that the result would violate the formal signature of the operation. The sliced format still encodes the type IDs of the most-derived type as well as all intermediate types. However, unlike the 1.0

encoding, Ice no longer encodes the type ID for the base `Object` type in class instances such that, along with other improvements in the 1.1 encoding, the sliced format is still more efficient than the 1.0 encoding.

Choosing a Format

Ice uses the `compact` format by default, so an application that needs slicing behavior must explicitly enable it as follows:

- Set the `Ice.Default.SlicedFormat` property to a non-zero value to force the Ice run time to use the sliced format by default.
- Annotate your Slice definitions with `format` metadata to selectively enable the sliced format for certain operations or interfaces.

For example, suppose an application can safely use the compact format most of the time, but still needs slicing in a few situations. In this case the application can use metadata to enable the sliced format where necessary:

Slice
<pre>interface Ledger { Account getAccount(string id); // Uses compact format ["format:sliced"] Account importAccount(string source); // Uses sliced format };</pre>

The semantics implied by these definitions state that the caller of `getAccount` assumes it will know every type that that might be returned, but the same cannot be said for `importAccount`. By enabling the sliced format here, we allow the client to "slice off" what it does not recognize, even if that means the client is left with only an instance of `Account` and not an instance of some derived type.

Now let's examine the opposite case: use the sliced format by default, and the compact format only in certain cases:

Slice
<pre>["format:sliced"] interface Ledger { ["format:compact"] Account getAccount(string id); // Uses compact format Account importAccount(string source); // Uses sliced format };</pre>

Here we specify that all operations in `Ledger` use the sliced format unless overridden at the operation level, which we do for `getAccount`.

Keep the following points in mind when using the `format` metadata:

- The chosen format only controls how Ice encodes a value and has no effect on the decoding process.
- The format affects the input parameters, output parameters, and exceptions of an operation. Consider this example:

Slice

```
exception IncompatibleAccount { ... };

interface Ledger
{
    ["format:compact"]
    Account migrateAccount(Account oldAccount) throws
    IncompatibleAccount;
};
```

The metadata forces the client to use the compact format when marshaling the input parameter `oldAccount`, and forces the server to use the compact format when marshaling the return value or the exception. For a given operation, it is not possible to use one format for the parameters and a different format for the exceptions.

- If you decide to use the `Ice.Default.SlicedFormat` property, be aware that this property only affects the sender of a class or exception. For example, if you enable this property in the client but not the server, then all objects sent by the client use the sliced format by default, but all objects and exceptions returned by the server use the compact format by default.

By offering two alternative formats, Ice gives you a great deal of flexibility in designing your applications. The compact format is ideal for applications that place a greater emphasis on efficiency, while the sliced format is helpful when clients and servers evolve independently.

Optional Objects

Declaring a data member of type `class` to be optional does not eliminate the Ice run time's requirement for type information. Suppose a client uses the following Slice definitions:

Slice

```
class UserInfo
{
    string name;
    optional(1) string organization;
};
```

Also suppose that the server is using a newer version of the definitions:

Slice

```
class GroupInfo
{
    ...;
};

class UserInfo
{
    string name;
    optional(1) string organization;
    optional(2) GroupInfo group;
};
```

When receiving an instance of `UserInfo`, the Ice run time in the client ignores the `group` member because it does not recognize its tag, but Ice must still be able to unmarshal (or skip) the `GroupInfo` instance data in the message. If the server used the compact format for its reply, the client will receive an exception while attempting to decode the message. On the other hand, this scenario would succeed when using the sliced format because the format embeds enough information for the receiver to skip instances of unknown types.

The lesson here is that adding a new class type to your application can have unexpected repercussions, especially when using the compact format. Remember that the *sender* can change formats without necessarily needing to update the receiver. For example, after adding the `group` member to `UserInfo`, the server could begin using the sliced format for all operations that return `UserInfo` to ensure that any existing clients would be able to ignore this member.

Preserving Slices

The concept of [slicing](#) involves discarding the slices of unknown types when decoding an instance of a Slice class or exception. Here is a simple example:

Slice

```

class Base
{
    int b;
};

class Intermediate extends Base
{
    int i;
};

class Derived extends Intermediate
{
    int d;
};

interface Relay
{
    Base transform(Base b);
};

```

The server implementing the `Relay` object must know the type `Base` (because it is statically referenced in the interface definition), but may not know `Intermediate` or `Derived`. Suppose the implementation of `transform` involves forwarding the object to another back-end server for processing and returning the transformed object to the caller. In effect, the `Relay` server is an intermediary. If the `Relay` server does not know the types `Intermediate` and `Derived`, it will slice an instance to `Base` and discard the data members of any more-derived types, which is clearly not the intended result because the back-end server *does* know those types. The only way the `Relay` server could successfully forward these objects is by knowing all possible derived types, which makes the application more difficult to evolve over time because the intermediary must be updated each time a new derived type is added.

To address this limitation, Ice supports a new metadata directive that allows an instance of a Slice class or exception to be forwarded with all of its slices intact, even if the intermediary does not know one or more of the instance's derived types. The new directive, `preserve-slice`, is shown below:

Slice

```

["preserve-slice"]
class Base
{
    int b;
};

class Intermediate extends Base
{
    int i;
};

class Derived extends Intermediate
{
    int d;
};

["format:sliced"]
interface Relay
{
    Base transform(Base b);
};

```

With this change, all instances of `Base`, and types derived from `Base`, are encoded in a format that allows them to be forwarded intact. Also notice the addition of the `format:sliced` metadata on the `Relay` interface, which ensures that its operations use the sliced format and not the default compact format.

Unknown Sliced Objects

The combination of preserved slices and the sliced format means Ice applications now have a subtle new capability that was not available prior to Ice 3.5. Suppose we modify our `Relay` example as shown below:

Slice

```

["preserve-slice"]
class Base
{
    int b;
};

class Intermediate extends Base
{
    int i;
};

class Derived extends Intermediate
{
    int d;
};

["format:sliced"]
interface Relay
{
    Object transform(Object b);
};

```

The only difference here is the signature of the `transform` operation, which now uses the `Object` type. Technically, it is not necessary for the intermediary server to know *any* of the class types that might be relayed via this new definition of `transform` because the formal types in its signature do not impose any requirements. As long as any object types known by the intermediary are marked with `preserve-slice`, and the `transform` operation uses the sliced format, this intermediary is capable of relaying objects of any type.

If the Ice run time in the intermediary does not know any of the types in an object's inheritance hierarchy, and the formal type is `Object`, Ice uses an instance of `UnknownSlicedObject` to represent the object:

C++

```

namespace Ice {
class UnknownSlicedObject : public Object, ... {
public:

    const std::string& getUnknownTypeId() const;
    SlicedDataPtr getSlicedData() const;

    ...
};
}

```

The implementation of `transform` receives an instance of `UnknownSlicedObject` and can use that object as its return value. If necessary, the implementation can determine the most-derived type of the object by calling `getUnknownTypeId`. The actual encoded state of the object is encapsulated by the `SlicedData` class:

Slice

```

namespace Ice {
struct SliceInfo : public IceUtil::Shared {
    std::string typeId;
    std::vector<Byte> bytes;
    std::vector<ObjectPtr> objects;
    bool hasOptionalMembers;
    bool isLastSlice;
};

class SlicedData : public ... {
public:
    SlicedData(const SliceInfoSeq&);
    const SliceInfoSeq slices;

    ...
};
}

```

Applications do not normally need to use these types, but they provide all of the information the run time requires to forward an instance.

The definition of `UnknownSlicedObject`, `SlicedData` and `SliceInfo` are very similar in the other language mappings and are not shown here.

Dynamic Ice

The Ice streaming API allows you to serialize and deserialize Slice types using either the Ice encoding or an encoding of your choice (for example, XML). This is useful, for example, if you want to store Slice types in a data base.

The dynamic invocation and dispatch interfaces allow you to write generic clients and servers that need not have compile-time knowledge of the Slice types used by an application. This makes it possible to create applications such as object browsers, protocol analyzers, or protocol bridges. In addition, the dynamic invocation and dispatch interfaces permit services such as IceStorm to be implemented without the need to unmarshal and remarshal every message, with considerable performance improvements.

Keep in mind that applications that use dynamic invocation and dispatch are tedious to implement and harder to prove correct (because what normally would be a compile-time error appears only as a run-time error with dynamic invocation and dispatch). Therefore, you should use the dynamic interfaces only if your application truly benefits from this trade-off.

Streaming Interfaces

Ice provides convenient interfaces for streaming Slice types to and from a sequence of bytes. You can use these interfaces in many situations, such as when serializing types for persistent storage, and when using Ice's [dynamic invocation and dispatch facility](#).

The streaming interfaces are not defined in Slice, but are rather a collection of native classes provided by each language mapping.

The streaming interfaces are currently supported in C++, Java, and .NET.

A default implementation of the interfaces uses the [Ice encoding](#), but other implementations are possible.

There are two primary abstract classes: `InputStream` and `OutputStream`. As you might guess, `InputStream` is used to extract Slice types from a sequence of bytes, while `OutputStream` is used to convert Slice types into a sequence of bytes. The classes provide the functions necessary to manipulate all of the core Slice types:

- Primitives (`bool`, `int`, `string`, etc.)
- Sequences of primitives
- Proxies
- Objects

The classes also provide functions that handle various details of the Ice encoding. Using these functions, you can manually insert and extract constructed types, such as dictionaries and structures, but doing so is tedious and error-prone. To make insertion and extraction of constructed types easier, the Slice compilers can optionally generate helper functions that manage the low-level details for you.

The remainder of this section describes the streaming interfaces for each supported language mapping. To properly use the streaming interfaces, you should be familiar with the [Ice encoding](#). An example that demonstrates the use of the streaming interfaces is located in `demo/ice/invoke` in your Ice distribution.

The InputStream API in C++

An `InputStream` that uses the Ice encoding can be created using the following functions:

C++

```

namespace Ice {
    InputStreamPtr createInputStream(
        const CommunicatorPtr& communicator,
        const std::vector<Ice::Byte>& data);

    InputStreamPtr createInputStream(
        const CommunicatorPtr& communicator,
        const std::vector<Ice::Byte>& data,
        const EncodingVersion& version);

    InputStreamPtr createInputStream(
        const CommunicatorPtr& communicator,
        const std::pair<const Ice::Byte*, const Ice::Byte*>& data);

    InputStreamPtr createInputStream(
        const CommunicatorPtr& communicator,
        const std::pair<const Ice::Byte*, const Ice::Byte*>& data,
        const EncodingVersion& version);

    InputStreamPtr wrapInputStream(
        const CommunicatorPtr& communicator,
        const std::vector<Ice::Byte>& data);

    InputStreamPtr wrapInputStream(
        const CommunicatorPtr& communicator,
        const std::vector<Ice::Byte>& data,
        const EncodingVersion& version);

    InputStreamPtr wrapInputStream(
        const CommunicatorPtr& communicator,
        const std::pair<const Ice::Byte*, const Ice::Byte*>& data);

    InputStreamPtr wrapInputStream(
        const CommunicatorPtr& communicator,
        const std::pair<const Ice::Byte*, const Ice::Byte*>& data,
        const EncodingVersion& version);
}

```

You can optionally specify an encoding version for the stream, otherwise the stream uses the communicator's default encoding version.

Note that the `createInputStream` functions make a copy of the supplied data, whereas the `wrapInputStream` functions avoid copies by keeping a reference to the data. If you use `wrapInputStream`, it is your responsibility to ensure that the memory buffer remains valid and unmodified for the lifetime of the `InputStream` object.

The `InputStream` class is shown below.

C++

```

namespace Ice {
    class InputStream : ... {
    public:
        virtual CommunicatorPtr communicator() const = 0;

        virtual void sliceObjects(bool slice) = 0;

        virtual void read(bool& v) = 0;

};

```

```

    typedef ... InputStreamPtr;
}

```

Extracting from an InputStream in C++

An `InputStream` provides a number of overloaded `read` member functions that allow you to read any parameter from the stream by simply calling `read`.

For example, you can extract a double value followed by a string from a stream as follows:

C++

```

vector<Ice::Byte> data = ...;
in = Ice::createInputStream(communicator, data);
double d;
in->read(d);
string s;
in->read(s);

```

Likewise, you can extract a sequence of a built-in type, or a complex type, or any other type from the stream as follows:

C++

```

vector<Ice::Byte> data = ...;
in = Ice::createInputStream(communicator, data);
// ...
IntSeq s; // Slice: sequence<int> IntSeq;
in->read(s);

ComplexType c;
in->read(c);

```

Extracting Sequences of Built-In Types using Zero-Copy in C++

`InputStream` provides a number of overloads that accept a pair of pointers. For example, you can extract a sequence of bytes as follows:

C++

```

vector<Ice::Byte> data = ...;
in = Ice::wrapInputStream(communicator, data);
std::pair<const Ice::Byte*, const Ice::Byte*> p;
in->read(p);

```

The same extraction works for the other built-in integral and floating-point types, such `int` and `double`.

If the extraction is for a byte sequence, the returned pointers always point at memory in the stream's internal marshaling buffer.

For the other built-in types, the pointers refer to the internal marshaling buffer only if the Ice encoding is compatible with the machine and compiler representation of the type, otherwise the pointers refer to a temporary array allocated to hold the unmarshaled data. The overloads for zero-copy extraction accept an additional parameter of type `IceUtil::ScopedArray` that holds this temporary array when necessary.

Here is an example to illustrate how to extract a sequence of integers, regardless of whether the machine's encoding of integers matches the on-the-wire representation or not:

```
C++
```

```
#include <IceUtil/ScopedArray.h>
...
in = Ice::wrapInputStream(communicator, data);
std::pair<const Ice::Int*, const Ice::Int*> p;
IceUtil::ScopedArray<Ice::Int> a;
in->read(p, a);

for(const Ice::Int* i = p.first; i != p.second; ++i) {
    cout << *i << endl;
}
```

If the on-the-wire encoding matches that of the machine, and therefore zero-copy is possible, the returned pair of pointers points into the run time's internal marshaling buffer. Otherwise, the run time allocates an array, unmarshals the data into the array, and sets the pair of pointers to point into that array. Use of the `ScopedArray` helper template ensures that the array is deallocated once you let the `ScopedArray` go out of scope, so there is no need to call `delete[]`. `ScopedArray` is comparable to a `std::unique_ptr` for arrays.

Other InputStream Methods in C++

The remaining member functions of `InputStream` have the following semantics:

- `void sliceObjects(bool slice)`
Determines the behavior of the stream when extracting Ice objects. An Ice object is "sliced" when a factory cannot be found for a Slice type ID, resulting in the creation of an object of a less-derived type. Slicing is typically disabled when the application expects all object factories to be present, in which case the exception `NoObjectFactoryException` is raised. The default behavior is to allow slicing.
- `void read(std::string& v, bool convert = true)`
`void read(std::vector<std::string>& v, bool convert)`
The `bool` argument determines whether the strings unmarshaled by these methods are processed by the `string converter`, if one is installed. The default behavior is to convert the strings.
- `void read(const char* s, size_t& slen)`
`void read(const char* s, size_t& slen, std::string& holder)`
The first read with only two arguments reads a string without string conversion, even if a `string converter` is installed; `s` points to memory managed by the `InputStream`. The second read with three arguments uses the `string converter`, if one is installed, and puts the resulting converted string in the `holder` parameter; `holder` is empty when no string conversion occurs.
- `Int readEnum(Int maxValue)`
Unmarshals the integer value of an enumerator. The `maxValue` argument represents the highest enumerator value in the enumeration. Consider the following definitions:

```
Slice
```

```
enum Color { red, green, blue };
enum Fruit { Apple, Pear=3, Orange };
```

The maximum value for `Color` is 2, and the maximum value for `Fruit` is 4.

In general, you should simply use `read` for your enum values. `read` with an enum parameter calls `readEnum` with the `maxValue` provided by the code generated by `slice2cpp`.

- `Ice::Int readSize()`
The `Ice` encoding has a compact representation to indicate size. This function extracts a size and returns it as an integer.
- `Ice::Int readAndCheckSeqSize(int minWireSize)`
Like `readSize`, this function reads a size and returns it, but also verifies that there is enough data remaining in the unmarshaling buffer to successfully unmarshal the elements of the sequence. The `minWireSize` parameter indicates the smallest possible `on-the-wire representation` of a single sequence element. If the unmarshaling buffer contains insufficient data to unmarshal the sequence, the function throws `UnmarshalOutOfBoundsException`.
- `Ice::ObjectPrx readProxy()`
This function returns an instance of the base proxy type, `ObjectPrx`. Calling `read` with a proxy parameter has the same effect.
- `void readObject(const Ice::ReadObjectCallbackPtr &)`
The `Ice` encoding for class instances requires extraction to occur in stages. The `readObject` function accepts a callback object of type `ReadObjectCallback`, whose definition is shown below:

C++

```

namespace Ice {
    class ReadObjectCallback : ... {
    public:
        virtual void invoke(const Ice::ObjectPtr&) = 0;
    };
    typedef ... ReadObjectCallbackPtr;
}

```

When the object instance is available, the callback object's `invoke` member function is called. The application must call `readPendingObjects` to ensure that all instances are properly extracted. If you are not interested in receiving a callback when the object is extracted, it is easier to call `read` with a `Ptr` parameter. Note that calling `endEncapsulation` implicitly calls `readPendingObjects` if necessary.

- `void throwException()`
`void throwException(const UserExceptionReaderFactoryPtr& factory)`
These functions `extract a user exception` from the stream and throw it. If the stored exception is of an unknown type, the functions attempt to extract and throw a less-derived exception. If that also fails, an exception is thrown: for the 1.0 encoding, the exception is `UnmarshalOutOfBoundsException`, for the 1.1 encoding, the exception is `UnknownUserException`.
- `void startObject()`
`SlicedDataPtr endObject(bool preserve)`
The `startObject` method must be called prior to reading the slices of an object. The `endObject` method must be called after all slices have been read. Pass `true` to `endObject` in order to preserve the slices of any unknown more-derived types, or `false` to discard the slices. If `preserve` is `true` and the stream actually preserved any slices, the return value of `endObject` is a non-nil `SlicedData` object that encapsulates the slice data. If the caller later wishes to forward the object with any preserved slices intact, it must supply this `SlicedData` object to the output stream.
- `void startException()`
`SlicedDataPtr endException(bool preserve)`
The `startException` method must be called prior to reading the slices of an exception. The `endException` method must be called after all slices have been read. Pass `true` to `endException` in order to preserve the slices of any unknown more-derived types, or `false` to discard the slices. If `preserve` is `true` and the stream actually preserved any slices, the return value of `endException` is a non-nil `SlicedData` object that encapsulates the slice data. If the caller later wishes to forward the exception with any preserved slices intact, it must supply this `SlicedData` object to the output stream.
- `std::string startSlice()`
`void endSlice()`
`void skipSlice()`

Start, end, and skip a slice of member data, respectively. These functions are used when manually extracting the slices of an [Ice object](#) or [user exception](#). The `startSlice` method returns the [type ID](#) of the next slice, which may be an empty string depending on the format used to encode the object or exception.

- `EncodingVersion startEncapsulation()`
`void endEncapsulation()`
`EncodingVersion skipEncapsulation()`
 Start, end, and skip an [encapsulation](#), respectively. The `startEncapsulation` and `skipEncapsulation` methods return the encoding version used to encode the contents of the encapsulation.
- `EncodingVersion getEncoding()`
 Returns the encoding version currently in use by the stream.
- `void readPendingObjects()`
 An application must call this function after all other data has been extracted. This function extracts the state of Ice objects and invokes their corresponding callback objects (see `readObject`). For backward compatibility with encoding version 1.0, this function must only be called when non-optional data members or parameters use class types.
- `void rewind()`
 Resets the position of the stream to the beginning.
- `void skip(Int sz)`
 Skips the given number of bytes.
- `void skipSize()`
 Reads a size at the current position and skips that number of bytes.
- `bool readOptional(Int tag, OptionalFormat fmt)`
 Returns true if an optional value with the given tag and format is present, or false otherwise. If this method returns true, the data associated with that optional value must be read next. Optional values must be read in order by tag from least to greatest. The `OptionalFormat` enumeration is defined as follows:

C++

```
namespace Ice {
    enum OptionalFormat {
        OptionalFormatF1, OptionalFormatF2, OptionalFormatF4,
        OptionalFormatF8,
        OptionalFormatSize, OptionalFormatVSize,
        OptionalFormatFSize,
        OptionalFormatEndMarker
    };
}
```

Refer to the [encoding](#) discussion for more information on the meaning of these values.

- `void closure(void* p)`
`void* closure() const`
 Allows an arbitrary value to be associated with the stream.

The OutputStream Interface in C++

On this page:

- [The OutputStream API in C++](#)
- [Inserting into an OutputStream in C++](#)
- [Inserting Sequences of Built-In Types in C++](#)
- [Other OutputStream Member Functions in C++](#)

The outputStream API in C++

An OutputStream is created using the following functions:

```

C++

namespace Ice {
    OutputStreamPtr createOutputStream(const CommunicatorPtr& communica
tor);

    OutputStreamPtr createOutputStream(constCommunicatorPtr&
communicator,
                                     const EncodingVersion& version);
}

```

You can optionally specify an encoding version for the stream, otherwise the stream uses the communicator's default encoding version.

The OutputStream class is shown below.

```

C++

namespace Ice {
    class OutputStream : ... {
    public:
        virtual CommunicatorPtr communicator() const = 0;

        virtual void write(bool) = 0;
        virtual void write(Byte) = 0;
        virtual void write(Short) = 0;
        virtual void write(Int) = 0;
        virtual void write(Long) = 0;
        virtual void write(Float) = 0;
        virtual void write(Double) = 0;
        virtual void write(const std::string&, bool = true) = 0;
        virtual void write(const char*, size_t, bool = true) = 0;
        virtual void write(const char*, bool = true) = 0;
        virtual void write(const std::wstring&) = 0;

        virtual void write(const std::vector<bool>&) = 0;

        virtual void write(const bool* begin, const bool* end) = 0;
        virtual void write(const Byte* begin, const Byte* end) = 0;
        virtual void write(const Short* begin, const Short* end) = 0;
        virtual void write(const Int* begin, const Int* end) = 0;
    };
}

```

```

virtual void write(const Long* begin, const Long* end) = 0;
virtual void write(const Float* begin, const Float* end) = 0;
virtual void write(const Double* begin,
const Double* end) = 0;

virtual void write(const std::vector<std::string>& v,
bool convert) = 0;

void writeEnum(Int v, Int maxValue) { ... }

virtual bool writeOptional(Int tag, OptionalFormat fmt) = 0;

template<typename T> inline void
write(const T& v) { ... }

virtual void writeSize(Int sz) = 0;
virtual void startSize() = 0;
virtual void endSize() = 0;

virtual void writeProxy(const ObjectPrx& v) = 0;

template<typename T> inline void
write(const IceInternal::ProxyHandle<T>& v) { ... }

virtual void writeObject(const ObjectPtr&) = 0;

template<typename T> inline void
write(const IceInternal::Handle<T>& v) { ... }

virtual void writeException(const UserException& e) = 0;

virtual void startObject(const SlicedDataPtr& sd) = 0;
virtual void endObject() = 0;

virtual void startException(const SlicedDataPtr& sd) = 0;
virtual void endException() = 0;

virtual void startSlice(const std::string& typeId, bool last) =
0;
virtual void endSlice() = 0;

virtual void startEncapsulation(const EncodingVersion& v,
FormatType fmt) = 0;
virtual void startEncapsulation() = 0;
virtual void endEncapsulation() = 0;

virtual EncodingVersion getEncoding() const = 0;

virtual void writePendingObjects() = 0;

```

```
virtual void finished(std::vector<Byte>& v) = 0;  
virtual std::pair<const Byte*, const Byte*> finished() = 0;  
  
virtual size_type pos() = 0;  
virtual void rewrite(Int v, size_type pos) = 0;  
  
virtual void reset(bool) = 0;
```

```

    };
}

```

Inserting into an OutputStream in C++

An `OutputStream` provides a number of overloaded `write` member functions that allow you to insert any parameter into the stream by simply calling `write`.

For example, you can insert a double value followed by a string into a stream as follows:

```

C++
out = Ice::createOutputStream(communicator);
Ice::Double d = 3.14;
out->write(d);
string s = "Hello";
out->write(s);

```

Likewise, you can insert a sequence of built-in type, or a sequence of a complex constructed type, or any other type, with the same syntax:

```

C++
out = Ice::createOutputStream(communicator);
IntSeq s = ...;
out->write(s);

ComplexType c = ...;
out->write(c);

```

Inserting Sequences of Built-In Types in C++

`OutputStream` provides a number of overloads that accept a pair of pointers. For example, you can insert a sequence of bytes as follows:

```

C++
out = Ice::createOutputStream(communicator);
vector<Ice::Byte> v = ...;
out->write(&v[0], &v[v.size()]);

```

The same insertion technique works for the other built-in integral and floating-point types, such `int` and `double`. Insertion with these functions is a straight copy into the marshaling buffer when the internal representation of the data in memory is the same as the on-the-wire representation. (Note that the two pointers must point at a contiguous block of memory.)

Other OutputStream Member Functions in C++

The remaining member functions of `OutputStream` have the following semantics:

- `void write(const std::string& v, bool convert = true)`
`void write(const char* v, size_t vlen, bool convert = true)`

```
void write(const char* v, bool convert = true)
void write(const std::vector<std::string>&, bool convert)
```

The boolean argument determines whether the strings marshaled by these methods are processed by the `string converter`, if one is installed. The default behavior is to convert the strings.

- `void writeEnum(Int val, Int maxValue)`
Writes the integer value of an enumerator. The `maxValue` argument represents the highest enumerator value in the enumeration. Consider the following definitions:

```
Slice
```

```
enum Color { red, green, blue };
enum Fruit { Apple, Pear=3, Orange };
```

The maximum value for `Color` is 2, and the maximum value for `Fruit` is 4.

In general, you should simply use `write` for your enum values. `write` with an enum parameter calls `writeEnum` with the `maxValue` provided by the code generated by `slice2cpp`.

- `void writeSize(Ice::Int sz)`
The `Ice encoding` has a compact representation to indicate size. This function converts the given non-negative integer into the proper encoded representation.
- `void startSize()`
`void endSize()`
The encoding for optional values uses a 32-bit integer to hold the size of variable-length types. Calling `startSize` writes a placeholder value for the size; after writing the data, call `endSize` to patch the placeholder with the actual size.
- `bool writeOptional(Int tag, OptionalFormat fmt)`
Prepares the stream to write an optional value with the given tag and format. Returns true if the value should be written, or false otherwise. A return value of false indicates that the encoding version in use by the stream does not support optional values. If this method returns true, the data associated with that optional value must be written next. Optional values must be written in order by tag from least to greatest. The `OptionalFormat` enumeration is defined as follows:

```
C++
```

```
namespace Ice {
    enum OptionalFormat {
        OptionalFormatF1, OptionalFormatF2, OptionalFormatF4,
OptionalFormatF8,
        OptionalFormatSize, OptionalFormatVSize,
OptionalFormatFSize,
        OptionalFormatEndMarker
    };
}
```

Refer to the `encoding` discussion for more information on the meaning of these values.

- `void writeProxy(const Ice::ObjectPrx&)`
Inserts a proxy into the stream. It is equivalent to calling `write` with a proxy parameter.
- `void writeObject(const Ice::ObjectPtr&)`
Inserts an Ice object. The `Ice encoding for class instances` may cause the insertion of this object to be delayed, in which case the stream retains a reference to the given object and the stream does not insert its state until `writePendingObjects` is invoked on the stream. It is equivalent to calling `write` with a `Ptr` parameter.
- `void writeException(const Ice::UserException & ex)`
Inserts a `user exception`. It is equivalent to calling `write` with a user exception. The exception argument may be an instance of `UserExceptionWriter`, which allows you to `implement your own exception marshaling logic`.

- `void startObject(const SlicedDataPtr& sd)`
`void endObject()`
 When marshaling the slices of an object, the application must first call `startObject`, then marshal the slices, and finally call `endObject`. The caller can pass a `SlicedData` object containing the preserved slices of unknown more-derived types, or 0 if there are no preserved slices.
- `void startException(const SlicedDataPtr& sd)`
`void endException()`
 When marshaling the slices of an exception, the application must first call `startException`, then marshal the slices, and finally call `endException`. The caller can pass a `SlicedData` object containing the preserved slices of unknown more-derived types, or 0 if there are no preserved slices.
- `void startSlice(const std::string& typeId, bool last)`
`void endSlice()`
 Starts and ends a slice of `object` or `exception` member data. The call to `startSlice` must include the type ID for the current slice, and a boolean indicating whether this is the last slice of the object or exception.
- `void startEncapsulation(const EncodingVersion& v, FormatType fmt)`
`void startEncapsulation()`
`void endEncapsulation()`
 Starts and ends an `encapsulation`, respectively. The first overloading of `startEncapsulation` allows you to specify the encoding version as well as the format to use for any objects and exceptions marshaled within this encapsulation.
- `EncodingVersion getEncoding()`
 Returns the encoding version currently being used by the stream.
- `void writePendingObjects()`
 Encodes the state of `Ice objects` whose insertion was delayed during `writeObject`. This member function must only be called once. For backward compatibility with encoding version 1.0, this function must only be called when non-optional data members or parameters use class types.
- `void finished(std::vector< Ice::Byte >& data)`
`std::pair<const Byte*, const Byte*> finished()`
 Indicates that marshaling is complete. This member function must only be called once. In the first overloading, the given byte sequence is filled with a copy of the encoded data. The second overloading avoids a copy by returning a pair of pointers to the stream's internal memory; these pointers are valid for the lifetime of the `OutputStream` object.
- `size_type pos()`
`void rewrite(Int v, size_type pos)`
 The `pos` method returns the stream's current position, and `rewrite` allows you to overwrite a 32-bit integer value at the given position in the stream. Calling `rewrite` does not change the stream's current position.
- `void reset(bool clearBuffer)`
 Resets the writing position of the stream to the beginning. If `clearBuffer` is true, the stream releases the memory it has allocated to hold the encoded data.

Intercepting Object Insertion and Extraction in C++

In some situations it may be necessary for an application to intercept the insertion and extraction of Ice objects. For example, the [Ice extension for PHP](#) is implemented using Ice for C++ but represents Ice objects as native PHP objects. The PHP extension accomplishes this by manually encoding and decoding Ice objects as directed by the [data encoding](#) rules. However, the extension obviously cannot pass a native PHP object to the C++ stream function for writing objects. To bridge this gap between object systems, Ice supplies the helper classes described below.

On this page:

- [Inserting Objects in C++](#)
- [Extracting Objects in C++](#)

Inserting Objects in C++

The `ObjectWriter` base class facilitates the insertion of objects to a stream:

C++

```

namespace Ice {
    class ObjectWriter : public Ice::Object {
    public:
        virtual void write(const OutputStreamPtr&) const = 0;
        // ...
    };
    typedef ... ObjectWriterPtr;
}

```

A foreign Ice object is inserted into a stream using the following technique:

1. A C++ "wrapper" class is derived from `ObjectWriter`. This class wraps the foreign object and implements the `write` member function.
2. An instance of the wrapper class is passed to `writeObject`. (This is possible because `ObjectWriter` derives from `Ice::Object`.) Eventually, the `write` member function is invoked on the wrapper instance.
3. The implementation of `write` encodes the object's state as directed by the [data encoding rules for classes](#).

It is the application's responsibility to ensure that there is a one-to-one mapping between foreign Ice objects and wrapper objects. This is necessary in order to ensure the proper encoding of object graphs.

Extracting Objects in C++

The `ObjectReader` class facilitates the extraction of objects from a stream:

C++

```

namespace Ice {
    class ObjectReader : public Ice::Object {
    public:
        virtual void read(const InputStreamPtr&) = 0;
        // ...
    };
    typedef ... ObjectReaderPtr;

    class CompactIdResolver : public IceUtil::Shared {
    public:
        virtual std::string resolve(Ice::Int) const = 0;
    };
    typedef ... CompactIdResolverPtr;
}

```

Extracting the state of a foreign Ice object is more complicated than insertion:

1. A C++ "wrapper" class is derived from `ObjectReader`. An instance of this class represents a foreign Ice object.
2. An [object factory](#) is installed that returns instances of the wrapper class. Note that a single object factory can be used for all Slice types if it is registered with an empty Slice type ID.
3. A C++ callback class is derived from `ReadObjectCallback`. The implementation of `invoke` expects its argument to be either nil or an instance of the wrapper class as returned by the object factory.
4. An instance of the callback class is passed to `readObject`.
5. When the stream is ready to extract the state of an object, it invokes `read` on the wrapper class. The implementation of `read` decodes the object's state as directed by the [data encoding rules for classes](#).
6. The callback object passed to `readObject` is invoked, passing the instance of the wrapper object. All other callback objects representing the same instance in the stream (in case of object graphs) are invoked with the same wrapper object.

If your class definitions use [compact type IDs](#), you must also supply an implementation of `CompactIdResolver` when [initializing the communicator](#). This object is responsible for translating numeric type IDs into their string equivalents.

Intercepting User Exception Insertion and Extraction in C++

Inserting a User Exception in C++

As in the case of [Ice objects](#), a Dynamic Ice application may represent user exceptions in a native format that is not directly compatible with the Ice API. If the application needs to raise such a user exception to the Ice run time (so that it will be marshaled and sent back to the client), the exception must be wrapped in a subclass of `Ice::UserException`. The Dynamic Ice API provides a class to simplify this process:

C++

```

namespace Ice {
  class UserExceptionWriter : public UserException {
  public:
    UserExceptionWriter(const CommunicatorPtr&);

    virtual void write(const OutputStreamPtr&) const = 0;

    virtual std::string ice_name() const = 0;
    virtual Ice::Exception* ice_clone() const = 0;
    virtual void ice_throw() const = 0;

    // ...
  };
  typedef ... UserExceptionWriterPtr;
}

```

A subclass of `UserExceptionWriter` is responsible for supplying a communicator to the constructor, and for implementing the following methods:

- `void write(const OutputStreamPtr&) const`
This method is invoked when the Ice run time is ready to marshal the exception. The subclass must marshal the exception using the [encoding rules for exceptions](#).
- `std::string ice_name() const`
Return the Slice name of the exception.
- `Ice::Exception* ice_clone() const`
Return a copy of the exception.
- `void ice_throw() const`
Raise the exception by calling `throw *this`.

Extracting a User Exception in C++

An application extracts a user exception by calling one of two versions of the `throwException` method defined in the [InputStream](#) class:

C++

```

namespace Ice {
    class InputStream : ... {
    public:
        virtual void throwException() = 0;
        virtual void throwException(const
UserExceptionReaderFactoryPtr&) = 0;

        // ...
    };
}

```

The version without any arguments attempts to locate and throw a C++ implementation of the encoded exception, relying on statically-generated type information emitted by the Slice-to-C++ compiler.

If your goal is to create an exception in another type system, such as a native PHP exception object, you must call the second version of `throwException` and pass an implementation of `UserExceptionReaderFactory`:

C++

```

namespace Ice {
    class UserExceptionReaderFactory : public IceUtil::Shared {
    public:
        virtual void createAndThrow(const std::string& typeId) const =
0;
    };
    typedef ... UserExceptionReaderFactoryPtr;
}

```

As the stream iterates over slices of an exception from most-derived to least-derived, it invokes `createAndThrow` passing the `type ID` of each slice, giving the application an opportunity to raise an instance of `UserExceptionReader`:

C++

```

namespace Ice {
    class UserExceptionReader : public UserException {
    public:
        UserExceptionReader(const CommunicatorPtr&);
        ~UserExceptionReader() throw();

        virtual void read(const InputStreamPtr&) const = 0;

        virtual std::string ice_name() const = 0;
        virtual UserException* ice_clone() const = 0;
        virtual void ice_throw() const = 0;
    protected:
        const CommunicatorPtr _communicator;
    };
}

```

Subclasses of `UserExceptionReader` must implement the pure virtual functions. In particular, the implementation of `read` must call `InputStream::startException`, unmarshal the remaining slices, and then call `InputStream::endException`.

- [The OutputStream Interface in Java](#)
- [Intercepting Object Insertion and Extraction in Java](#)
- [Intercepting User Exception Insertion and Extraction in Java](#)
- [Stream Helper Methods in Java](#)

The InputStream Interface in Java

An `InputStream` is created using the following functions:

```

Java

package Ice;

public class Util {
    public static InputStream
        createInputStream(Communicator communicator, byte[] data);

    public static InputStream
        createInputStream(Communicator communicator, byte[] data,
            EncodingVersion version);

    public static InputStream
        wrapInputStream(Communicator communicator, byte[] data);

    public static InputStream
        wrapInputStream(Communicator communicator, byte[] data,
            EncodingVersion version);
}

```

You can optionally specify an encoding version for the stream, otherwise the stream uses the communicator's default encoding version.

Note that the `createInputStream` functions make a copy of the supplied data, whereas the `wrapInputStream` functions avoid copies by keeping a reference to the data. If you use `wrapInputStream`, it is your responsibility to ensure that the byte array remains unmodified for the lifetime of the `InputStream` object.

The `InputStream` interface is shown below.

```

Java

package Ice;

public interface InputStream {
    Communicator communicator();

    void sliceObjects(boolean slice);

    boolean readBool();
    boolean[] readBoolSeq();

    byte readByte();
    byte[] readByteSeq();

    short readShort();
    short[] readShortSeq();
}

```

```
int readInt();
int[] readIntSeq();

long readLong();
long[] readLongSeq();

float readFloat();
float[] readFloatSeq();

double readDouble();
double[] readDoubleSeq();

String readString();
String[] readStringSeq();

int readSize();
int readAndCheckSeqSize(int minSizeWireSize);

ObjectPrx readProxy();

void readObject(ReadObjectCallback cb);

int readEnum(int maxValue);

void throwException() throws UserException;
void throwException(UserExceptionReaderFactory factory) throws
UserException;

void startObject();
SlicedData endObject(boolean preserve);

void startException();
SlicedData endException(boolean preserve);

String startSlice();
void endSlice();
void skipSlice();

EncodingVersion startEncapsulation();
void endEncapsulation();
EncodingVersion skipEncapsulation();

EncodingVersion getEncoding();

void readPendingObjects();
java.io.Serializable readSerializable();

void rewind();

void skip(int sz);
```

```
void skipSize();
```

```
boolean readOptional(int tag, OptionalFormat format);
```

```
int pos();
```

```

    void destroy();
}

```

Member functions are provided for extracting all of the primitive types, as well as sequences of primitive types; these are self-explanatory. The remaining member functions have the following semantics:

- `void sliceObjects(boolean slice)` Determines the behavior of the stream when extracting [Ice objects](#). An Ice object is "sliced" when a factory cannot be found for a [Slice type ID](#), resulting in the creation of an object of a less-derived type. Slicing is typically disabled when the application expects all object factories to be present, in which case the exception `NoObjectFactoryException` is raised. The default behavior is to allow slicing.
- `int readSize()`
The [Ice encoding](#) has a compact representation to indicate size. This function extracts a size and returns it as an integer.
- `int readAndCheckSeqSize(int minWireSize)`
Like `readSize`, this function reads a size and returns it, but also verifies that there is enough data remaining in the unmarshaling buffer to successfully unmarshal the elements of the sequence. The `minWireSize` parameter indicates the smallest possible [on-the-wire representation](#) of a single sequence element. If the unmarshaling buffer contains insufficient data to unmarshal the sequence, the function throws `UnmarshalOutOfBoundsException`.
- `Ice.ObjectPrx readProxy()`
This function returns an instance of the base proxy type, `ObjectPrx`. The Slice compiler optionally generates helper functions to extract proxies of user-defined types.
- `void readObject(ReadObjectCallback cb)`
The [Ice encoding for class instances](#) requires extraction to occur in stages. The `readObject` function accepts a callback object of type `ReadObjectCallback`, whose definition is shown below:

Java

```

package Ice;

public interface ReadObjectCallback {
    void invoke(Ice.Object obj);
}

```

When the object instance is available, the callback object's `invoke` member function is called. The application must call `readPendingObjects` to ensure that all instances are properly extracted. Note that applications rarely need to invoke this member function directly; the [helper functions](#) generated by the Slice compiler are easier to use.

- `int readEnum(int maxValue)`
Unmarshals the integer value of an enumerator. The `maxValue` argument represents the highest enumerator value in the enumeration. Consider the following definitions:

Slice

```

enum Color { red, green, blue };
enum Fruit { Apple, Pear=3, Orange };

```

The maximum value for `Color` is 2, and the maximum value for `Fruit` is 4.

- `void throwException()` throws `UserException`
`void throwException(UserExceptionReaderFactory factory)`

These functions [extract a user exception](#) from the stream and throw it. If the stored exception is of an unknown type, the functions

attempt to extract and throw a less-derived exception. If that also fails, an exception is thrown: for the 1.0 encoding, the exception is `UnmarshalOutOfBoundsException`, for the 1.1 encoding, the exception is `UnknownUserException`.

- `String startSlice()`
`void endSlice()`
`void skipSlice()`
 Start, end, and skip a slice of member data, respectively. These functions are used when manually extracting the slices of an [Ice object](#) or [user exception](#). The `startSlice` method returns the [type ID](#) of the next slice, which may be an empty string depending on the format used to encode the object or exception.
- `void startObject()`
`SlicedData endObject(boolean preserve)`
 The `startObject` method must be called prior to reading the slices of an object. The `endObject` method must be called after all slices have been read. Pass true to `endObject` in order to preserve the slices of any unknown more-derived types, or false to discard the slices. If `preserve` is true and the stream actually preserved any slices, the return value of `endObject` is a non-nil `SlicedData` object that encapsulates the slice data. If the caller later wishes to forward the object with any preserved slices intact, it must supply this `SlicedData` object to the output stream.
- `void startException()`
`SlicedData endException(boolean preserve)`
 The `startException` method must be called prior to reading the slices of an exception. The `endException` method must be called after all slices have been read. Pass true to `endException` in order to preserve the slices of any unknown more-derived types, or false to discard the slices. If `preserve` is true and the stream actually preserved any slices, the return value of `endException` is a non-nil `SlicedData` object that encapsulates the slice data. If the caller later wishes to forward the exception with any preserved slices intact, it must supply this `SlicedData` object to the output stream.
- `EncodingVersion startEncapsulation()`
`void endEncapsulation()`
`EncodingVersion skipEncapsulation()`
 Start, end, and skip an [encapsulation](#), respectively. The `startEncapsulation` and `skipEncapsulation` methods return the encoding version used to encode the contents of the encapsulation.
- `EncodingVersion getEncoding()`
 Returns the encoding version currently in use by the stream.
- `void readPendingObjects()`
 An application must call this function after all other data has been extracted, but only if [Ice objects](#) were encoded. This function extracts the state of Ice objects and invokes their corresponding callback objects (see `readObject`). For backward compatibility with encoding version 1.0, this function must only be called when non-optional data members or parameters use class types.
- `java.io.Serializable readSerializable()`
 Reads a [serializable Java object](#) from the stream.
- `void rewind()`
 Resets the position of the stream to the beginning.
- `void skip(int sz)`
 Skips the given number of bytes.
- `void skipSize()`
 Reads a size at the current position and skips that number of bytes.
- `boolean readOptional(int tag, OptionalFormat fmt)`
 Returns true if an optional value with the given tag and format is present, or false otherwise. If this method returns true, the data associated with that optional value must be read next. Optional values must be read in order by tag from least to greatest. The `OptionalFormat` enumeration is defined as follows:

Java

```
package Ice;
enum OptionalFormat {
    OptionalFormatF1, OptionalFormatF2, OptionalFormatF4,
    OptionalFormatF8,
    OptionalFormatSize, OptionalFormatVSize, OptionalFormatFSize,
    OptionalFormatEndMarker
}
```

Refer to the [encoding](#) discussion for more information on the meaning of these values.

- `void destroy()`
Applications must call this function in order to reclaim resources.

Here is a simple example that demonstrates how to extract a boolean and a sequence of strings from a stream:

Java

```
byte[] data = ...
Ice.InputStream in =
    Ice.Util.createInputStream(communicator, data);
try {
    boolean b = in.readBool();
    String[] seq = in.readStringSeq();
} finally {
    in.destroy();
}
```

The OutputStream Interface in Java

An `OutputStream` is created using the following function:

```

Java

package Ice;

public class Util {
    public static OutputStream
        createOutputStream(Communicator communicator);

    public static OutputStream
        createOutputStream(Communicator communicator, EncodingVersion
version);
}

```

You can optionally specify an encoding version for the stream, otherwise the stream uses the communicator's default encoding version.

The `OutputStream` class is shown below.

```

Java

package Ice;

public interface OutputStream {
    Communicator communicator();

    void writeBool(boolean v);
    void writeBoolSeq(boolean[] v);

    void writeByte(byte v);
    void writeByteSeq(byte[] v);

    void writeShort(short v);
    void writeShortSeq(short[] v);

    void writeInt(int v);
    void writeIntSeq(int[] v);

    void writeLong(long v);
    void writeLongSeq(long[] v);

    void writeFloat(float v);
    void writeFloatSeq(float[] v);

    void writeDouble(double v);
    void writeDoubleSeq(double[] v);
}

```

```
void writeString(String v);
void writeStringSeq(String[] v);

void writeSize(int sz);

void writeProxy(ObjectPrx v);

void writeObject(Ice.Object v);

void writeEnum(int v, int maxValue);

void writeException(UserException ex);

void startObject(SlicedData sd);
void endObject();

void startException(SlicedData sd);
void endException();

void startSlice(String typeId, boolean last);
void endSlice();

void startEncapsulation(EncodingVersion encoding, FormatType
format);
void startEncapsulation();
void endEncapsulation();

EncodingVersion getEncoding();

void writePendingObjects();

boolean writeOptional(int tag, OptionalFormat format);

int pos();

void rewrite(int sz, int pos);

void startSize();
void endSize();

byte[] finished();

void reset(boolean clearBuffer);

void writeSerializable(java.io.Serializable o);
```

```

    void destroy();
}

```

Member functions are provided for inserting all of the primitive types, as well as sequences of primitive types; these are self-explanatory. The remaining member functions have the following semantics:

- `void writeSize(int sz)`
The `Ice encoding` has a compact representation to indicate size. This function converts the given non-negative integer into the proper encoded representation.
- `void writeProxy(Ice.ObjectPrx v)`
Inserts a proxy.
- `void writeObject(Ice.Object v)`
Inserts an Ice object. The `Ice encoding for class instances` may cause the insertion of this object to be delayed, in which case the stream retains a reference to the given object and does not insert its state until `writePendingObjects` is invoked on the stream.
- `void writeEnum(int val, int maxValue)`
Writes the integer value of an enumerator. The `maxValue` argument represents the highest enumerator value in the `enumeration`. Consider the following definitions:

Slice

```

enum Color { red, green, blue };
enum Fruit { Apple, Pear=3, Orange };

```

The maximum value for `Color` is 2, and the maximum value for `Fruit` is 4.

- `void writeException(UserException ex)`
Inserts a `user exception`. The exception argument may be an instance of `UserExceptionWriter`, which allows you to `implement your own exception marshaling logic`.
- `void startObject(SlicedData sd)`
`void endObject()`
When marshaling the slices of an object, the application must first call `startObject`, then marshal the slices, and finally call `endObject`. The caller can pass a `SlicedData` object containing the preserved slices of unknown more-derived types, or 0 if there are no preserved slices.
- `void startException(SlicedData sd)`
`void endException()`
When marshaling the slices of an exception, the application must first call `startException`, then marshal the slices, and finally call `endException`. The caller can pass a `SlicedData` object containing the preserved slices of unknown more-derived types, or 0 if there are no preserved slices.
- `void startSlice(String typeId, boolean last)`
`void endSlice()`
Starts and ends a slice of `object` or `exception` member data. The call to `startSlice` must include the type ID for the current slice, and a boolean indicating whether this is the last slice of the object or exception.
- `void startEncapsulation(EncodingVersion encoding, FormatType format)`
`void startEncapsulation()`
`void endEncapsulation()`
Starts and ends an `encapsulation`, respectively. The first overloading of `startEncapsulation` allows you to specify the encoding version as well as the format to use for any objects and exceptions marshaled within this encapsulation.
- `EncodingVersion getEncoding()`
Returns the encoding version currently being used by the stream.
- `void writePendingObjects()`
Encodes the state of Ice objects whose insertion was delayed during `writeObject`. This member function must only be called once. For backward compatibility with encoding version 1.0, this function must only be called when non-optional data members or

parameters use class types.

- `boolean writeOptional(int tag, OptionalFormat fmt)`
Prepares the stream to write an optional value with the given tag and format. Returns true if the value should be written, or false otherwise. A return value of false indicates that the encoding version in use by the stream does not support optional values. If this method returns true, the data associated with that optional value must be written next. Optional values must be written in order by tag from least to greatest. The `OptionalFormat` enumeration is defined as follows:

Java

```

package Ice;
enum OptionalFormat {
    OptionalFormatF1, OptionalFormatF2, OptionalFormatF4,
    OptionalFormatF8,
    OptionalFormatSize, OptionalFormatVSize, OptionalFormatFSize,
    OptionalFormatEndMarker
}

```

Refer to the [encoding](#) discussion for more information on the meaning of these values.

- `int pos()`
`void rewrite(int sz, int pos)`
The `pos` method returns the stream's current position, and `rewrite` allows you to overwrite a 32-bit integer value at the given position in the stream. Calling `rewrite` does not change the stream's current position.
- `void startSize()`
`void endSize()`
The encoding for optional values uses a 32-bit integer to hold the size of variable-length types. Calling `startSize` writes a placeholder value for the size; after writing the data, call `endSize` to patch the placeholder with the actual size.
- `byte[] finished()`
Indicates that marshaling is complete and returns the encoded byte sequence. This member function must only be called once.
- `void reset(boolean clearBuffer)`
Resets the writing position of the stream to the beginning. The boolean argument `clearBuffer` determines whether the stream releases the internal buffer it allocated to hold the encoded data. If `clearBuffer` is true, the stream releases the buffer in order to make it eligible for garbage collection. If `clearBuffer` is false, the stream retains the buffer to avoid generating unnecessary garbage.
- `void writeSerializable(java.io.Serializable v)`
Writes a [serializable Java object](#) to the stream.
- `void destroy()`
Applications must call this function in order to reclaim resources.

Here is a simple example that demonstrates how to insert a boolean and a sequence of strings into a stream:

Java

```
final String[] seq = { "Ice", "rocks!" };
Ice.OutputStream out = Ice.Util.createOutputStream(communicator);
try {
    out.writeBool(true);
    out.writeStringSeq(seq);
    byte[] data = out.finished();
} finally {
    out.destroy();
}
```

Intercepting Object Insertion and Extraction in Java

In some situations it may be necessary for an application to intercept the insertion and extraction of Ice objects. For example, the [Ice extension for PHP](#) is implemented using Ice for C++ but represents Ice objects as native PHP objects. The PHP extension accomplishes this by manually encoding and decoding Ice objects as directed by the [data encoding](#) rules. However, the extension obviously cannot pass a native PHP object to the C++ stream function for writing objects. To bridge this gap between object systems, Ice supplies the helper classes described below.

On this page:

- [Inserting Objects in Java](#)
- [Extracting Objects in Java](#)

Inserting Objects in Java

The `ObjectWriter` base class facilitates the insertion of objects to a stream:

Java

```
package Ice;

public abstract class ObjectWriter extends ObjectImpl {
    public abstract void write(OutputStream out);
    // ...
}
```

A foreign Ice object is inserted into a stream using the following technique:

1. A Java "wrapper" class is derived from `ObjectWriter`. This class wraps the foreign object and implements the `write` member function.
2. An instance of the wrapper class is passed to `writeObject`. (This is possible because `ObjectWriter` derives from `Ice.Object`.) Eventually, the `write` member function is invoked on the wrapper instance.
3. The implementation of `write` encodes the object's state as directed by the [data encoding rules for classes](#).

It is the application's responsibility to ensure that there is a one-to-one mapping between foreign Ice objects and wrapper objects. This is necessary in order to ensure the proper encoding of object graphs.

Extracting Objects in Java

The `ObjectReader` class facilitates the extraction of objects from a stream:

Java

```

package Ice;

public abstract class ObjectReader extends ObjectImpl {
    public abstract void read(InputStream in);
    // ...
}

public interface CompactIdResolver {
    String resolve(int id);
}

```

Extracting the state of a foreign Ice object is more complicated than insertion:

1. A Java "wrapper" class is derived from `ObjectReader`. An instance of this class represents a foreign Ice object.
2. An [object factory](#) is installed that returns instances of the wrapper class. Note that a single object factory can be used for all Slice types if it is registered with an empty Slice type ID.
3. A Java callback class implements the `ReadObjectCallback` interface. The implementation of `invoke` expects its argument to be either null or an instance of the wrapper class as returned by the object factory.
4. An instance of the callback class is passed to `readObject`.
5. When the stream is ready to extract the state of an object, it invokes `read` on the wrapper class. The implementation of `read` decodes the object's state as directed by the [data encoding rules for classes](#).
6. The callback object passed to `readObject` is invoked, passing the instance of the wrapper object. All other callback objects representing the same instance in the stream (in case of object graphs) are invoked with the same wrapper object.

If your class definitions use [compact type IDs](#), you must also supply an implementation of `CompactIdResolver` when [initializing the communicator](#). This object is responsible for translating numeric type IDs into their string equivalents.

Intercepting User Exception Insertion and Extraction in Java

Inserting a User Exception in Java

As in the case of [Ice objects](#), a Dynamic Ice application may represent user exceptions in a native format that is not directly compatible with the Ice API. If the application needs to raise such a user exception to the Ice run time, the exception must be wrapped in a subclass of `Ice.UserException`. The Dynamic Ice API provides a class to simplify this process:

```

Java

package Ice;

public abstract class UserExceptionWriter extends UserException {

    public UserExceptionWriter(Communicator communicator);

    public abstract void write(Ice.OutputStream os);

    // ...
}

```

A subclass of `UserExceptionWriter` is responsible for supplying a communicator to the constructor, and for implementing the following methods:

- `void write(OutputStream os)`
This method is invoked when the Ice run time is ready to marshal the exception. The subclass must marshal the exception using the [encoding rules for exceptions](#).

Extracting a User Exception in Java

An application extracts a user exception by calling one of two versions of the `throwException` method defined in the `InputStream` class:

```

Java

package Ice;

public interface InputStream {

    void throwException() throws UserException;

    void throwException(UserExceptionReaderFactory factory) throws
    UserException;

    // ...
}

```

The version without any arguments attempts to locate and throw a Java implementation of the encoded exception using classes generated by the [Slice-to-Java compiler](#).

If your goal is to create an exception in another type system, such as a native PHP exception object, you must call the second version of `throwException` and pass an implementation of `UserExceptionReaderFactory`:

Java

```
package Ice;

public interface UserExceptionReaderFactory {
    void createAndThrow(String typeId) throws UserException;
}
```

As the stream iterates over slices of an exception from most-derived to least-derived, it invokes `createAndThrow` passing the `type ID` of each slice, giving the application an opportunity to raise an instance of `UserExceptionReader`:

Java

```
package Ice;

public abstract class UserExceptionReader extends UserException {
    protected UserExceptionReader(Communicator communicator);

    public abstract void read(InputStream is);

    public abstract String ice_name();

    protected Communicator _communicator;
}
```

Subclasses of `UserExceptionReader` must implement the abstract functions. In particular, the implementation of `read` must call `InputStream.startException`, unmarshal the remaining slices, and then call `InputStream.endException`.

Stream Helper Methods in Java

The stream classes provide all of the low-level methods necessary for [encoding and decoding](#) Ice types. However, it would be tedious and error-prone to manually encode complex Ice types such as classes, structs, and dictionaries using these low-level functions. For this reason, the [Slice compiler](#) optionally generates helper methods for streaming complex Ice types.

We will use the following Slice definitions to demonstrate the language mapping:

Slice

```
module M {
  sequence<...> Seq;
  dictionary<...> Dict;
  struct S {
    ...
  };
  enum E { ... };
  class C {
    ...
  };
};
```

The Slice compiler generates the corresponding helper methods shown below:

Java

```

package M;

public class SeqHelper {
    public static T[] read(Ice.InputStream in);
    public static void write(Ice.OutputStream out, T[] v);
    public static void Ice.OptionalFormat optionalFormat();
}

public class DictHelper {
    public static java.util.Map read(Ice.InputStream in);
    public static void write(Ice.OutputStream out, java.util.Map<...,
...> v);
    public static void Ice.OptionalFormat optionalFormat();
}

public class SHelper {
    public static S read(Ice.InputStream in);
    public static void write(Ice.OutputStream out, S v);
    public static void Ice.OptionalFormat optionalFormat();
}

public class EHelper {
    public static E read(Ice.InputStream in);
    public static void write(Ice.OutputStream out, E v);
    public static void Ice.OptionalFormat optionalFormat();
}

public class CHelper {
    public static void read(Ice.InputStream in, CHolder h);
    public static void write(Ice.OutputStream out, C v);
    public static void Ice.OptionalFormat optionalFormat();
}

public class CPrxHelper {
    public static CPrx read(Ice.InputStream in);
    public static void write(Ice.OutputStream out, CPrx v);
    public static void Ice.OptionalFormat optionalFormat();
}

```

The `optionalFormat` method simplifies the task of writing [optional values](#).

The Slice compiler also generates the following methods for `struct` and `enum` types:

Java

```
public class S ... {
    ...
    public void ice_read(Ice.InputStream in);
    public void ice_write(Ice.OutputStream out);
};
public class E... {
    ...
    public void ice_read(Ice.InputStream in);
    public void ice_write(Ice.OutputStream out);
}
```

Be aware that a call to `CHelper.read` does not result in the immediate extraction of an Ice object. The `value` member of the given `CHolder` object is updated when `readPendingObjects` is invoked on the [input stream](#).

C-Sharp Streaming Interfaces

We discuss the stream classes first, followed by the helper functions, and finish with an advanced use case.

Topics

- [The InputStream Interface in C-Sharp](#)
- [The OutputStream Interface in C-Sharp](#)
- [Stream Helper Methods in C-Sharp](#)
- [Intercepting Object Insertion and Extraction in C-Sharp](#)
- [Intercepting User Exception Insertion and Extraction in C-Sharp](#)

The InputStream Interface in C-Sharp

An `InputStream` is created using the following function:

```

C#

namespace Ice
{
    public sealed class Util
    {
        public static InputStream createInputStream(
            Communicator communicator,
            byte[] bytes);

        public static InputStream createInputStream(
            Communicator communicator,
            byte[] bytes,
            EncodingVersion version);

        public static InputStream wrapInputStream(
            Communicator communicator,
            byte[] bytes);

        public static InputStream wrapInputStream(
            Communicator communicator,
            byte[] bytes,
            EncodingVersion version);
    }
}

```

You can optionally specify an encoding version for the stream, otherwise the stream uses the communicator's default encoding version.

Note that the `createInputStream` functions make a copy of the supplied data, whereas the `wrapInputStream` functions avoid copies by keeping a reference to the data. If you use `wrapInputStream`, it is your responsibility to ensure that the memory buffer remains unmodified for the lifetime of the `InputStream` object.

The `InputStream` interface is shown below.

```

C#

namespace Ice
{
    public interface InputStream
    {
        Communicator communicator();

        void sliceObjects(bool slice);

        bool readBool();
        bool[] readBoolSeq();
    }
}

```

```
byte readByte();
byte[] readByteSeq();

short readShort();
short[] readShortSeq();

int readInt();
int[] readIntSeq();

long readLong();
long[] readLongSeq();

float readFloat();
float[] readFloatSeq();

double readDouble();
double[] readDoubleSeq();

string readString();
string[] readStringSeq();

int readSize();
int readAndCheckSeqSize(int minSize);

ObjectPrx readProxy();

void readObject(ReadObjectCallback cb);

int readEnum(int maxValue);

void throwException();
void throwException(UserExceptionReaderFactory factory);

void startObject();
SlicedData endObject(bool preserve);

void startException();
SlicedData endException(bool preserve);

string startSlice();
void endSlice();
void skipSlice();

EncodingVersion startEncapsulation();
void endEncapsulation();
EncodingVersion skipEncapsulation();
EncodingVersion getEncoding();

void readPendingObjects();
```

```
object readSerializable();

void rewind();

void skip(int sz);
void skipSize();

bool readOptional(int tag, OptionalFormat format);

int pos();

void destroy();
```

```

    }
}

```

Member functions are provided for extracting all of the primitive types, as well as sequences of primitive types; these are self-explanatory. The remaining member functions have the following semantics:

- `void sliceObjects(boolean slice)`
Determines the behavior of the stream when extracting [Ice objects](#). An Ice object is "sliced" when a factory cannot be found for a [Slice type ID](#), resulting in the creation of an object of a less-derived type. Slicing is typically disabled when the application expects all object factories to be present, in which case the exception `NoObjectFactoryException` is raised. The default behavior is to allow slicing.
- `int readSize()`
The [Ice encoding](#) has a compact representation to indicate size. This function extracts a size and returns it as an integer.
- `int readAndCheckSeqSize(int minWireSize)`
Like `readSize`, this function reads a size and returns it, but also verifies that there is enough data remaining in the unmarshaling buffer to successfully unmarshal the elements of the sequence. The `minWireSize` parameter indicates the smallest possible [on-the-wire representation](#) of a single sequence element. If the unmarshaling buffer contains insufficient data to unmarshal the sequence, the function throws `UnmarshalOutOfBoundsException`.
- `Ice.ObjectPrx readProxy()`
This function returns an instance of the base proxy type, `ObjectPrx`. The Slice compiler optionally generates [helper functions](#) to extract proxies of user-defined types.
- `void readObject(ReadObjectCallback cb)`
The [Ice encoding for class instances](#) requires extraction to occur in stages. The `readObject` function accepts a callback object of type `ReadObjectCallback`, whose definition is shown below:

C#

```

namespace Ice {
    public interface ReadObjectCallback {
        void invoke(Ice.Object obj);
    }
}

```

When the object instance is available, the callback object's `invoke` member function is called. The application must call `readPendingObjects` to ensure that all instances are properly extracted. Note that applications rarely need to invoke this member function directly; the [helper functions](#) generated by the Slice compiler are easier to use.

- `int readEnum(int maxValue)`
Unmarshals the integer value of an enumerator. The `maxValue` argument represents the highest enumerator value in the enumeration. Consider the following definitions:

Slice

```

enum Color { red, green, blue };
enum Fruit { Apple, Pear=3, Orange };

```

The maximum value for `Color` is 2, and the maximum value for `Fruit` is 4.

- `void throwException()`
`void throwException(UserExceptionReaderFactory factory)`
These functions [extract a user exception](#) from the stream and throw it. If the stored exception is of an unknown type, the functions

attempt to extract and throw a less-derived exception. If that also fails, an exception is thrown: for the 1.0 encoding, the exception is `UnmarshalOutOfBoundsException`, for the 1.1 encoding, the exception is `UnknownUserException`.

- `void startObject()`
`SlicedData endObject(bool preserve)`
 The `startObject` method must be called prior to reading the slices of an object. The `endObject` method must be called after all slices have been read. Pass true to `endObject` in order to preserve the slices of any unknown more-derived types, or false to discard the slices. If `preserve` is true and the stream actually preserved any slices, the return value of `endObject` is a non-nil `SlicedData` object that encapsulates the slice data. If the caller later wishes to forward the object with any preserved slices intact, it must supply this `SlicedData` object to the output stream.
- `void startException()`
`SlicedData endException(bool preserve)`
 The `startException` method must be called prior to reading the slices of an exception. The `endException` method must be called after all slices have been read. Pass true to `endException` in order to preserve the slices of any unknown more-derived types, or false to discard the slices. If `preserve` is true and the stream actually preserved any slices, the return value of `endException` is a non-nil `SlicedData` object that encapsulates the slice data. If the caller later wishes to forward the exception with any preserved slices intact, it must supply this `SlicedData` object to the output stream.
- `string startSlice()`
`void endSlice()`
`void skipSlice()`
 Start, end, and skip a slice of member data, respectively. These functions are used when manually extracting the slices of an [Ice object](#) or [user exception](#). The `startSlice` method returns the `type ID` of the next slice, which may be an empty string depending on the format used to encode the object or exception.
- `EncodingVersion startEncapsulation()`
`void endEncapsulation()`
`EncodingVersion skipEncapsulation()`
 Start, end, and skip an [encapsulation](#), respectively. The `startEncapsulation` and `skipEncapsulation` methods return the encoding version used to encode the contents of the encapsulation.
- `EncodingVersion getEncoding()`
 Returns the encoding version currently in use by the stream.
- `void readPendingObjects()`
 An application must call this function after all other data has been extracted, but only if [Ice objects](#) were encoded. This function extracts the state of Ice objects and invokes their corresponding callback objects (see `readObject`). Note that `endEncapsulation` implicitly calls `readPendingObjects` if necessary.
- `void readPendingObjects()`
 An application must call this function after all other data has been extracted, but only if [Ice objects](#) were encoded. This function extracts the state of Ice objects and invokes their corresponding callback objects (see `readObject`). For backward compatibility with encoding version 1.0, this function must only be called when non-optional data members or parameters use class types.
- `object readSerializable()`
 Reads a [serializable .NET object](#) from the stream.
- `void rewind()`
 Resets the position of the stream to the beginning.
- `void skip(int sz)`
 Skips the given number of bytes.
- `void skipSize()`
 Reads a size at the current position and skips that number of bytes.
- `bool readOptional(int tag, OptionalFormat fmt)`
 Returns true if an optional value with the given tag and format is present, or false otherwise. If this method returns true, the data associated with that optional value must be read next. Optional values must be read in order by tag from least to greatest. The `OptionalFormat` enumeration is defined as follows:

C#

```

namespace Ice {
    enum OptionalFormat {
        OptionalFormatF1, OptionalFormatF2, OptionalFormatF4,
OptionalFormatF8,
        OptionalFormatSize, OptionalFormatVSize,
OptionalFormatFSize,
        OptionalFormatEndMarker
    }
}

```

Refer to the [encoding](#) discussion for more information on the meaning of these values.

- `void destroy()`
Applications must call this function in order to reclaim resources.

Here is a simple example that demonstrates how to extract a boolean and a sequence of strings from a stream:

C#

```

byte[] data = ...
Ice.InputStream inStream =
    Ice.Util.createInputStream(communicator, data);
try {
    bool b = inStream.readBool();
    string[] seq = inStream.readStringSeq();
} finally {
    inStream.destroy();
}

```

The OutputStream Interface in C-Sharp

An `OutputStream` is created using the following function:

```

C#

namespace Ice
{
    public sealed class Util
    {
        public static OutputStream
        createOutputStream(Communicator communicator);

        public static OutputStream
        createOutputStream(Communicator communicator, EncodingVersion
        version);
    }
}

```

You can optionally specify an encoding version for the stream, otherwise the stream uses the communicator's default encoding version.

The `OutputStream` class is shown below.

```

C#

namespace Ice
{
    public interface OutputStream
    {
        Communicator communicator();

        void writeBool(bool v);
        void writeBoolSeq(bool[] v);

        void writeByte(byte v);
        void writeByteSeq(byte[] v);

        void writeShort(short v);
        void writeShortSeq(short[] v);

        void writeInt(int v);
        void writeIntSeq(int[] v);

        void writeLong(long v);
        void writeLongSeq(long[] v);

        void writeFloat(float v);
        void writeFloatSeq(float[] v);
    }
}

```

```
void writeDouble(double v);
void writeDoubleSeq(double[] v);

void writeString(string v);
void writeStringSeq(string[] v);

void writeSize(int sz);

void writeProxy(ObjectPrx v);

void writeObject(Ice.Object v);

void writeEnum(int v, int maxValue);

void writeException(UserException ex);

void startObject(SlicedData sd);
void endObject();

void startException(SlicedData sd);
void endException();

void startSlice(string typeId, bool last);
void endSlice();

void startEncapsulation(EncodingVersion encoding, FormatType
format);
void startEncapsulation();
void endEncapsulation();

EncodingVersion getEncoding();

void writePendingObjects();

bool writeOptional(int tag, OptionalFormat format);

int pos();

void rewrite(int sz, int pos);

void startSize();
void endSize();

byte[] finished();

void reset(bool clearBuffer);

void writeSerializable(object v);

void destroy();
```

```

    }
}

```

Member functions are provided for inserting all of the primitive types, as well as sequences of primitive types; these are self-explanatory. The remaining member functions have the following semantics:

- `void writeSize(int sz)`
The `Ice encoding` has a compact representation to indicate size. This function converts the given non-negative integer into the proper encoded representation.
- `void writeObject(Ice.Object v)`
Inserts an Ice object. The `Ice encoding for class instances` may cause the insertion of this object to be delayed, in which case the stream retains a reference to the given object and does not insert its state until `writePendingObjects` is invoked on the stream.
- `void writeProxy(Ice.ObjectPrx v)`
Inserts a proxy.
- `void writeEnum(int val, int maxValue)`
Writes the integer value of an enumerator. The `maxValue` argument represents the highest enumerator value in the `enumeration`. Consider the following definitions:

Slice

```

enum Color { red, green, blue };
enum Fruit { Apple, Pear=3, Orange };

```

The maximum value for `Color` is 2, and the maximum value for `Fruit` is 4.

- `void writeException(UserException ex)`
Inserts a `user exception`. The exception argument may be an instance of `UserExceptionWriter`, which allows you to `implement your own exception marshaling logic`.
- `void startObject(SlicedData sd)`
`void endObject()`
When marshaling the slices of an object, the application must first call `startObject`, then marshal the slices, and finally call `endObject`. The caller can pass a `SlicedData` object containing the preserved slices of unknown more-derived types, or 0 if there are no preserved slices.
- `void startException(SlicedData sd)`
`void endException()`
When marshaling the slices of an exception, the application must first call `startException`, then marshal the slices, and finally call `endException`. The caller can pass a `SlicedData` object containing the preserved slices of unknown more-derived types, or 0 if there are no preserved slices.
- `void startSlice(string typeId, bool last)`
`void endSlice()`
Starts and ends a slice of `object` or `exception` member data. The call to `startSlice` must include the type ID for the current slice, and a boolean indicating whether this is the last slice of the object or exception.
- `void startEncapsulation(EncodingVersion encoding, FormatType format)`
`void startEncapsulation()`
`void endEncapsulation()`
Starts and ends an `encapsulation`, respectively. The first overloading of `startEncapsulation` allows you to specify the encoding version as well as the format to use for any objects and exceptions marshaled within this encapsulation.
- `EncodingVersion getEncoding()`
Returns the encoding version currently being used by the stream.
- `void writePendingObjects()`
Encodes the state of Ice objects whose insertion was delayed during `writeObject`. This member function must only be called once. For backward compatibility with encoding version 1.0, this function must only be called when non-optional data members or

parameters use class types.

- `bool writeOptional(int tag, OptionalFormat fmt)`
Prepares the stream to write an optional value with the given tag and format. Returns true if the value should be written, or false otherwise. A return value of false indicates that the encoding version in use by the stream does not support optional values. If this method returns true, the data associated with that optional value must be written next. Optional values must be written in order by tag from least to greatest. The `OptionalFormat` enumeration is defined as follows:

C#

```

namespace Ice {
    enum OptionalFormat {
        OptionalFormatF1, OptionalFormatF2, OptionalFormatF4,
OptionalFormatF8,
        OptionalFormatSize, OptionalFormatVSize,
OptionalFormatFSize,
        OptionalFormatEndMarker
    }
}

```

Refer to the [encoding](#) discussion for more information on the meaning of these values.

- `int pos()`
`void rewrite(int sz, int pos)`
The `pos` method returns the stream's current position, and `rewrite` allows you to overwrite a 32-bit integer value at the given position in the stream. Calling `rewrite` does not change the stream's current position.
- `byte[] finished()`
Indicates that marshaling is complete and returns the encoded byte sequence. This member function must only be called once.
- `void reset(bool clearBuffer)`
Resets the writing position of the stream to the beginning. The boolean argument `clearBuffer` determines whether the stream releases the internal buffer it allocated to hold the encoded data. If `clearBuffer` is true, the stream releases the buffer in order to make it eligible for garbage collection. If `clearBuffer` is false, the stream retains the buffer to avoid generating unnecessary garbage.
- `void writeSerializable(object v)`
Writes a [serializable .NET object](#) to the stream.
- `void destroy()`
Applications must call this function in order to reclaim resources.

Here is a simple example that demonstrates how to insert a boolean and a sequence of strings into a stream:

C#

```
string[] seq = { "Ice", "rocks!" };
Ice.OutputStream outputStream
    = Ice.Util.createOutputStream(communicator);
try {
    outputStream.writeBool(true);
    outputStream.writeStringSeq(seq);
    byte[] data = outputStream.finished();
} finally {
    outputStream.destroy();
}
```

Stream Helper Methods in C-Sharp

The stream classes provide all of the low-level methods necessary for [encoding and decoding](#) Ice types. However, it would be tedious and error-prone to manually encode complex Ice types such as classes, structs, and dictionaries using these low-level functions. For this reason, the [Slice compiler](#) optionally generates helper methods for streaming complex Ice types.

We will use the following Slice definitions to demonstrate the language mapping:

Slice
<pre> module M { sequence<...> Seq; dictionary<...> Dict; struct S { ... }; enum E { ... }; class C { ... }; }; </pre>

The Slice compiler generates the corresponding helper methods shown below:

C#
<pre> namespace M { public sealed class SeqHelper { public static int[] read(Ice.InputStream _in); public static void write(Ice.OutputStream _out, int[] _v); public static Ice.OptionalFormat optionalFormat(); } public sealed class DictHelper { public static Dictionary<...> read(Ice.InputStream _in); public static void write(Ice.OutputStream _out, Dictionary<...> _v); public static Ice.OptionalFormat optionalFormat(); } public sealed class SHelper { public static S read(Ice.InputStream _in); public static void write(Ice.OutputStream _out, S _v); public static Ice.OptionalFormat optionalFormat(); } } </pre>

```
public sealed class EHelper
{
    public static M.E read(Ice.InputStream _in);
    public static void write(Ice.OutputStream _out, M.E _v);
    public static Ice.OptionalFormat optionalFormat();
}

public sealed class CHelper
{
    public CHelper(Ice.InputStream _in);
    public void read();
    public static void write(Ice.OutputStream _out, C _v);
    public M.C value
    {
        get;
    }
    public static Ice.OptionalFormat optionalFormat();
    // ...
}

public sealed class CPrxHelper : Ice.ObjectPrxHelperBase, CPrx
{
    public static CPrx read(Ice.InputStream _in);
    public static void write(Ice.OutputStream _out, CPrx _v);
    public static Ice.OptionalFormat optionalFormat();
}
```

```

    }
}

```

The `optionalFormat` method simplifies the task of writing optional values.

The Slice compiler also generates the following methods for `struct` types:

```

C#

public struct S {
    ...
    public void ice_read(Ice.InputStream in);
    public void ice_write(Ice.OutputStream out);
}

```

Be aware that a call to `CHelper.read` does not result in the immediate extraction of an Ice object. The `value` property of the given `CHelper` object is updated when `readPendingObjects` is invoked on the input stream.

Intercepting Object Insertion and Extraction in C-Sharp

In some situations it may be necessary for an application to intercept the insertion and extraction of Ice objects. For example, the [Ice extension for PHP](#) is implemented using Ice for C++ but represents Ice objects as native PHP objects. The PHP extension accomplishes this by manually encoding and decoding Ice objects as directed by the [data encoding](#) rules. However, the extension obviously cannot pass a native PHP object to the C++ stream function `writeObject`. To bridge this gap between object systems, Ice supplies the helper classes described below.

On this page:

- [Inserting Objects in C#](#)
- [Extracting Objects in C#](#)

Inserting Objects in C#

The `ObjectWriter` base class facilitates the insertion of objects to a stream:

C#

```

namespace Ice
{
    public abstract class ObjectWriter : ObjectImpl
    {
        public abstract void write(OutputStream outputStream);
        // ...
    }
}

```

A foreign Ice object is inserted into a stream using the following technique:

1. A C# "wrapper" class is derived from `ObjectWriter`. This class wraps the foreign object and implements the `write` member function.
2. An instance of the wrapper class is passed to `writeObject`. (This is possible because `ObjectWriter` derives from `Ice.Object`.) Eventually, the `write` member function is invoked on the wrapper instance.
3. The implementation of `write` encodes the object's state as directed by the [data encoding rules for classes](#).

It is the application's responsibility to ensure that there is a one-to-one mapping between foreign Ice objects and wrapper objects. This is necessary in order to ensure the proper encoding of object graphs.

Extracting Objects in C#

The `ObjectReader` class facilitates the extraction of objects from a stream:

C#

```

namespace Ice
{
    public abstract class ObjectReader : ObjectImpl
    {
        public abstract void read(InputStream inStream);
        // ...
    }

    public delegate string CompactIdResolver(int id);
}

```

Extracting the state of a foreign Ice object is more complicated than insertion:

1. A C# "wrapper" class is derived from `ObjectReader`. An instance of this class represents a foreign Ice object.
2. An [object factory](#) is installed that returns instances of the wrapper class. Note that a single object factory can be used for all Slice types if it is registered with an empty Slice type ID.
3. A C# callback class implements the `ReadObjectCallback` interface. The implementation of `invoke` expects its argument to be either null or an instance of the wrapper class as returned by the object factory.
4. An instance of the callback class is passed to `readObject`.
5. When the stream is ready to extract the state of an object, it invokes `read` on the wrapper class. The implementation of `read` decodes the object's state as directed by the [data encoding rules for classes](#).
6. The callback object passed to `readObject` is invoked, passing the instance of the wrapper object. All other callback objects representing the same instance in the stream (in case of object graphs) are invoked with the same wrapper object.

If your class definitions use [compact type IDs](#), you must also supply an implementation of `CompactIdResolver` when [initializing the communicator](#). This object is responsible for translating numeric type IDs into their string equivalents.

Intercepting User Exception Insertion and Extraction in C-Sharp

Inserting a User Exception in C#

As in the case of [Ice objects](#), a Dynamic Ice application may represent user exceptions in a native format that is not directly compatible with the Ice API. If the application needs to raise such a user exception to the Ice run time, the exception must be wrapped in a subclass of `Ice.UserException`. The Dynamic Ice API provides a class to simplify this process:

```

C#

```

namespace Ice
{
 public abstract class UserExceptionWriter : UserException
 {
 public UserExceptionWriter(Communicator communicator);

 public abstract void write(OutputStream os);

 // ...
 }
}

```

```

A subclass of `UserExceptionWriter` is responsible for supplying a communicator to the constructor, and for implementing the following methods:

- `void write(OutputStream os)`
This method is invoked when the Ice run time is ready to marshal the exception. The subclass must marshal the exception using the [encoding rules for exceptions](#).

Extracting a User Exception in C#

An application extracts a user exception by calling one of two versions of the `throwException` method defined in the `InputStream` class:

```

C#

```

namespace Ice {
 public interface InputStream {
 void throwException();
 void throwException(UserExceptionReaderFactory factory);

 // ...
 }
}

```

```

The version without any arguments attempts to locate and throw a C# implementation of the encoded exception using classes generated by the [Slice-to-C# compiler](#).

If your goal is to create an exception in another type system, such as a native PHP exception object, you must call the second version of `throwException` and pass an implementation of `UserExceptionReaderFactory`:

C#

```
namespace Ice {
    public interface UserExceptionReaderFactory {
        void createAndThrow(string typeId);
    }
}
```

As the stream iterates over slices of an exception from most-derived to least-derived, it invokes `createAndThrow` passing the `type ID` of each slice, giving the application an opportunity to raise an instance of `UserExceptionReader`:

C#

```
namespace Ice {
    public abstract class UserExceptionReader : UserException {
        protected UserExceptionReader(Communicator communicator);

        public abstract void read(InputStream is);

        public abstract string ice_name();

        protected Communicator _communicator;
    }
}
```

Subclasses of `UserExceptionReader` must implement the abstract functions. In particular, the implementation of `read` must call `InputStream.startException`, unmarshal the remaining slices, and then call `InputStream.endException`.

Dynamic Invocation and Dispatch Overview

On this page:

- [Use Cases for Dynamic Invocation and Dispatch](#)
- [Dynamic Invocation using `ice_invoke`](#)
- [Dynamic Dispatch using `Blobject`](#)

Use Cases for Dynamic Invocation and Dispatch

Ice applications generally use the static invocation model, in which the application invokes a Slice operation by calling a member function on a generated proxy class. In the server, the static dispatch model behaves similarly: the request is dispatched to the servant as a statically-typed call to a member function. Underneath this statically-typed facade, the Ice run times in the client and server are exchanging sequences of bytes representing the encoded request arguments and results. These interactions are illustrated below:

Interactions in a static invocation.

1. The client initiates a call to the Slice operation `add` by calling the member function `add` on a proxy.
2. The generated proxy class marshals the arguments into a sequence of bytes and transmits them to the server.
3. In the server, the generated servant class unmarshals the arguments and calls `add` on the subclass.
4. The servant marshals the results and returns them to the client.
5. Finally, the client's proxy unmarshals the results and returns them to the caller.

The application is blissfully unaware of this low-level machinery, and in the majority of cases that is a distinct advantage. In some situations, however, an application can leverage this machinery to accomplish tasks that are not possible in a statically-typed environment. Ice provides the dynamic invocation and dispatch models for these situations, allowing applications to send and receive requests as encoded sequences of bytes instead of statically-typed arguments.

The dynamic invocation and dispatch models offer several unique advantages to Ice services that forward requests from senders to receivers, such as [Glacier2](#) and [IceStorm](#). For these services, the request arguments are an opaque byte sequence that can be forwarded without the need to unmarshal and remarshal the arguments. Not only is this significantly more efficient than a statically-typed implementation, it also allows intermediaries such as [Glacier2](#) and [IceStorm](#) to be ignorant of the Slice types in use by senders and receivers.

Another use case for the dynamic invocation and dispatch models is scripting language integration. The Ice extensions for Python, PHP, and Ruby invoke Slice operations using the dynamic invocation model; the request arguments are encoded using the [streaming interfaces](#).

It may be difficult to resist the temptation of using a feature like dynamic invocation or dispatch, but we recommend that you carefully consider the risks and complexities of such a decision. For example, an application that uses the streaming interface to manually encode and decode request arguments has a high risk of failure if the argument signature of an operation changes. In contrast, this risk is greatly reduced in the static invocation and dispatch models because errors in a strongly-typed language are found early, during compilation. Therefore, we caution you against using this capability except where its advantages significantly outweigh the risks.

Dynamic Invocation using `ice_invoke`

Dynamic invocation is performed using the proxy member function `ice_invoke`, defined in the proxy base class `ObjectPrx`. If we were to define the function in Slice, it would look like this:

```

Slice
sequence<byte> ByteSeq;

bool ice_invoke(
    string operation,
    Ice::OperationMode mode,
    ByteSeq inParams,
    out ByteSeq outParams
);

```

The first argument is the name of the Slice operation.

This is the Slice name of the operation, not the name as it might be mapped to any particular language. For example, the string "while" is the name of the Slice operation `while`, and not `"_cpp_while"` (C++) or `"_while"` (Java).

The second argument is an enumerator from the Slice type `Ice::OperationMode`; the possible values are `Normal` and `Idempotent`. The third argument, `inParams`, represents an encapsulation of the encoded in-parameters of the operation.

A return value of `true` indicates a successful invocation, in which case an encapsulation of the marshaled form of the operation's results (if any) is provided in `outParams`. A return value of `false` signals the occurrence of a user exception whose encapsulated data is provided in `outParams`. The caller must also be prepared to catch local exceptions, which are thrown directly.

Dynamic Dispatch using `Blobject`

A server enables dynamic dispatch by creating a subclass of `Blobject` (the name is derived from *blob*, meaning a blob of bytes). The Slice equivalent of `Blobject` is shown below:

```

Slice
sequence<byte> ByteSeq;

interface Blobject {
    bool ice_invoke(ByteSeq inParams, out ByteSeq outParams);
};

```

The `inParams` argument supplies an encapsulation of the encoded in-parameters. The contents of the `outParams` argument depends on the outcome of the invocation: if the operation succeeded, `ice_invoke` must return `true` and place an encapsulation of the encoded results in `outParams`; if a user exception occurred, `ice_invoke` must return `false`, in which case `outParams` contains an encapsulation of the encoded exception. The operation may also raise local exceptions such as `OperationNotExistException`.

The language mappings add a trailing argument of type `Ice::Current` to `ice_invoke`, and this provides the implementation with the name of the operation being dispatched.

Because `Blobject` derives from `Object`, an instance is a regular Ice servant just like instances of the classes generated for user-defined Slice interfaces. The primary difference is that all operation invocations on a `Blobject` instance are dispatched through the `ice_invoke` member function.

If a `Blobject` subclass intends to decode the in-parameters (and not simply forward the request to another object), then the implementation

obviously must know the signatures of all operations it supports. How a `Blobject` subclass determines its type information is an implementation detail that is beyond the scope of this manual.

Note that a `Blobject` servant is also useful if you want to create a message forwarding service, such as [Glacier2](#). In this case, there is no need to decode any parameters; instead, the implementation simply forwards each request unchanged to a new destination. You can register a `Blobject` servant as a [default servant](#) to easily achieve this.

Dynamic Invocation and Dispatch in C++

This page describes the C++ mapping for the `ice_invoke` proxy function and the `Blobject` class.

On this page:

- [ice_invoke in C++](#)
- [Using Streams with ice_invoke in C++](#)
- [Subclassing Blobject in C++](#)
- [Using the Array Mapping for ice_invoke and Blobject in C++](#)

`ice_invoke` in C++

The mapping for `ice_invoke` is shown below:

C++
<pre>bool ice_invoke(const std::string& operation, Ice::OperationMode mode, const std::vector< Ice::Byte >& inParams, std::vector< Ice::Byte >& outParams);</pre>

Another overloading of `ice_invoke` (not shown) adds a trailing argument of type `Ice::Context`.

As an example, the code below demonstrates how to invoke the operation `op`, which takes no `in` parameters:

C++
<pre>Ice::ObjectPrx proxy = ... try { std::vector<Ice::Byte> inParams, outParams; if (proxy->ice_invoke("op", Ice::Normal, inParams, outParams)) { // Handle success } else { // Handle user exception } } catch (const Ice::LocalException& ex) { // Handle exception }</pre>

As a convenience, the Ice run time accepts an empty byte sequence when there are no input parameters and internally translates it into an empty encapsulation. In all other cases, the value for `inParams` must be an encapsulation of the encoded parameters.

Using Streams with `ice_invoke` in C++

The [streaming interfaces](#) provide the tools an application needs to dynamically invoke operations with arguments of any Slice type. Consider the following Slice definition:

Slice

```

module Calc {
    exception Overflow {
        int x;
        int y;
    };
    interface Compute {
        idempotent int add(int x, int y)
            throws Overflow;
    };
};

```

Now let's write a client that dynamically invokes the add operation:

C++

```

Ice::ObjectPrx proxy = ...
try {
    std::vector< Ice::Byte > inParams, outParams;

    Ice::OutputStreamPtr out = Ice::createOutputStream(communicator);
    out->startEncapsulation();
    out->writeInt(100); // x
    out->writeInt(-1); // y
    out->endEncapsulation();
    out->finished(inParams);

    if (proxy->ice_invoke("add", Ice::Idempotent, inParams,
outParams)) {
        // Handle success
        Ice::InputStreamPtr in =
Ice::createInputStream(communicator, outParams);
        in->startEncapsulation();
        int result = in->readInt();
        in->endEncapsulation();
        assert(result == 99);
    } else {
        // Handle user exception
    }
} catch (const Ice::LocalException& ex) {
    // Handle exception
}

```

You can see here that the input and output parameters are enclosed in encapsulations.

We neglected to handle the case of a user exception in this example, so let's implement that now. We assume that we have compiled our

program with the Slice-generated code, therefore we can call `throwException` on the input stream and catch `Overflow` directly:

```
C++
```

```

    if (proxy->ice_invoke("add", Ice::Idempotent, inParams,
outParams)) {
        // Handle success
        // ...
    } else {
        // Handle user exception
        Ice::InputStreamPtr in =
Ice::createInputStream(communicator, outParams);
        try {
            in->startEncapsulation();
            in->throwException();
        } catch (const Calc::Overflow& ex) {
            cout << "overflow while adding " << ex.x
<< " and " << ex.y << endl;
        } catch (const Ice::UserException& ex) {
            // Handle unexpected user exception
        }
    }
}

```

This is obviously a contrived example: if the Slice-generated code is available, why bother using dynamic dispatch? In the absence of Slice-generated code, the caller would need to manually unmarshal the user exception, which is outside the scope of this manual.

As a defensive measure, the code traps `Ice::UserException`. This could be raised if the Slice definition of `add` is modified to include another user exception but this segment of code did not get updated accordingly.

Subclassing `Blobject` in C++

Implementing the dynamic dispatch model requires writing a subclass of `Ice::Blobject`. We continue using the `Compute` interface to demonstrate a `Blobject` implementation:

```
C++
```

```

class ComputeI : public Ice::Blobject {
public:
    virtual bool ice_invoke(
        const std::vector<Ice::Byte>& inParams,
        std::vector<Ice::Byte>& outParams,
        const Ice::Current& current);
};

```

An instance of `ComputeI` is an Ice object because `Blobject` derives from `Object`, therefore an instance can be added to an `object adapter` like any other servant.

For the purposes of this discussion, the implementation of `ice_invoke` handles only the `add` operation and raises `OperationNotExistE`

exception for all other operations. In a real implementation, the servant must also be prepared to receive invocations of the following `Object` operations:

- `string ice_id()`
Returns the Slice `type ID` of the servant's most-derived type.
- `StringSeq ice_ids()`
Returns a sequence of strings representing all of the Slice interfaces supported by the servant, including `"::Ice::Object"`.
- `bool ice_isA(string id)`
Returns `true` if the servant supports the interface denoted by the given Slice `type ID`, or `false` otherwise. This operation is invoked by the proxy function `checkedCast`.
- `void ice_ping()`
Verifies that the object denoted by the `identity` and `facet` contained in `Ice::Current` is reachable.

With that in mind, here is our simplified version of `ice_invoke`:

C++

```

bool ComputeI::ice_invoke(
    const std::vector<Ice::Byte>& inParams,
    std::vector<Ice::Byte>& outParams,
    const Ice::Current& current)
{
    if (current.operation == "add") {
        Ice::CommunicatorPtr communicator =
current.adapter->getCommunicator();
        Ice::InputStreamPtr in =
Ice::createInputStream(communicator, inParams);
        in->startEncapsulation();
        int x = in->readInt();
        int y = in->readInt();
        in->endEncapsulation();

        Ice::OutputStreamPtr out =
Ice::createOutputStream(communicator);
        if (checkOverflow(x, y)) {
            Calc::Overflow ex;
            ex.x = x;
            ex.y = y;
            out->startEncapsulation();
            out->writeException(ex);
            out->endEncapsulation();
            out->finished(outParams);
            return false;
        } else {
            out->startEncapsulation();
            out->writeInt(x + y);
            out->endEncapsulation();
            out->finished(outParams);
            return true;
        }
    } else {
        Ice::OperationNotExistException ex(__FILE__, __LINE__);
        ex.id = current.id;
        ex.facet = current.facet;
        ex.operation = current.operation;
        throw ex;
    }
}

```

If an overflow is detected, the code "raises" the `Calc::Overflow` user exception by calling `writeException` on the output stream and returning `false`, otherwise the return value is encoded and the function returns `true`.

Using the Array Mapping for `ice_invoke` and `Blobject` in C++

Ice for C++ supports an [alternative mapping](#) for sequence input parameters that avoids the overhead of extra copying. Since the `ice_invoke` functions treat the encoded input parameters as a value of type `sequence<byte>`, the dynamic invocation and dispatch facility includes interfaces that use the array mapping for the input parameter `blob`.

Ice provides two overloaded versions of the proxy function `ice_invoke` that use the array mapping. The version that omits the trailing `Ice::Context` argument is shown below:

```
C++
```

```
bool ice_invoke(
    const std::string& operation,
    Ice::OperationMode mode,
    const std::pair< const Ice::Byte*, const Ice::Byte* >& in,
    std::vector< Ice::Byte >& out
);
```

A `Blobject` servant uses the array mapping by deriving its implementation class from `Ice::BlobjectArray` and overriding its `ice_invoke` function:

```
C++
```

```
class BlobjectArray {
public:
    virtual bool ice_invoke(
        const std::pair<const Ice::Byte*, const Ice::Byte*>& in,
        std::vector<Ice::Byte>& out,
        const Ice::Current& current) = 0;
};
```

Dynamic Invocation and Dispatch in Java

This page describes the Java mapping for the `ice_invoke` proxy function and the `Blobject` class.

On this page:

- [ice_invoke in Java](#)
- [Using Streams with ice_invoke in Java](#)
- [Subclassing Blobject in Java](#)

ice_invoke in Java

The mapping for `ice_invoke` is shown below:

```

Java

boolean ice_invoke(
    String operation,
    Ice.OperationMode mode,
    byte[] inParams,
    Ice.ByteSeqHolder outParams
);

```

Another overloading of `ice_invoke` (not shown) adds a trailing argument of type `Ice.Context`.

As an example, the code below demonstrates how to invoke the operation `op`, which takes no `in` parameters:

```

Java

Ice.ObjectPrx proxy = ...
try {
    Ice.ByteSeqHolder outParams = new Ice.ByteSeqHolder();
    if (proxy.ice_invoke("op", Ice.OperationMode.Normal, null,
outParams)) {
        // Handle success
    } else {
        // Handle user exception
    }
} catch (Ice.LocalException ex) {
    // Handle exception
}

```

As a convenience, the Ice run time accepts an empty or null byte sequence when there are no input parameters and internally translates it into an empty encapsulation. In all other cases, the value for `inParams` must be an encapsulation of the encoded parameters.

Using Streams with ice_invoke in Java

The [streaming interfaces](#) provide the tools an application needs to dynamically invoke operations with arguments of any Slice type. Consider the following Slice definition:

Slice

```

module Calc {
    exception Overflow {
        int x;
        int y;
    };
    interface Compute {
        idempotent int add(int x, int y)
            throws Overflow;
    };
};

```

Now let's write a client that dynamically invokes the add operation:

Java

```

Ice.ObjectPrx proxy = ...
try {
    Ice.OutputStream out = Ice.Util.createOutputStream(communicator);
    out.startEncapsulation();
    out.writeInt(100); // x
    out.writeInt(-1); // y
    out.endEncapsulation();
    byte[] inParams = out.finished();

    Ice.ByteSeqHolder outParams = new Ice.ByteSeqHolder();
    if (proxy.ice_invoke("add", Ice.OperationMode.Idempotent,
        inParams, outParams)) {
        // Handle success
        Ice.InputStream in = Ice.Util.createInputStream(communicator,
            outParams.value);
        in.startEncapsulation();
        int result = in.readInt();
        in.endEncapsulation();
        assert(result == 99);
    } else {
        // Handle user exception
    }
} catch (Ice.LocalException ex) {
    // Handle exception
}

```

You can see here that the input and output parameters are enclosed in encapsulations.

We neglected to handle the case of a user exception in this example, so let's implement that now. We assume that we have compiled our program with the Slice-generated code, therefore we can call `throwException` on the input stream and catch `Overflow` directly:

Java

```

    if (proxy.ice_invoke("add", Ice.OperationMode.Idempotent,
inParams, outParams)) {
        // Handle success
        // ...
    } else {
        // Handle user exception
        Ice.InputStream in = Ice.Util.createInputStream(communicator,
outParams.value);
        try {
            in.startEncapsulation();
            in.throwException();
        } catch (Calc.Overflow ex) {
            System.out.println("overflow while adding " + ex.x +
" and " + ex.y);
        } catch (Ice.UserException ex) {
            // Handle unexpected user exception
        }
    }
}

```

This is obviously a contrived example: if the Slice-generated code is available, why bother using dynamic dispatch? In the absence of Slice-generated code, the caller would need to manually unmarshal the user exception, which is outside the scope of this manual.

As a defensive measure, the code traps `Ice.UserException`. This could be raised if the Slice definition of `add` is modified to include another user exception but this segment of code did not get updated accordingly.

Subclassing `Blobject` in Java

Implementing the dynamic dispatch model requires writing a subclass of `Ice.Blobject`. We continue using the `Compute` interface to demonstrate a `Blobject` implementation:

Java

```

public class ComputeI extends Ice.Blobject {
    public boolean ice_invoke(
        byte[] inParams,
        Ice.ByteSeqHolder outParams,
        Ice.Current current)
    {
        // ...
    }
}

```

An instance of `ComputeI` is an Ice object because `Blobject` derives from `Object`, therefore an instance can be added to an `object adapter` like any other servant.

For the purposes of this discussion, the implementation of `ice_invoke` handles only the `add` operation and raises `OperationNotExistException` for all other operations. In a real implementation, the servant must also be prepared to receive invocations of the following `Object` operations:

- `string ice_id()`
Returns the Slice `type ID` of the servant's most-derived type.
- `StringSeq ice_ids()`
Returns a sequence of strings representing all of the Slice interfaces supported by the servant, including `"::Ice::Object"`.
- `bool ice_isA(string id)`
Returns `true` if the servant supports the interface denoted by the given Slice `type ID`, or `false` otherwise. This operation is invoked by the proxy function `checkedCast`.
- `void ice_ping()`
Verifies that the object denoted by the `identity` and `facet` contained in `Ice::Current` is reachable.

With that in mind, here is our simplified version of `ice_invoke`:

Java

```

public boolean ice_invoke(
    byte[] inParams,
    Ice.ByteSeqHolder outParams,
    Ice.Current current)
{
    if (current.operation.equals("add")) {
        Ice.Communicator communicator =
current.adapter.getCommunicator();
        Ice.InputStream in =
Ice.Util.createInputStream(communicator, inParams);
        in.startEncapsulation();
        int x = in.readInt();
        int y = in.readInt();
        in.endEncapsulation();

        Ice.OutputStream out =
Ice.Util.createOutputStream(communicator);
        try {
            if (checkOverflow(x, y)) {
                Calc.Overflow ex = new Calc.Overflow();
                ex.x = x;
                ex.y = y;
                out.startEncapsulation();
                out.writeException(ex);
                out.endEncapsulation();
                outParams.value = out.finished();
                return false;
            } else {
                out.startEncapsulation();
                out.writeInt(x + y);
                out.endEncapsulation();
                outParams.value = out.finished();
                return true;
            }
        } finally {
            out.destroy();
        }
    } else {
        Ice.OperationNotExistException ex =
new Ice.OperationNotExistException();
        ex.id = current.id;
        ex.facet = current.facet;
        ex.operation = current.operation;
        throw ex;
    }
}

```

If an overflow is detected, the code "raises" the `Calc::Overflow` user exception by calling `writeException` on the output stream and returning `false`, otherwise the return value is encoded and the function returns `true`.

Dynamic Invocation and Dispatch in C-Sharp

This page describes the C# mapping for the `ice_invoke` proxy function and the `Blobject` class.

On this page:

- [ice_invoke in C#](#)
- [Using Streams with ice_invoke in C#](#)
- [Subclassing Blobject in C#](#)

`ice_invoke` in C#

The mapping for `ice_invoke` is shown below:

```

C#

```

namespace Ice
{
 public interface ObjectPrx
 {
 bool ice_invoke(string operation,
 OperationMode mode,
 byte[] inParams,
 out byte[] outParams);

 // ...
 }
}

```

```

Another overloading of `ice_invoke` (not shown) adds a trailing argument of type `Ice.Context`.

As an example, the code below demonstrates how to invoke the operation `op`, which takes no `in` parameters:

```

C#

```

Ice.ObjectPrx proxy = ...
try {
 byte[] outParams;
 if (proxy.ice_invoke("op", Ice.OperationMode.Normal, null,
outParams)) {
 // Handle success
 } else {
 // Handle user exception
 }
} catch (Ice.LocalException ex) {
 // Handle exception
}

```

```

As a convenience, the Ice run time accepts a null or empty byte sequence when there are no input parameters and internally translates it into an empty encapsulation. In all other cases, the value for `inParams` must be an encapsulation of the encoded parameters.

Using Streams with `ice_invoke` in C#

The [streaming interfaces](#) provide the tools an application needs to dynamically invoke operations with arguments of any Slice type. Consider the following Slice definition:

```

Slice

```
module Calc {
 exception Overflow {
 int x;
 int y;
 };
 interface Compute {
 idempotent int add(int x, int y)
 throws Overflow;
 };
};
```

```

Now let's write a client that dynamically invokes the `add` operation:

C#

```

Ice.ObjectPrx proxy = ...
try {
    Ice.OutputStream outputStream =
Ice.Util.createOutputStream(communicator);
    outputStream.startEncapsulation();
    outputStream.writeInt(100); // x
    outputStream.writeInt(-1); // y
    outputStream.endEncapsulation();
    byte[] inParams = outputStream.finished();

    byte[] outParams;
    if (proxy.ice_invoke("add", Ice.OperationMode.Idempotent,
inParams, out outParams)) {
        // Handle success
        Ice.InputStream inputStream =
Ice.Util.createInputStream(communicator, outParams);
        inputStream.startEncapsulation();
        int result = inputStream.readInt();
        inputStream.endEncapsulation();
        System.Diagnostics.Debug.Assert(result == 99);
    } else {
        // Handle user exception
    }
} catch (Ice.LocalException ex) {
    // Handle exception
}

```

You can see here that the input and output parameters are enclosed in encapsulations.

We neglected to handle the case of a user exception in this example, so let's implement that now. We assume that we have compiled our program with the Slice-generated code, therefore we can call `throwException` on the input stream and catch `Overflow` directly:

C#

```

    if (proxy.ice_invoke("add", Ice.OperationMode.Idempotent,
inParams, out outParams)) {
        // Handle success
        ...
    } else {
        // Handle user exception
        Ice.InputStream inStream =
Ice.Util.createInputStream(communicator, outParams);
        try {
            inStream.startEncapsulation();
            inStream.throwException();
        } catch (Calc.Overflow ex) {
            System.Console.WriteLine("overflow while adding " +
                                     ex.x + " and " + ex.y);
        } catch (Ice.UserException) {
            // Handle unexpected user exception
        }
    }
}

```

This is obviously a contrived example: if the Slice-generated code is available, why bother using dynamic dispatch? In the absence of Slice-generated code, the caller would need to manually unmarshal the user exception, which is outside the scope of this book.

As a defensive measure, the code traps `Ice.UserException`. This could be raised if the Slice definition of `add` is modified to include another user exception but this segment of code did not get updated accordingly.

Subclassing `Blobject` in C#

Implementing the dynamic dispatch model requires writing a subclass of `Ice.Blobject`. We continue using the `Compute` interface to demonstrate a `Blobject` implementation:

C#

```

public class ComputeI : Ice.Blobject {
    public bool ice_invoke(byte[] inParams, out byte[] outParams,
Ice.Current current);
    {
        ...
    }
}

```

An instance of `ComputeI` is an Ice object because `Blobject` derives from `Object`, therefore an instance can be added to an [object adapter](#) like any other servant.

For the purposes of this discussion, the implementation of `ice_invoke` handles only the `add` operation and raises `OperationNotExistE` xception for all other operations. In a real implementation, the servant must also be prepared to receive invocations of the following `Objec`

t operations:

- `string ice_id()`
Returns the Slice `type ID` of the servant's most-derived type.
- `StringSeq ice_ids()`
Returns a sequence of strings representing all of the Slice interfaces supported by the servant, including `"::Ice::Object"`.
- `bool ice_isA(string id)`
Returns `true` if the servant supports the interface denoted by the given Slice `type ID`, or `false` otherwise. This operation is invoked by the proxy function `checkedCast`.
- `void ice_ping()`
Verifies that the object denoted by the `identity` and `facet` contained in `Ice::Current` is reachable.

With that in mind, here is our simplified version of `ice_invoke`:

C#

```

    public bool ice_invoke(byte[] inParams, out byte[] outParams,
Ice.Current current);
    {
        if (current.operation.Equals("add")) {
            Ice.Communicator communicator =
current.adapter.getCommunicator();
            Ice.InputStream inStream =
Ice.Util.createInputStream(communicator, inParams);
            inStream.startEncapsulation();
            int x = inStream.readInt();
            int y = inStream.readInt();
            inStream.endEncapsulation();

            Ice.OutputStream outStream =
Ice.Util.createOutputStream(communicator);
            try {
                if (checkOverflow(x, y)) {
                    Calc.Overflow ex = new Calc.Overflow();
                    ex.x = x;
                    ex.y = y;
                    outStream.startEncapsulation();
                    outStream.writeException(ex);
                    outStream.endEncapsulation();
                    outParams = outStream.finished();
                    return false;
                } else {
                    outStream.startEncapsulation();
                    outStream.writeInt(x + y);
                    outStream.endEncapsulation();
                    outParams = outStream.finished();
                    return true;
                }
            } finally {
                outStream.destroy();
            }
        } else {
            Ice.OperationNotExistException ex =
new Ice.OperationNotExistException();
            ex.id = current.id;
            ex.facet = current.facet;
            ex.operation = current.operation;
            throw ex;
        }
    }
}

```

If an overflow is detected, the code "raises" the `Calc::Overflow` user exception by calling `writeException` on the output stream and

returning `false`, otherwise the return value is encoded and the function returns `true`.

Asynchronous Dynamic Invocation and Dispatch in C++

This page describes the asynchronous C++ mapping for the `ice_invoke` proxy function and the `Blobject` class.

On this page:

- [Calling `ice_invoke` Asynchronously in C++](#)
 - [Basic Asynchronous Mapping for `ice_invoke` in C++](#)
 - [Generic Asynchronous Callback Mapping for `ice_invoke` in C++](#)
 - [Type-Safe Asynchronous Callback Mapping for `ice_invoke` in C++](#)
- [Subclassing `BlobjectAsync` in C++](#)
- [Subclassing `BlobjectArrayAsync` in C++](#)

Calling `ice_invoke` Asynchronously in C++

The asynchronous mapping for `ice_invoke` resembles that of the [static AMI mapping](#). Multiple overloads are provided to support the use of callbacks, [request contexts](#), and [zero-copy semantics](#). The return value and the parameters `operation`, `mode`, and `inParams` have the same semantics as for the [synchronous version](#) of `ice_invoke`.

Basic Asynchronous Mapping for `ice_invoke` in C++

The basic mapping is shown below:

C++
<pre>Ice::AsyncResultPtr begin_ice_invoke(const std::string& operation, Ice::OperationMode mode, const std::vector<Ice::Byte>& inParams); Ice::AsyncResultPtr begin_ice_invoke(const std::string& operation, Ice::OperationMode mode, const std::vector<Ice::Byte>& inParams, const Ice::Context& __ctx); Ice::AsyncResultPtr begin_ice_invoke(const std::string& operation, Ice::OperationMode mode, const std::pair<const Ice::Byte*, const Ice::Byte*>& inParams); Ice::AsyncResultPtr begin_ice_invoke(const std::string& operation, Ice::OperationMode mode, const std::pair<const Ice::Byte*, const Ice::Byte*>& inParams, const Ice::Context& __ctx, const Ice::LocalObjectPtr& __cookie = 0); bool end_ice_invoke(std::vector<Ice::Byte>&, const Ice::AsyncResultPtr&);</pre>

User exceptions are handled differently than for static asynchronous invocations. Calling `end_ice_invoke` can raise system exceptions but

never raises user exceptions. Instead, the boolean return value of `end_ice_invoke` indicates whether the operation completed successfully (true) or raised a user exception (false). If the return value is true, the byte sequence contains an encapsulation of the results; otherwise, the byte sequence contains an encapsulation of the user exception.

Generic Asynchronous Callback Mapping for `ice_invoke` in C++

The generic callback API is also available:

C++
<pre>Ice::AsyncResultPtr begin_ice_invoke(const std::string& operation, Ice::OperationMode mode, const std::vector<Ice::Byte>& inParams, const Ice::CallbackPtr& __del, const Ice::LocalObjectPtr& __cookie = 0); Ice::AsyncResultPtr begin_ice_invoke(const std::string& operation, Ice::OperationMode mode, const std::vector<Ice::Byte>& inParams, const Ice::Context& __ctx, const Ice::CallbackPtr& __del, const Ice::LocalObjectPtr& __cookie = 0); Ice::AsyncResultPtr begin_ice_invoke(const std::string& operation, Ice::OperationMode mode, const std::pair<const Ice::Byte*, const Ice::Byte*>& inParams, const Ice::CallbackPtr& __del, const Ice::LocalObjectPtr& __cookie = 0); Ice::AsyncResultPtr begin_ice_invoke(const std::string& operation, Ice::OperationMode mode, const std::pair<const Ice::Byte*, const Ice::Byte*>& inParams, const Ice::Context& __ctx, const Ice::CallbackPtr& __del, const Ice::LocalObjectPtr& __cookie = 0);</pre>

Use the `Ice::newCallback` function to create callback objects, as shown in the [static AMI mapping](#).

Type-Safe Asynchronous Callback Mapping for `ice_invoke` in C++

The type-safe callback API looks as follows:

C++

```

Ice::AsyncResultPtr begin_ice_invoke(
    const std::string& operation,
    Ice::OperationMode mode,
    const std::vector<Ice::Byte>& inParams,
    const Ice::Callback_Object_ice_invokePtr& __del,
    const Ice::LocalObjectPtr& __cookie = 0);

Ice::AsyncResultPtr begin_ice_invoke(
    const std::string& operation,
    Ice::OperationMode mode,
    const std::vector<Ice::Byte>& inParams,
    const Ice::Context& __ctx,
    const Ice::Callback_Object_ice_invokePtr& __del,
    const Ice::LocalObjectPtr& __cookie = 0);

Ice::AsyncResultPtr begin_ice_invoke(
    const std::string& operation,
    Ice::OperationMode mode,
    const std::pair<const Ice::Byte*, const Ice::Byte*>& inParams,
    const Ice::Callback_Object_ice_invokePtr& __del,
    const Ice::LocalObjectPtr& __cookie = 0);

Ice::AsyncResultPtr begin_ice_invoke(
    const std::string& operation,
    Ice::OperationMode mode,
    const std::pair<const Ice::Byte*, const Ice::Byte*>& inParams,
    const Ice::Context& __ctx,
    const Ice::Callback_Object_ice_invokePtr& __del,
    const Ice::LocalObjectPtr& __cookie = 0);

```

Several overloads of `Ice::newCallback_Object_ice_invoke` allow you to create callback objects. Versions are provided to support zero-copy semantics for the byte sequence containing the operation's results, as well as a cookie value whose type is inferred and represented here by the `CT` symbol:

C++

```

template<class T> Callback_Object_ice_invokePtr
newCallback_Object_ice_invoke(const IceUtil::Handle<T>& instance,
                             void (T::*cb)(bool, const
std::vector<Ice::Byte>&),
                             void (T::*excb)(const ::Ice::Exception&),
                             void (T::*sentcb)(bool) = 0);

template<class T> Callback_Object_ice_invokePtr
newCallback_Object_ice_invoke(const IceUtil::Handle<T>& instance,
                             void (T::*cb)(bool, const std::pair<const
Byte*, const Byte*>&),
                             void (T::*excb)(const ::Ice::Exception&),
                             void (T::*sentcb)(bool) = 0);

template<class T, typename CT> Callback_Object_ice_invokePtr
newCallback_Object_ice_invoke(const IceUtil::Handle<T>& instance,
                             void (T::*cb)(bool, const
std::vector<Ice::Byte>&, const CT&),
                             void (T::*excb)(const ::Ice::Exception&,
const CT&),
                             void (T::*sentcb)(bool, const CT&) = 0);

template<class T, typename CT> Callback_Object_ice_invokePtr
newCallback_Object_ice_invoke(const IceUtil::Handle<T>& instance,
                             void (T::*cb)(bool, const std::pair<const
Byte*, const Byte*>&,
                             const CT&),
                             void (T::*excb)(const ::Ice::Exception&,
const CT&),
                             void (T::*sentcb)(bool, const CT&) = 0);

template<class T> Callback_Object_ice_invokePtr
newCallback_Object_ice_invoke(const IceUtil::Handle<T>& instance,
                             void (T::*excb)(const ::Ice::Exception&),
                             void (T::*sentcb)(bool) = 0);

template<class T, typename CT> Callback_Object_ice_invokePtr
newCallback_Object_ice_invoke(const IceUtil::Handle<T>& instance,
                             void (T::*excb)(const ::Ice::Exception&,
const CT&),
                             void (T::*sentcb)(bool, const CT&) = 0);

```

Subclassing BObjectAsync in C++

BObjectAsync is the name of the asynchronous counterpart to BObject:

C++

```

namespace Ice {
    class BlobjectAsync : virtual public Ice::Object {
    public:
        virtual void ice_invoke_async(
            const AMD_Object_ice_invokePtr& cb,
            const std::vector<Ice::Byte>& inParams,
            const Ice::Current& current) = 0;
    };
}

```

To implement asynchronous dynamic dispatch, a server must subclass `BlobjectAsync` and override `ice_invoke_async`.

The first argument to the servant's member function is a callback object of type `Ice::AMD_Object_ice_invoke`, shown here:

C++

```

namespace Ice {
    class AMD_Object_ice_invoke : ... {
    public:
        virtual void ice_response(
            bool result,
            const std::vector<Ice::Byte>& outParams) = 0;

        virtual void ice_response(
            bool result,
            const std::pair<const Ice::Byte*,
const Ice::Byte*>& outParams) = 0;

        virtual void ice_exception(const std::exception&) = 0;
        virtual void ice_exception() = 0;
    };
}

```

Upon a successful invocation, the servant must invoke one of the `ice_response` methods on the callback object, passing `true` as the first argument and encoding the encapsulated operation results into `outParams`. To report a user exception, the servant invokes `ice_response` with `false` as the first argument and the encapsulated form of the exception in `outParams`. Note that the second overloading of `ice_response` uses the array mapping (see the next section below).

`ice_exception` has several overloadings. Note however that in the dynamic dispatch model, the `ice_exception` function must not be used to report user exceptions; doing so results in the caller receiving `UnknownUserException`.

Subclassing `BlobjectArrayAsync` in C++

To implement an asynchronous `Blobject` servant that uses the array mapping, derive your implementation class from `Ice::BlobjectArrayAsync` and override the `ice_invoke_async` function:

C++

```
class BlobObjectArrayAsync : virtual public Ice::Object {
public:
    virtual void ice_invoke_async(
        const AMD_Object_ice_invokePtr& cb,
        const std::pair<const Ice::Byte*, const Ice::Byte*>& in,
        const Ice::Current& current) = 0;
};
```

As shown in the previous section, the AMD callback class provides an overloaded `ice_response` method that supports the array mapping for the encoded `out` parameter blob.

The discussion of [sequences](#) provides more information on the array mapping.

Asynchronous Dynamic Invocation and Dispatch in Java

This page describes the asynchronous Java mapping for the `ice_invoke` proxy function and the `BObject` class.

On this page:

- [Calling `ice_invoke` Asynchronously in Java](#)
 - [Basic Asynchronous Mapping for `ice_invoke` in Java](#)
 - [Generic Asynchronous Callback Mapping for `ice_invoke` in Java](#)
 - [Type-Safe Asynchronous Callback Mapping for `ice_invoke` in Java](#)
- [Subclassing `BObjectAsync` in Java](#)

Calling `ice_invoke` Asynchronously in Java

The asynchronous mapping for `ice_invoke` resembles that of the [static AMI mapping](#). Multiple overloads are provided to support the use of callbacks and [request contexts](#). The return value and the parameters `operation`, `mode`, and `inParams` have the same semantics as for the [synchronous version](#) of `ice_invoke`.

Basic Asynchronous Mapping for `ice_invoke` in Java

The basic mapping is shown below:

Java
<pre>Ice.AsyncResult begin_ice_invoke(String operation, Ice.OperationMode mode, byte[] inParams); Ice.AsyncResult begin_ice_invoke(String operation, Ice.OperationMode mode, byte[] inParams, java.util.Map<String, String> __context); boolean end_ice_invoke(Ice.ByteSeqHolder outParams, Ice.AsyncResult __result);</pre>

User exceptions are handled differently than for static asynchronous invocations. Calling `end_ice_invoke` can raise system exceptions but never raises user exceptions. Instead, the boolean return value of `end_ice_invoke` indicates whether the operation completed successfully (true) or raised a user exception (false). If the return value is true, the byte sequence contains an encapsulation of the results; otherwise, the byte sequence contains an encapsulation of the user exception.

Generic Asynchronous Callback Mapping for `ice_invoke` in Java

The generic callback API is also available:

Java

```
Ice.AsyncResult begin_ice_invoke(
    String operation,
    Ice.OperationMode mode,
    byte[] inParams,
    Ice.Callback __cb);

Ice.AsyncResult begin_ice_invoke(
    String operation,
    Ice.OperationMode mode,
    byte[] inParams,
    java.util.Map<String, String> __context,
    Ice.Callback __cb);
```

Refer to the [static AMI mapping](#) for an example of subclassing `Ice.Callback`.

Type-Safe Asynchronous Callback Mapping for `ice_invoke` in Java

The type-safe callback API looks as follows:

Java

```
Ice.AsyncResult begin_ice_invoke(
    String operation,
    Ice.OperationMode mode,
    byte[] inParams,
    Ice.Callback_Object_ice_invoke __cb);

Ice.AsyncResult begin_ice_invoke(
    String operation,
    Ice.OperationMode mode,
    byte[] inParams,
    java.util.Map<String, String> __context,
    Ice.Callback_Object_ice_invoke __cb);
```

Callers must supply a subclass of `Ice.Callback_Object_ice_invoke`:

Java

```
package Ice;

public abstract class Callback_Object_ice_invoke extends ...
{
    public abstract void response(boolean __ret, byte[] outParams);

    public abstract void exception(LocalException __ex);
}
```

The boolean argument to `response` indicates whether the operation completed successfully (true) or raised a user exception (false). If the return value is true, the byte sequence contains an encapsulation of the results; otherwise, the byte sequence contains an encapsulation of the user exception.

Subclassing `BlobjectAsync` in Java

`BlobjectAsync` is the name of the asynchronous counterpart to `Blobject`:

Java

```
package Ice;

public abstract class BlobjectAsync extends Ice.ObjectImpl {
    public abstract void ice_invoke_async(
        Ice.AMD_Object_ice_invoke cb,
        byte[] inParams,
        Ice.Current current);

    // ...
}
```

To implement asynchronous dynamic dispatch, a server must subclass `BlobjectAsync` and override `ice_invoke_async`.

As with any other asynchronous operation, the first argument to the servant's member function is always a callback object. In this case, the callback object is of type `Ice.AMD_Object_ice_invoke`, shown here:

Java

```
package Ice;

public interface AMD_Object_ice_invoke {
    void ice_response(boolean result, byte[] outParams);
    void ice_exception(java.lang.Exception ex);
}
```

Upon a successful invocation, the servant must invoke `ice_response` on the callback object, passing `true` as the first argument and encoding the encapsulated operation results into `outParams`. To report a user exception, the servant invokes `ice_response` with `false` as the first argument and the encapsulated form of the exception in `outParams`.

In the dynamic dispatch model, the `ice_exception` function must not be used to report user exceptions; doing so results in the caller receiving `UnknownUserException`.

Asynchronous Dynamic Invocation and Dispatch in C-Sharp

This page describes the asynchronous C# mapping for the `ice_invoke` proxy function and the `BlobObject` class.

On this page:

- [Calling `ice_invoke` Asynchronously in C#](#)
 - [Basic Asynchronous Mapping for `ice_invoke` in C#](#)
 - [Generic Asynchronous Callback Mapping for `ice_invoke` in C#](#)
 - [Type-Safe Asynchronous Callback Mapping for `ice_invoke` in C#](#)
- [Subclassing `BlobObjectAsync` in C#](#)

Calling `ice_invoke` Asynchronously in C#

The asynchronous mapping for `ice_invoke` resembles that of the [static AMI mapping](#). Multiple overloads are provided to support the use of callbacks and [request contexts](#). The return value and the parameters `operation`, `mode`, and `inParams` have the same semantics as for the [synchronous version](#) of `ice_invoke`.

Basic Asynchronous Mapping for `ice_invoke` in C#

The basic mapping is shown below:

C#
<pre>Ice.AsyncResult<Ice.Callback_Object_ice_invoke> begin_ice_invoke(string operation, Ice.OperationMode mode, byte[] inParams); Ice.AsyncResult<Callback_Object_ice_invoke> begin_ice_invoke(string operation, Ice.OperationMode mode, byte[] inParams, Dictionary<string, string> context__); bool end_ice_invoke(out byte[] outParams, AsyncResult r__);</pre>

User exceptions are handled differently than for static asynchronous invocations. Calling `end_ice_invoke` can raise system exceptions but never raises user exceptions. Instead, the boolean return value of `end_ice_invoke` indicates whether the operation completed successfully (true) or raised a user exception (false). If the return value is true, the byte sequence contains an encapsulation of the results; otherwise, the byte sequence contains an encapsulation of the user exception.

Generic Asynchronous Callback Mapping for `ice_invoke` in C#

The generic callback API is also available:

C#

```

Ice.AsyncResult begin_ice_invoke(
    string operation,
    Ice.OperationMode mode,
    byte[] inParams,
    Ice.AsyncCallback cb__,
    object cookie__);

Ice.AsyncResult begin_ice_invoke(
    string operation,
    Ice.OperationMode mode,
    byte[] inParams,
    Dictionary<string, string> context__,
    Ice.AsyncCallback cb__,
    object cookie__);

```

Refer to the [static AMI mapping](#) for a callback example.

Type-Safe Asynchronous Callback Mapping for ice_invoke in C#

For the type-safe callback API, you register callbacks on the `AsyncResult` object just as in the [static AMI mapping](#):

C#

```

public class MyCallback
{
    public void responseCB(bool ret, byte[] results)
    {
        if(ret)
            System.Console.Out.WriteLine("Success");
        else
            System.Console.Out.WriteLine("User exception");
    }

    public void failureCB(Ice.Exception ex)
    {
        System.Console.Err.WriteLine("Exception is: " + ex);
    }
}

...

Ice.AsyncResult<Ice.Callback_Object_ice_invoke> r =
proxy.begin_ice_invoke(...);
MyCallback cb = new MyCallback();
r.whenCompleted(cb.responseCB, cb.failureCB);

```

The caller invokes `whenCompleted` on the `AsyncResult` object and supplies delegates to handle response and failure. The response

delegate must match the signature of `Ice.Callback_Object_ice_invoke`:

```
C#
```

```
public delegate void Callback_Object_ice_invoke(bool ret__, byte[]
outParams);
```

Subclassing `BlobjectAsync` in C#

`BlobjectAsync` is the name of the asynchronous counterpart to `Blobject`:

```
C#
```

```
public abstract class BlobjectAsync : Ice.ObjectImpl
{
    public abstract void ice_invoke_async(
        AMD_Object_ice_invoke cb,
        byte[] inParams,
        Current current);
}
```

To implement asynchronous dynamic dispatch, a server must subclass `BlobjectAsync` and override `ice_invoke_async`.

The first argument to the servant's member function is a callback object of type `Ice.AMD_Object_ice_invoke`, shown here:

```
C#
```

```
namespace Ice
{
    public interface AMD_Object_ice_invoke
    {
        void ice_response(bool ok, byte[] outParams);
        void ice_exception(System.Exception ex);
    }
}
```

Upon a successful invocation, the servant must invoke `ice_response` on the callback object, passing `true` as the first argument and encoding the encapsulated operation results into `outParams`. To report a user exception, the servant invokes `ice_response` with `false` as the first argument and the encapsulated form of the exception in `outParams`.

In the dynamic dispatch model, the `ice_exception` function must not be used to report user exceptions; doing so results in the caller receiving `UnknownUserException`.

- [Request Contexts](#)
- [Dynamic Invocation and Dispatch Overview](#)

Facets

Facets provide a general-purpose mechanism for non-intrusively extending the type system of an application, by loosely coupling new type instances to existing ones. This shifts the type selection process from compile to run time and implements a form of late binding. This is particularly useful for versioning an application.

On this page:

- [Ice Objects as Collections of Facets](#)
- [Server-Side Facet Operations](#)
- [Client-Side Facet Operations](#)
- [Facet Exception Semantics](#)

Ice Objects as Collections of Facets

Up to this point, we have presented an Ice object as a single conceptual entity, that is, as an object with a single most-derived interface and a single *identity*, with the object being implemented by a single servant. However, an Ice object is more correctly viewed as a collection of one or more sub-objects known as facets, as shown below:

An Ice object with five facets sharing a single object identity.

The diagram above shows a single Ice object with five facets. Each facet has a name, known as the *facet name*. Within a single Ice object, all facets must have unique names. Facet names are arbitrary strings that are assigned by the server that implements an Ice object. A facet with an empty facet name is legal and known as the *default facet*. Unless you arrange otherwise, an Ice object has a single default facet; by default, operations that involve Ice objects and servants operate on the default facet.

Note that all the facets of an Ice object share the same single identity, but have different facet names. Recall the definition of `Ice::Current` once more:

Slice

```

module Ice {
  local dictionary<string, string> Context;

  enum OperationMode { Normal, \Nonmutating, \Idempotent };

  local struct Current {
    ObjectAdapter  adapter;
    Identity       id;
    string         facet;
    string         operation;
    OperationMode mode;
    Context        ctx;
    int            requestId;
    EncodingVersion encoding;
  };
};

```

By definition, if two facets have the same `id` field, they are part of the same Ice object. Also by definition, if two facets have the same `id` field, their `facet` fields have different values.

Even though Ice objects usually consist of just the default facet, it is entirely legal for an Ice object to consist of facets that all have non-empty names (that is, it is legal for an Ice object not to have a default facet).

Each facet has a single most-derived interface. There is no need for the interface types of the facets of an Ice object to be unique. It is legal for two facets of an Ice object to implement the same most-derived interface.

Each facet is implemented by a servant. All the usual implementation techniques for servants are available to implement facets — for example, you can implement a facet using a servant locator. Typically, each facet of an Ice object has a separate servant, although, if two facets of an Ice object have the same type, they can also be implemented by a single servant (for example, using a [default servant](#)).

Server-Side Facet Operations

On the server side, the [object adapter](#) offers a number of operations to support facets:

Slice

```

namespace Ice {
    dictionary<string, Object> FacetMap;

    local interface ObjectAdapter {
        Object* addFacet(Object servant, Identity id, string facet);
        Object* addFacetWithUUID(Object servant, string facet);
        Object removeFacet(Identity id, string facet);
        Object findFacet(Identity id, string facet);

        FacetMap findAllFacets(Identity id);
        FacetMap removeAllFacets(Identity id);
        // ...
    };
};

```

These operations have the same semantics as the corresponding "normal" operations for [servant activation and deactivation](#) (`add`, `addWithUUID`, `remove`, and `find`), but also accept a facet name. The corresponding "normal" operations are simply convenience operations that supply an empty facet name. For example, `remove(id)` is equivalent to `removeFacet(id, "")`, that is, `remove(id)` operates on the default facet.

`findAllFacets` returns a dictionary of `<facet-name, servant>` pairs that contains all the facets for the given identity.

`removeAllFacets` removes all facets for a given identity from the active servant map, that is, it removes the corresponding Ice object entirely. The operation returns a dictionary of `<facet-name, servant>` pairs that contains all the removed facets.

These operations are sufficient for the server to create Ice objects with any number of facets. For example, assume that we have the following Slice definitions:

Slice

```

module Filesystem {
    // ...

    interface File extends Node {
        idempotent Lines read();
        idempotent void write(Lines text) throws GenericError;
    };
};

module FilesystemExtensions {
    // ...

    class DateTime extends TimeOfDay {
        // ...
    };

    struct Times {
        DateTime createdDate;
        DateTime accessedDate;
        DateTime modifiedDate;
    };

    interface Stat {
        idempotent Times getTimes();
    };
};

```

Here, we have a `File` interface that provides operations to read and write a file, and a `Stat` interface that provides access to the file creation, access, and modification time. (Note that the `Stat` interface is defined in a different module and could also be defined in a different source file.) If the server wants to create an Ice object that contains a `File` instance as the default facet and a `Stat` instance that provides access to the time details of the file, it could do so as follows:

C++

```

// Create a File instance.
//
Filesystem::FilePtr file = new FileI;

// Create a Stat instance.
//
FilesystemExctensions::DateTimePtr dt
= new FilesystemExtensions::DateTime;
FilesystemExtensions::Times times;
times.createdDate = dt;
times.accessedDate = dt;
times.modifiedDate = dt;
FilesystemExtensions::StatPtr stat = new StatI(times);

// Register the File instance as the default facet.
//
Filesystem::FilePrx filePrx = myAdapter->addWithUUID(file);

// Register the Stat instance as a facet with name "Stat".
//
myAdapter->addFacet(stat, filePrx->ice_getIdentity(), "Stat");

```

The first few lines simply create and initialize a `FileI` and `StatI` instance. (The details of this do not matter here.) All the action is in the last two statements:

C++

```

Filesystem::FilePrx filePrx = myAdapter->addWithUUID(file);
myAdapter->addFacet(stat, filePrx->ice_getIdentity(), "Stat");

```

This registers the `FileI` instance with the object adapter as usual. (In this case, we let the Ice run time generate a UUID as the object identity.) Because we are calling `addWithUUID` (as opposed to `addFacetWithUUID`), the instance becomes the default facet.

The second line adds a facet to the instance with the facet name `Stat`. Note that we call `ice_getIdentity` on the `File` proxy to pass an object identity to `addFacet`. This guarantees that the two facets share the same object identity.

Note that, in general, it is a good idea to use `ice_getIdentity` to obtain the identity of an existing facet when adding a new facet. That way, it is guaranteed that the facets share the same identity. (If you accidentally pass a different identity to `addFacet`, you will not add a facet to an existing Ice object, but instead register a new Ice object; using `ice_getIdentity` makes this mistake impossible.)

Client-Side Facet Operations

On the client side, which facet a request is addressed to is implicit in the proxy that is used to send the request. For an application that does not use facets, the facet name is always empty so, by default, requests are sent to the default facet.

The client can use a `checkedCast` to obtain a proxy for a particular facet. For example, assume that the client obtains a proxy to a `File` instance as shown [above](#). The client can cast between the `File` facet and the `Stat` facet (and back) as follows:

C++

```

// Get a File proxy.
//
Filesystem::FilePrx file = ...;

// Get the Stat facet.
//
FilesystemExtensions::StatPrx stat =
    FilesystemExtensions::StatPrx::checkedCast(file, "Stat");

// Go back from the Stat facet to the File facet.
//
Filesystem::FilePrx file2 = Filesystem::FilePrx::checkedCast(stat, "");

assert(file2 == file); // The two proxies are identical.

```

This example illustrates that, given any facet of an Ice object, the client can navigate to any other facet by using a `checkedCast` with the facet name.

If an Ice object does not provide the specified facet, `checkedCast` returns null:

C++

```

FilesystemExtensions::StatPrx stat =
    FilesystemExtensions::StatPrx::checkedCast(file, "Stat");

if (!stat) {
    // No Stat facet on this object, handle error...
} else {
    FilesystemExtensions::Times times = stat->getTimes();

    // Use times struct...
}

```

Note that `checkedCast` also returns a null proxy if a facet exists, but the cast is to the wrong type. For example:

C++

```

// Get a File proxy.
//
Filesystem::FilePrx file = ...;

// Cast to the wrong type.
//
SomeTypePrx prx = SomeTypePrx::checkedCast(file, "Stat");

assert(!prx); // checkedCast returns a null proxy.

```

If you want to distinguish between non-existence of a facet and the facet being of the incorrect type, you can first obtain the facet as type `Object` and then down-cast to the correct type:

```

C++

// Get a File proxy.
//
Filesystem::FilePrx file = ...;

// Get the facet as type Object.
//
Ice::ObjectPrx obj = Ice::ObjectPrx::checkedCast(file, "Stat");
if (!obj) {
    // No facet with name "Stat" on this Ice object.
} else {
    FilesystemExtensions::StatPrx stat =
        FilesystemExtensions::StatPrx::checkedCast(file);
    if (!stat) {
        // There is a facet with name "Stat", but it is not
        // of type FilesystemExtensions::Stat.
    } else {
        // Use stat...
    }
}

```

This last example also illustrates that

```

C++

StatPrx::checkedCast(prx, "")

```

is *not* the same as

```

C++

StatPrx::checkedCast(prx)

```

The first version explicitly requests a cast to the default facet. This means that the Ice run time first looks for a facet with the empty name and then attempts to down-cast that facet (if it exists) to the type `Stat`.

The second version requests a down-cast that *preserves* whatever facet is currently effective in the proxy. For example, if the `prx` proxy currently holds the facet name "Joe", then (if `prx` points at an object of type `Stat`) the run time returns a proxy of type `StatPrx` that also stores the facet name "Joe".

It follows that, to navigate between facets, you must always use the two-argument version of `checkedCast`, whereas, to down-cast to another type while preserving the facet name, you must always use the single-argument version of `checkedCast`.

You can always check what the current facet of a proxy is by calling `ice_getFacet`:

C++

```
Ice::ObjectPrx obj = ...;

cout << obj->ice_getFacet() << endl; // Print facet name
```

This prints the facet name. (For the default facet, `ice_getFacet` returns the empty string.)

Facet Exception Semantics

The common exceptions `ObjectNotExistException` and `FacetNotExistException` have the following semantics:

- `ObjectNotExistException`
This exception is raised only if no facets exist at all for a given object identity.
- `FacetNotExistException`
This exception is raised only if at least one facet exists for a given object identity, but not the specific facet that is the target of an operation invocation.

If you are using [servant locators](#) or [default servants](#), you must take care to preserve these semantics. In particular, if you return null from a servant locator's `locate` operation, this appears to the client as an `ObjectNotExistException`. If the object identity for a request is known (that is, there is at least one facet with that identity), but no facet with the specified name exists, you must explicitly throw a `FacetNotExistException` from `locate` instead of simply returning null.

Versioning

Once you have developed and deployed a distributed application, and once the application has been in use for some time, it is likely that you will want to make some changes to the application. For example, you may want to add new functionality to a later version of the application, or you may want to change some existing aspect of the application. Of course, ideally, such changes are accomplished without breaking already deployed software, that is, the changes should be backward compatible. Evolving an application in this way is generally known as *versioning*.

Topics

- [Versioning through Incremental Updates](#)
- [Versioning with Facets](#)

Versioning through Incremental Updates

Ice allows you to update your applications and Slice definitions in a backwards-compatible manner - in such a way that the existing applications (using the existing Slice definitions) and the updated applications (using the updated Slice definitions) can easily and safely communicate with each other.

You can safely update your Slice using the techniques described on this page:

- [Adding Operations](#)
- [Optional Operation Parameters and Class Data Members](#)

Adding Operations

Suppose that we have deployed our [file system](#) application and want to add extra functionality to a new version. Specifically, let us assume that the original version (version 1) only provides the basic functionality to use files, but does not provide extra information, such as the modification date or the file size. The question is then, how can we upgrade the existing application with this new functionality? Here is a small excerpt of the original (version 1) Slice definitions once more:

```

Slice

```
// Version 1

module Filesystem {
 // ...

 interface File extends Node {
 idempotent Lines read();
 idempotent void write(Lines text) throws GenericError;
 };
};
```

```

Your first attempt at upgrading the application might look as follows:

Slice

```
// Version 2

module Filesystem {
    // ...

    class DateTime extends TimeOfDay { // New in version 2
        // ...
    };

    class Times { // New in version 2
        DateTime createdDate;
        DateTime accessedDate;
    };

    interface File extends Node {
        idempotent Lines read();
        idempotent void write(Lines text) throws GenericError;

        idempotent Times getTimes(); // New in version 2
    };
};
```

Note that the version 2 definition does not change anything that was present in version 1; instead, it only adds two new types and adds an operation to the `File` interface. Version 1 clients can continue to work with both version 1 and version 2 `File` objects because version 1 clients do not know about the `getTimes` operation and therefore will not call it; version 2 clients, on the other hand, can take advantage of the new functionality. The reason this works is that the Ice protocol invokes an operation by sending the operation name as a string on the wire (rather than using an ordinal number or hash value to identify the operation). Ice guarantees that any future version of the protocol will retain this behavior, so it is safe to add a new operation to an existing interface without recompiling all clients.

However, this approach contains a pitfall: the tacit assumption built into this approach is that no version 2 client will ever use a version 1 object. If the assumption is violated (that is, a version 2 client uses a version 1 object), the version 2 client will receive an `OperationNotExistException` when it invokes the new `getTimes` operation because that operation is supported only by version 2 objects.

Whether you can make this assumption depends on your application. In some cases, it may be possible to ensure that version 2 clients will never access a version 1 object, for example, by simultaneously upgrading all servers from version 1 to version 2, or by taking advantage of application-specific constraints that ensure that version 2 clients only contact version 2 objects. However, for some applications, doing this is impractical.

Note that you could write version 2 clients to catch and react to an `OperationNotExistException` when they invoke the `getTimes` operation: if the operation succeeds, the client is dealing with a version 2 object, and if the operation raises `OperationNotExistsException`, the client is dealing with a version 1 object.

Optional Operation Parameters and Class Data Members

You can safely add one or more optional parameters to an operation without breaking clients or servers that don't know anything of these new parameters.

For example, we could add an optional parameter to the `read` operation in our `Filesystem File` interface optionally limit the number of lines returned:

Slice

```
interface File extends Node {
    idempotent Lines read(optional (1) int max);
    ...
};
```

A client using the updated Slice definition can set this maximum value, and if its request is received by a new server, the server will receive this max value and should behave accordingly. An old server wouldn't receive this optional parameter, and would continue to behave as before.

You can likewise add optional data members to an existing class without breaking existing applications that use this class. Let's go back to the `FileSystem` version 2 presented above - say we need to add a third data member to `Times`, while preserving existing applications that use the existing two-data-members `Times`. The solution is to add an optional data member, for example:

Slice

```
class Times {
    DateTime createdDate;
    DateTime accessedDate;
    optional (1) DateTime modifiedDate;
};
```

Older applications that know nothing about `modifiedDate` will continue to receive, create, send (etc.) `Times` instances as before (without a `modifiedDate` data member), while newer applications can set and retrieve the optional `modifiedDate` member.

Versioning with Facets

In the most general sense, facets provide a mechanism for implementing multiple interfaces for a single object. The key point is that, to add a new interface to an object, none of the existing definitions have to be touched, so no compatibility issues can arise. More importantly, the decision as to which facet to use is made at run time instead of at compile time.

Used judiciously, facets can handle versioning requirements when the incremental updates approach described earlier is no longer sufficient.

On this page:

- [Facet Selection](#)
- [Behavioral Versioning](#)
- [Facets Design Considerations](#)

Facet Selection

Given that we have decided to extend an application with facets, we have to deal with the question of how clients select the correct facet. The answer typically involves an explicit selection of a facet sometime during client start-up. For example, in our file system application, clients always begin their interactions with the file system by creating a proxy to the root directory. Let us assume that our versioning requirements have led to version 1 and version 2 definitions of directories as follows:

Slice
<pre> module Filesystem { // Original version // ... interface Directory extends Node { idempotent NodeSeq list(); // ... }; }; module FilesystemV2 { // ... enum NodeType { Directory, File }; class NodeDetails { NodeType type; string name; DateTime createdTime; DateTime accessedTime; DateTime modifiedTime; // ... }; interface Directory extends Filesystem::Node { idempotent NodeDetailsSeq list(); // ... }; }; </pre>

In this case, the semantics of the `list` operation have changed in version 2. A version 1 client uses the following code to obtain a proxy to

the root directory:

```

C++
// Create a proxy for the root directory
//
Ice::ObjectPrx base
= communicator()->stringToProxy("RootDir:default -p 10000");
if (!base)
    throw "Could not create proxy";

// Down-cast the proxy to a Directory proxy
//
Filesystem::DirectoryPrx rootDir
= Filesystem::DirectoryPrx::checkedCast(base);
if (!rootDir)
    throw "Invalid proxy";

```

For a version 2 client, the bootstrap code is almost identical — instead of down-casting to `Filesystem::Directory`, the client selects the "V2" facet during the down-cast to the type `FilesystemV2::Directory`:

```

C++
// Create a proxy for the root directory
//
Ice::ObjectPrx base
= communicator()->stringToProxy("RootDir:default -p 10000");
if (!base)
    throw "Could not create proxy";

// Down-cast the proxy to a V2 Directory proxy
//
FilesystemV2::DirectoryPrx rootDir
= FilesystemV2::DirectoryPrx::checkedCast(base, "V2");
if (!rootDir)
    throw "Invalid proxy";

```

Of course, we can also create a client that can deal with both version 1 and version 2 directories: if the down-cast to version 2 fails, the client is dealing with a version 1 server and can adjust its behavior accordingly.

Behavioral Versioning

On occasion, versioning requires changes in behavior that are not manifest in the interface of the system. For example, we may have an operation that performs some work, such as:

Slice

```
interface Foo {
    void doSomething();
};
```

The same operation on the same interface exists in both versions, but the *behavior* of `doSomething` in version 2 differs from that in version 1. The question is, how do we best deal with such behavioral changes?

Of course, one option is to simply create a version 2 facet and to carry that facet alongside the original version 1 facet. For example:

Slice

```
module V2 {

    interface Foo { // V2 facet
        void doSomething();
    };
};
```

This works fine, as far as it goes: a version 2 client asks for the "V2" facet and then calls `doSomething` to get the desired effect. Depending on your circumstances, this approach may be entirely reasonable. However, if there are such behavioral changes on several interfaces, the approach leads to a more complex type system because it duplicates each interface with such a change.

A better alternative can be to create two facets of the same type, but have the implementation of those facets differ. With this approach, both facets are of type `::Foo::doSomething`. However, the implementation of `doSomething` checks which facet was used to invoke the request and adjusts its behavior accordingly:

C++

```
void
FooI::doSomething(const Ice::Current& c)
{
    if (c.facet == "V2") {
        // Provide version 2 behavior...
    } else {
        // Provide version 1 behavior...
    }
}
```

This approach avoids creating separate types for the different behaviors, but has the disadvantage that version 1 and version 2 objects are no longer distinguishable to the type system. This can matter if, for example, an operation accepts a `Foo` proxy as a parameter. Let us assume that we also have an interface `FooProcessor` as follows:

Slice

```
interface FooProcessor {
    void processFoo(Foo* w);
};
```

If `FooProcessor` also exists as a version 1 and version 2 facet, we must deal with the question of what should happen if a version 1 `Foo` proxy is passed to a version 2 `processFoo` operation because, at the type level, there is nothing to prevent this from happening.

You have two options for dealing with this situation:

- Define working semantics for mixed-version invocations. In this case, you must come up with sensible system behavior for all possible combinations of versions.
- If some of the combinations are disallowed (such as passing a version 1 `Foo` proxy to a version 2 `processFoo` operation), you can detect the version mismatch in the server by looking at the `Current::facet` member and throwing an exception to indicate a version mismatch. Simultaneously, write your clients to ensure they only pass a permissible version to `processFoo`. Clients can ensure this by checking the facet name of a proxy before passing it to `processFoo` and, if there is a version mismatch, changing either the `Foo` proxy or the `FooProcessor` proxy to a matching facet:

```

C++

```

FooPrx foo = ...; // Get a Foo...
FooProcessorPrx fooP = ...; // Get a FooProcessor...

string fooFacet = foo->ice_getFacet();
string fooPFacet = fooP->ice_getFacet();
if (fooFacet != fooPFacet) {
 if (fooPFacet == "V2") {
 error("Cannot pass a V1 Foo to a V2 FooProcessor");
 } else {
 // Upgrade FooProcessor from V1 to V2
 fooP = FooProcessorPrx::checkedCast(fooP, "V2");
 if (!fooP) {
 error("FooProcessor does not have a V2 facet");
 } else {
 fooP->processFoo(foo);
 }
 }
}
}

```

```

Facets Design Considerations

Facets allow you to add versioning to a system, but they are merely a mechanism, not a solution. You still have to make a decision as to how to version something. For example, eventually you may want to deprecate a previous version's behavior; at that point, you must make a decision how to handle requests for the deprecated version. For behavioral changes, you have to decide whether to use separate interfaces or use facets with the same interface. And, of course, you must have compatibility rules to determine what should happen if, for example, a version 1 object is passed to an operation that implements version 2 behavior. In other words, facets cannot do your thinking for you and are no panacea for the versioning problem.

The biggest advantage of facets is also the biggest drawback: facets delay the decision about the types that are used and their behavior until run time. While this provides a lot of flexibility, it is significantly less type-safe than having explicit types that can be statically checked at compile time: if you have a problem relating to incorrect facet selection, the problem will be visible only at run time and, moreover, will be visible only if you actually execute the code that contains the problem, and execute it with just the right data.

Another danger of facets is the opportunity for abuse. As an extreme example, here is an interface that provides an arbitrary collection of objects of arbitrary type:

```

Slice

```

interface Collection {};

```

```

Even though this interface is empty, it can provide access to an unlimited number of objects of arbitrary type in the form of facets. While this example is extreme, it illustrates the design tension that is created by facets: you must decide, for a given versioning problem, how and at what point of the type hierarchy to split off a facet that deals with the changed functionality. The temptation may be to "simply add another facet" and be done with it. However, if you do that, your objects are in danger of being nothing more than loose conglomerates of facets without rhyme or reason, and with little visibility of their relationships in the type system.

In object modeling terms, the relationship among facets is weaker than an *is-a* relationship (because facets are often not type-compatible among each other). On the other hand, the relationship among facets is stronger than a *has-a* relationship (because all facets of an Ice object share the same [object identity](#)).

It is probably best to treat the relationship of a facet to its Ice object with the same respect as an inheritance relationship: if you were omniscient and could have designed your system for all current and future versions simultaneously, many of the operations that end up on separate facets would probably have been in the same interface instead. In other words, adding a facet to an Ice object most often implies that the facet has an *is-partly-a* relationship with its Ice object. In particular, if you think about the life cycle of an Ice object and find that, when an Ice object is deleted, all its facets must be deleted, this is a strong indication of a correct design. On the other hand, if you find that, at various times during an Ice object's life cycle, it has a varying number of facets of varying types, that is a good indication that you are using facets incorrectly.

Ultimately, the decision comes down to deciding whether the trade-off of static type safety versus dynamic type safety is worth the convenience and backward compatibility. The answer depends strongly on the design of your system and individual requirements, so we can only give broad advice here. Finally, there will be a point where no amount of facet trickery will get past the point when "yet one more version will be the straw that breaks the camel's back." At that point, it is time to stop supporting older versions and to redesign the system.

The admin Object

On this page:

- [Overview of the admin Object](#)
- [Facets of the admin Object](#)

Overview of the admin Object

When the Administrative Facility is enabled, you can configure Ice to host an administrative object in the `Ice.Admin` object adapter, or you can programmatically host this object in your own object adapter.

In this manual, we refer to the administrative object as the *admin object*.

You can retrieve a proxy to the admin object associated with your communicator, if any, by calling `getAdmin` on this communicator, for example:

C++

```
Ice::ObjectPrx adminProxy = myCommunicator->getAdmin();
```

Facets of the admin Object

An Ice object is actually a collection of sub-objects known as [facets](#) whose types are not necessarily related. Although facets are typically used for extending and versioning types, they also allow a group of interfaces with a common purpose to be consolidated into a single Ice object with an established interface for navigation. These qualities make facets an excellent match for the requirements of the administrative facility.

Each facet of the `admin` object represents a distinct administrative capability. The object does not have a default facet (that is, a facet with an empty name). However, the Ice run time implements several built-in facets that it adds to the `admin` object:

- the `Process` facet
- the `Properties` facet
- the `Logger` facet
- the `Metrics` facet

An application can control which facets are installed with a configuration property. An application can also install its own facets if necessary. Administrative facets are not required to inherit from a common Slice interface.

- [Custom Administrative Facets](#)
- [Ice.Admin.*](#)

Creating the admin Object

The administrative facility is disabled by default. To enable it, you must set the property `Ice.Admin.Enabled` to a numeric value greater than 0, or leave `Ice.Admin.Enabled` unset and specify endpoints for the `Ice.Admin` administrative object adapter using the property `Ice.Admin.Endpoints`. When `Ice.Admin.Enabled` is set to 0 or a negative value, the administrative facility is disabled, and `Ice.Admin.Endpoints` is ignored.

When the administrative facility is enabled, and

- The `Ice.Admin.Endpoints` property specifies endpoints for the `Ice.Admin` object adapter, and
- The `Ice.Admin.DelayCreation` property is not set, or is set to 0 or a negative value

Ice creates automatically the admin object during communicator initialization, and hosts all its [enabled facets](#) in the built-in `Ice.Admin` object adapter.

This admin object and its facets are created at the end of communicator initialization, after the initialization of all plugins. Ice gives this object the identity `instance-name/admin`, where `instance-name` is the value of the the `Ice.Admin.InstanceName` property. If `Ice.Admin.InstanceName` is not set or empty, Ice generates a UUID for `instance-name`.

If Ice does not create the admin object during communicator initialization as described above, you need to create the admin object after communicator initialization by calling `getAdmin` or `createAdmin` on the communicator:

Slice

```

local interface Communicator {
    // ...
    Object* getAdmin();
    Object* createAdmin(ObjectAdapter adminAdapter, Identity adminId);
    // ...
};

```

`getAdmin` is typically used to create the admin object when both `Ice.Admin.Endpoints` and `Ice.Admin.DelayCreation` are set. The resulting admin object's [enabled facets](#) are hosted in the `Ice.Admin` object adapter. The identity of this admin object is `instance-name/admin`, where `instance-name` corresponds to the value of `Ice.Admin.InstanceName` or a UUID, as described above.

`createAdmin` is used to create the admin object and host all its [enabled facets](#) in the object adapter of your choice (the `adminAdapter` parameter), with the identity of your choice (the `adminId` parameter). If `adminAdapter` is null and `Ice.Admin.Endpoints` specifies endpoints for the `Ice.Admin` object adapter, `createAdmin` creates and activates the `Ice.Admin` object adapter and hosts all the admin object's facets in that adapter. Note that only one admin object can be created for a given communicator. `createAdmin` will fail and raise an exception if there is already an admin object.

The administrative facility introduces additional [security considerations](#), therefore the endpoints for the object adapter where the admin object's facets are hosted must be chosen with caution.

- [Ice.Admin.*](#)
- [IceGrid and the Administrative Facility](#)
- [Security Considerations for Administrative Facets](#)
- [Using the admin Object](#)

Using the admin Object

A program can obtain a proxy for its admin object by calling the `getAdmin` operation on a communicator:

Slice

```

module Ice {
  local interface Communicator {
    // ...
    Object* getAdmin();
  };
};

```

This operation returns a null proxy if the administrative facility is disabled or the application has not created the admin object with `createAdmin`. The proxy returned by `getAdmin` cannot be used for invoking operations because it refers to the default facet and, as we mentioned previously, the admin object does not support a default facet. A program must first obtain a new version of the proxy that is configured with the name of a particular administrative facet before invoking operations on it. Although it cannot be used for invocations, the original proxy is still useful because it contains the endpoints of the [object adapter where the admin object is hosted](#), and therefore the program may elect to export that proxy to a remote client.

To administer a program remotely, somehow you must obtain a proxy for the program's admin object. There are several ways for the administrative client to accomplish this:

- Construct the proxy itself, assuming that it knows the admin object's identity, facets, and endpoints. The format of the [stringified proxy](#) is as follows:
adminId -f admin-facet.admin-endpoints
 The identity, represented here by *adminId*, is *instance-name/admin* for admin objects created during communicator initialization or with `getAdmin`, where *instance-name* is the value of the `Ice.Admin.InstanceName` property or a UUID if that property is not defined. (Clearly, the use of a UUID makes the proxy much more difficult for a client to construct on its own.) The name of the administrative facet is supplied as the value of the `-f` option, and the endpoints of the object adapter that hosts the admin object appear last in the proxy.
- Invoke an application-specific interface for retrieving the admin object's proxy.
- Use the `getServerAdmin` operation on the `IceGrid::Admin` interface, if the remote program was activated by IceGrid (see [IceGrid Server Activation](#)).

Having obtained the proxy, the administrative client must select a facet before invoking any operations. For example, the code below shows how to obtain the configuration properties of the remote program:

C++

```

// C++
Ice::ObjectPrx adminObj = ...;
Ice::PropertiesAdminPrx propAdmin =
Ice::PropertiesAdminPrx::checkedCast(adminObj, "Properties");
Ice::PropertyDict props = propAdmin->getPropertiesForPrefix("");

```

Here we used an overloaded version of `checkedCast` to supply the facet name of interest (`Properties`). We could have selected the facet using the [proxy method](#) `ice_facet` instead, as shown below:

C++

```
// C++
Ice::ObjectPrx adminObj = ...;
Ice::PropertiesAdminPrx propAdmin =
Ice::PropertiesAdminPrx::checkedCast(
    adminObj->ice_facet("Properties"));
Ice::PropertyDict props = propAdmin->getPropertiesForPrefix("");
```

This code is functionally equivalent to the first example.

A remote client must also know (or be able to determine) which facets are available in the target server. Typically this information is statically configured in the client, since the client must also know the interface types of any facets that it uses. If an invocation on a facet raises `FacetNotExistException`, the client may have used an incorrect facet name, or the server may have disabled the facet in question.

The Process Facet

An activation service, such as an `IceGrid` node, needs a reliable way to gracefully deactivate a server. One approach is to use a platform-specific mechanism, such as POSIX signals. This works well on POSIX platforms when the server is prepared to [intercept signals](#) and react appropriately. On Windows platforms, it works less reliably for C++ servers, and not at all for Java servers. For these reasons, the `Process` facet provides an alternative that is both portable and reliable.

Be aware of the [security considerations](#) associated with enabling the `Process` facet.

On this page:

- [The Process Interface](#)
- [Obtaining the Local Process Facet](#)
- [Application Requirements for the Process Facet](#)
- [Replacing the Process Facet](#)
- [Integrating the Process Facet with an Activation Service](#)

The Process Interface

The Slice interface `Ice::Process` allows an activation service to request a graceful shutdown of the program:

Slice

```

module Ice {
  interface Process {
    void shutdown();
    void writeMessage(string message, int fd);
  };
};

```

When `shutdown` is invoked, the object implementing this interface is expected to initiate the termination of its process. The activation service may expect the program to terminate within a certain period of time, after which it may terminate the program abruptly.

The `writeMessage` operation allows remote clients to print a message to the program's standard output (`fd == 1`) or standard error (`fd == 2`) channels.

Obtaining the Local Process Facet

We [already showed](#) how to obtain a proxy for a remote administrative facet, but suppose you want to interact with the facet in your local address space. The code below shows the necessary steps:

C++

```

Ice::ObjectPtr obj = communicator->findAdminFacet("Process");
if(obj) { // May be nil if the facet is not enabled
    Ice::ProcessPtr facet = Ice::ProcessPtr::dynamicCast(obj);
    ...
}

```

As shown here, the facet is registered with the name `Process` and a regular language cast is used to downcast the base object type to the

Process interface.

Application Requirements for the Process Facet

The default implementation of the `Process` facet requires cooperation from an application in order to successfully terminate a process. Specifically, the facet invokes `shutdown` on its `communicator` and assumes that the application uses this event as a signal to commence its termination procedure. For example, an application typically uses a thread (often the main thread) to call the communicator operation `waitForShutdown`, which blocks the calling thread until the communicator is shut down or destroyed. After `waitForShutdown` returns, the calling thread can initiate a graceful shutdown of its process.

Replacing the Process Facet

You can replace the default `Process` facet if your application requires a different scheme for gracefully shutting itself down. To define your own facet, create a servant that implements the `Ice::Process` interface. As an example, the servant definition shown below duplicates the functionality of the default `Process` facet:

```
C++
```

```
class ProcessI : public Ice::Process {
public:
    ProcessI(const Ice::CommunicatorPtr& communicator) :
        _communicator(communicator)
    {}

    void shutdown(const Ice::Current&)
    {
        _communicator->shutdown();
    }

    void writeMessage(const string& msg, Ice::Int fd,
const Ice::Current&)
    {
        if(fd == 1) cout << msg << endl;
        else if(fd == 2) cerr << msg << endl;
    }

private:
    const Ice::CommunicatorPtr _communicator;
};
```

As you can see, the default implementation of `shutdown` simply shuts down the communicator, which initiates an orderly termination of the Ice run time's server-side components and prevents object adapters from dispatching any new requests. You can add your own application-specific behavior to the `shutdown` method to ensure that your program terminates in a timely manner.

A servant **must not** invoke `destroy` on its communicator while executing a dispatched operation.

To avoid the risk of a race condition, the recommended strategy for replacing the `Process` facet is to delay creation of the administrative facets until after communicator initialization, so that your application has a chance to replace the facet:

```
# Delay admin object creation for admin object hosted in the Ice.Admin
object adapter
Ice.Admin.DelayCreation=1
```

With `Ice.Admin.DelayCreation` enabled, the application can safely remove the default `Process` facet and install its own:

C++

```
Ice::CommunicatorPtr communicator = ...
communicator->removeAdminFacet("Process");
Ice::ProcessPtr myProcessFacet = new MyProcessFacet(...);
communicator->addAdminFacet(myProcessFacet, "Process");
```

If you host the admin object in the `Ice.Admin` object adapter, the final step is to create the admin object by calling `getAdmin` on the communicator:

C++

```
communicator->getAdmin();
```

And if you host the admin object in your own object adapter, the final set is to create the admin object with `createAdmin`:

C++

```
communicator->createAdmin(myAdapter, myAdminId);
```

Integrating the Process Facet with an Activation Service

If the `Ice.Admin.ServerId` and `Ice.Default.Locator` properties are defined, the Ice run time performs the following steps after creating the admin object:

- Obtains proxies for the `Process` facet and the default locator
- Invokes `getRegistry` on the proxy to obtain a proxy for the locator registry
- Invokes `setServerProcessProxy` on the locator registry and supplies the value of `Ice.Admin.ServerId` along with a proxy for the `Process` facet

The identifier specified by `Ice.Admin.ServerId` must uniquely identify the process within the locator registry.

In the case of `IceGrid`, `IceGrid` defines the `Ice.Admin.ServerId` and `Ice.Default.Locator` properties for each deployed server. `IceGrid` also supplies a value for `Ice.Admin.Endpoints` if neither this property nor `Ice.Admin.Enabled` are defined by the server.

The Properties Facet

On this page:

- [The PropertiesAdmin Interface](#)
- [Obtaining the Local Properties Facet](#)
- [Property Update Notifications](#)
 - [Implementing a Property Update Callback in C++](#)
 - [Implementing a Property Update Callback in Java](#)
 - [Implementing a Property Update Callback in C#](#)

The PropertiesAdmin Interface

An administrator may find it useful to be able to view or modify the configuration properties of a remote Ice application. For example, the [Ice Grid](#) administrative tools allow you to query and update the properties of active servers. The `Properties` facet supplies this functionality.

The `Ice::PropertiesAdmin` interface provides access to the communicator's configuration properties:

Slice

```

module Ice {
  interface PropertiesAdmin {
    string getProperty(string key);
    PropertyDict getPropertiesForPrefix(string prefix);
    void setProperties(PropertyDict newProperties);
  };
};

```

The `getProperty` operation retrieves the value of a single property, and the `getPropertiesForPrefix` operation returns a dictionary of properties whose keys match the given prefix. These operations have the same semantics as those in the [Ice::Properties](#) interface.

The `setProperties` operation merges the entries in `newProperties` with the communicator's existing properties. If an entry in `newProperties` matches the name of an existing property, that property's value is replaced with the new value. If the new value is an empty string, the property is removed. Any existing properties that are not modified or removed by the entries in `newProperties` are retained with their original values. If the `Ice.Trace.Admin.Properties` property is enabled, Ice logs a message if a call to `setProperties` results in any changes to the property set.

Modifying a program's configuration properties at run time may not have an effect on the program. For example, many of Ice's standard configuration properties are read once during communicator initialization, and never again.

Obtaining the Local Properties Facet

We [already showed](#) how to obtain a proxy for a remote administrative facet, but suppose you want to interact with the facet in your local address space. The code below shows the necessary steps:

C++

```
Ice::ObjectPtr obj = communicator->findAdminFacet("Properties");
if(obj) { // May be nil if the facet is not enabled
    Ice::PropertiesAdminPtr facet =
Ice::PropertiesAdminPtr::dynamicCast(obj);
    ...
}
```

As shown here, the facet is registered with the name `Properties` and a regular language cast is used to downcast the base object type to the `PropertiesAdmin` interface.

Property Update Notifications

The Ice run time can notify an application whenever its properties change due to invocations of the `setProperty` operation on the `PropertiesAdmin` interface. This section describes the native API for receiving property updates.

Implementing a Property Update Callback in C++

The `Properties` facet object provided by the Ice run time derives from the class `NativePropertiesAdmin`:

C++

```
namespace Ice {
class NativePropertiesAdmin : virtual public IceUtil::Shared {
public:
    virtual void addUpdateCallback(const
PropertiesAdminUpdateCallbackPtr& cb);
    virtual void removeUpdateCallback(const
PropertiesAdminUpdateCallbackPtr& cb);
};
typedef IceUtil::Handle<NativePropertiesAdmin> NativePropertiesAdminPtr;
}
```

The application must supply an instance of `PropertiesAdminUpdateCallback`:

C++

```

namespace Ice {
class PropertiesAdminUpdateCallback : virtual public Ice::LocalObject {
public:
    virtual void updated(const PropertyDict& changes) = 0;
};
typedef IceUtil::Handle<PropertiesAdminUpdateCallback>
PropertiesAdminUpdateCallbackPtr;
}

```

The `updated` method receives a dictionary<string, string> value representing the properties that were added, changed or removed, with removed properties denoted by an entry whose value is an empty string. It is legal for the `updated` implementation to modify the set of callbacks, and Ice ignores any exceptions it might raise.

The following code demonstrates how to register a callback:

C++

```

Ice::ObjectPtr obj = communicator->findAdminFacet("Properties");
if(obj) { // May be nil if the facet is not enabled
    Ice::NativePropertiesAdminPtr facet =
Ice::NativePropertiesAdminPtr::dynamicCast(obj);
    Ice::PropertiesAdminUpdateCallbackPtr myCallback = new ...;
    facet->addUpdateCallback(myCallback);
}

```

Implementing a Property Update Callback in Java

The `Properties` facet object provided by the Ice run time derives from the class `NativePropertiesAdmin`:

Java

```

package Ice;

public interface NativePropertiesAdmin {
    void addUpdateCallback(PropertiesAdminUpdateCallback callback);
    void removeUpdateCallback(PropertiesAdminUpdateCallback callback);
}

```

The application must supply an instance of `PropertiesAdminUpdateCallback`:

Java

```
package Ice;

public interface PropertiesAdminUpdateCallback {
    void updated(java.util.Map<String, String> changes);
}
```

The `updated` method receives a `dictionary<string, string>` value representing the properties that were added, changed or removed, with removed properties denoted by an entry whose value is an empty string. It is legal for the `updated` implementation to modify the set of callbacks, and Ice ignores any exceptions it might raise.

The following code demonstrates how to register a callback:

Java

```
Ice.Object obj = communicator.findAdminFacet("Properties");
if(obj != null) { // May be nil if the facet is not enabled
    Ice.NativePropertiesAdmin facet = (Ice.NativePropertiesAdmin)obj;
    Ice.PropertiesAdminUpdateCallback myCallback = new ...;
    facet.addUpdateCallback(myCallback);
}
```

Implementing a Property Update Callback in C#

The `Properties` facet object provided by the Ice run time derives from the class `NativePropertiesAdmin`:

C#

```
namespace Ice {
    public interface NativePropertiesAdmin {
        void addUpdateCallback(PropertiesAdminUpdateCallback callback);
        void removeUpdateCallback(PropertiesAdminUpdateCallback
callback);
    }
}
```

The application must supply an instance of `PropertiesAdminUpdateCallback`:

C#

```
namespace Ice {
    public interface PropertiesAdminUpdateCallback {
        void updated(System.Collections.Generic.Dictionary<string,
string> changes);
    }
}
```

The `updated` method receives a `dictionary<string, string>` value representing the properties that were added, changed or removed, with removed properties denoted by an entry whose value is an empty string. It is legal for the `updated` implementation to modify the set of callbacks, and Ice ignores any exceptions it might raise.

The following code demonstrates how to register a callback:

C#

```
Ice.Object obj = communicator.findAdminFacet("Properties");
if(obj != null) { // May be nil if the facet is not enabled
    Ice.NativePropertiesAdmin facet = obj as Ice.NativePropertiesAdmin;
    Ice.PropertiesAdminUpdateCallback myCallback = new ...;
    facet.addUpdateCallback(myCallback);
}
```

The Logger Facet

On this page:

- [The RemoteLogger Interface](#)
- [The LoggerAdmin Interface](#)
- [Configuring the Logger Facet](#)

The RemoteLogger Interface

An administrator may find it useful to view the log of a running Ice application, without going through an intermediary file. This is especially useful for [Ice services](#) that use a system log, such as the Windows Event Log.

The `Logger` facet allows remote applications (such as administrative clients) to attach one or more remote loggers to the local `logger` of any Ice application (provided this application enables the admin object with a `Logger` facet). The implementation of the `Logger` facet installs its own logger, which intercepts the log messages sent to the local logger, caches the most recent log messages, and forwards these log messages (after optional filtering) to the attached remote loggers.

A remote logger is an Ice object that implements the `Ice::RemoteLogger` interface. Such object is typically implemented by an administrative client.

Slice

```

module Ice {

    enum LogMessageType { PrintMessage, TraceMessage, WarningMessage,
ErrorMessage };
    sequence<LogMessageType> LogMessageTypeSeq;
    struct LogMessage {
        LogMessageType type;
        long timestamp;
        string traceCategory;
        string message;
    };
    sequence<LogMessage> LogMessageSeq;

    interface RemoteLogger {
        void init(string prefix, LogMessageSeq logMessages);
        void log(LogMessage message);
    };
};

```

The `LogMessage` struct represents log messages sent to a local logger. Its `timestamp` data member is the number of microseconds since the [Unix Epoch](#) (January 1st, 1970 at 0:00 UTC).

When a remote logger is attached to a local logger, its `init` operation is called with the local logger's prefix and a list of recent log messages (see [The LoggerAdmin Interface](#) below). Then, each time a log message is sent to the local logger, the `Logger` facet forwards this message to the remote logger's `log` operation.

The `Logger` facet does not guarantee that `init` will be called on a remote logger before `log` is called on this remote logger, even though the log messages sent to `init` are always older than the log messages sent to `log`. It is indeed common for `log` to be called several times before `init` in applications that generate many logs. An implementation of `RemoteLogger` needs to handle this situation correctly: it can for example keep all log messages received before `init` in a queue, and later append this queue to the log messages received through `init`.

The LoggerAdmin Interface

The `Logger` facet implements the `Ice::LoggerAdmin` interface:

Slice
<pre> module Ice { interface LoggerAdmin { void attachRemoteLogger(RemoteLogger* prx, LogMessageTypeSeq messageTypes, StringSeq traceCategories, int messageMax) throws RemoteLoggerAlreadyAttachedException; bool detachRemoteLogger(RemoteLogger* prx); LogMessageSeq getLog(LogMessageTypeSeq messageTypes, StringSeq traceCategories, int messageMax, out string prefix); }; </pre>

The operation `attachRemoteLogger` attaches a remote logger (`prx`) to the local logger with the following optional filters:

- `messageTypes` specifies the types of log messages this remote logger wants to receive. An empty sequence means no filtering—the `Logger` facet will forward all log message types.
- `traceCategories` is a sequence of categories for trace messages. An empty sequence means no filtering—the `Logger` facet will forward all trace categories.
- `messageMax` is the maximum number of log messages sent to `init`. If `messageMax` is negative, all available log messages will be sent to `init` (provided they satisfy the `messageTypes` and `traceCategories` filters). If `messageMax` is 0, no log message will be sent to `init`. If `messageMax` is greater than 0, the most recent `messageMax` log messages that satisfy the `messageTypes` and `traceCategories` filters will be sent to `init`.

For example, you can attach a remote logger with no filtering at all as follows:

C++
<pre> Ice::RemoteLoggerPrx remoteLogger = // my remote logger, typically an object implemented by the local application Ice::ObjectPrx admin = // get proxy to the admin object for the target application Ice::LoggerAdminPrx loggerAdmin = Ice::LoggerAdminPrx::uncheckedCast(admin, "Logger"); loggerAdmin->attachRemoteLogger(remoteLogger, Ice::LogMessageTypeSeq(), Ice::StringSeq(), -1); </pre>

If you are interested only in errors and trace messages for category `Network` with no more than 10 such messages sent to `init`, you could write instead:

C++

```

Ice::RemoteLoggerPrx remoteLogger = // my remote logger, typically an
object implemented by the local application
Ice::ObjectPrx admin = // get proxy to the admin object for the target
application
Ice::LoggerAdminPrx loggerAdmin =
Ice::LoggerAdminPrx::uncheckedCast(admin, "Logger");

Ice::LogMessageTypeSeq messageTypes;
messageTypes.push_back(Ice::ErrorMessage);
messageTypes.push_back(Ice::TraceMessage);

Ice::StringSeq traceCategories;
traceCategories.push_back("Network");

loggerAdmin->attachRemoteLogger(remoteLogger, messageTypes,
traceCategories, 10);

```

The operation `detachRemoteLogger` detaches a remote logger (`prx`) from the local logger. `prx` does not need to match exactly the proxy provided to `attachRemoteLogger`: the `Logger` facet uses only the identity in this proxy. `detachRemoteLogger` returns true if this remote logger was found (and is now detached), and false otherwise.

The `Logger` facet automatically detaches a remote logger when a request sent to this remote logger fails. As a result, if an administrative client forgets to call `detachRemoteLogger` after destroying its remote logger, or crashes, this remote logger will remain attached only as long as it's not used.

The operation `getLog` retrieves the most recent `messageMax` log messages that match the optional `messageTypes` and `traceCategories` filters. These parameters have the same meaning as in the `attachRemoteLogger` operation described above. For example, if you want to retrieve only the 10 most recent errors and trace messages for category `Network`, you could write:

C++

```

Ice::ObjectPrx admin = // get proxy to the admin object for the target
application
Ice::LoggerAdminPrx loggerAdmin =
Ice::LoggerAdminPrx::uncheckedCast(admin, "Logger");

Ice::LogMessageTypeSeq messageTypes;
messageTypes.push_back(Ice::ErrorMessage);
messageTypes.push_back(Ice::TraceMessage);

Ice::StringSeq traceCategories;
traceCategories.push_back("Network");

string prefix;
Ice::LogMessageSeq logMessages = loggerAdmin->getLog(messageTypes,
traceCategories, 10, prefix);

```

Configuring the Logger Facet

The `Logger` facet caches the most recent log messages sent to application's `Logger`, to be able to provide these log messages to remote loggers (in the `init` operation) and to administrative clients that call `getLog` (see the [LoggerAdmin Interface](#) above). You can configure how many log messages are cached by the `Logger` facet with the `Ice.Admin.Logger.KeepLogs` and `Ice.Admin.Logger.KeepTraces` properties. The default is to keep the most recent 100 log messages other than trace messages plus the most recent 100 trace messages.

The Metrics Facet

The `Metrics` facet implements the [Instrumentation Facility](#) to provide convenient access to metrics for the Ice run time and select Ice services. The metrics provided by this facet include the number of threads currently running and their state, the number of connections, information on invocations and dispatch, as well as connection establishment and endpoint name resolution.

On this page:

- [Metrics Terminology](#)
- [Metrics Types](#)
- [The MetricsAdmin Interface](#)
- [Obtaining the Local Metrics Facet](#)
- [Metrics Attributes](#)

Metrics Terminology

- **metric:** an "analytical measurement intended to quantify the state of a system", recorded by the Ice run time, such as bytes sent over a connection.
- **metric name:** the name of the metric, such as "number of connections".
- **metrics map:** a collection of metrics objects.
- **metrics view:** a collection of metrics maps. A view contains metrics maps of different types (e.g., connections and threads). Several metrics views can be configured with different purposes. For example, you can have a "debug" metrics view to get detailed metrics of each of the instrumented objects in the Ice communicator. This view can be enabled from time to time for debugging purposes but it's disabled most of the time. You could also have a more coarse-grained metrics view to collect data at a higher level, such as the amount of bytes received and sent by all the connections from the communicator. This metrics view can be enabled all the time.

Metrics Types

Metrics are specified as Slice classes defined in the `Ice/Metrics.ice` Slice file. All the metrics types are defined in the `IceMX` module.

The base class is `IceMX::Metrics`:

Slice
<pre>class Metrics { string id; long total = 0; int current = 0; long totalLifetime = 0; int failures = 0; };</pre>

A metrics object is an instance of `IceMX::Metrics` and represents metrics of one or more instrumented objects. An instrumented object can be anything that supports instrumentation. The Ice run time supports instrumentation of the following objects and activities:

- Threads
- Connections
- Invocations
- Dispatch
- Connection establishment
- Endpoint resolution

The `id` of a metric identifies the instrumented object(s). The `total` and `current` members specify the total and current number of instrumented objects created since the creation of the Ice communicator, respectively. The `totalLifetime` member is the sum of the lifetime of each instrumented object and `failures` is the number of failures that have occurred for the metrics object(s).

Failures are specified using a separate `IceMX::MetricsFailures` structure:

Slice

```
struct MetricsFailures
{
    string id;
    StringIntDict failures;
};
```

The `failures` dictionary provides the count of each type of failure for a metric identified by `id`. Failures are dependent on the instrumented objects. For example, failures for Ice connections are represented with the name of the exception that caused the connection to fail (e.g., `Ice::ConnectionLostException` or `Ice::TimeoutException`).

A metrics map is simply defined as a sequence of `IceMX::Metrics` objects, and a metrics view is defined as a dictionary of metrics map:

Slice

```
sequence<Metrics> MetricsMap;
dictionary<string, MetricsMap> MetricsView;
```

The key for the metrics view dictionary is a string that identifies the metrics map. The Ice run time supports the following metrics maps:

Metrics map name	Slice class	Description
Connection	<code>IceMX::ConnectionMetrics</code>	Connection metrics.
Thread	<code>IceMX::ThreadMetrics</code>	Thread metrics. The Ice run time instruments threads for the communicator's thread pools as well as threads used internally.
Invocation	<code>IceMX::InvocationMetrics</code>	Client-side proxy invocation metrics.
Dispatch	<code>IceMX::DispatchMetrics</code>	Server-side dispatch metrics.
EndpointLookup	<code>IceMX::Metrics</code>	Endpoint lookup metrics. For tcp, ssl and udp endpoints, this corresponds to the DNS lookups made to resolve the host names in endpoints.
ConnectionEstablishment	<code>IceMX::Metrics</code>	Connection establishment metrics.

A metrics map can also contain sub-metrics maps. An example is the `Invocation` metrics map, which provides a `Remote` sub-metrics map to record metrics associated with remote invocations. The Slice class for remote invocation metrics is `IceMX::Metrics`.

The MetricsAdmin Interface

The Slice interface `IceMX::MetricsAdmin` allows you to retrieve the metrics associated with the Ice communicator:

Slice

```

module IceMX {
exception UnknownMetricsView {};

interface MetricsAdmin {
    Ice::StringSeq getMetricsViewNames(out Ice::StringSeq disableViews);
    void enableMetricsView(string name)
        throws UnknownMetricsView;
    void disableMetricsView(string name)
        throws UnknownMetricsView;
    MetricsView getMetricsView(string view, out long timestamp)
        throws UnknownMetricsView;
    MetricsFailuresSeq getMapMetricsFailures(string view, string map)
        throws UnknownMetricsView;
    MetricsFailures getMetricsFailures(string view, string map, string
id)
        throws UnknownMetricsView;
};
};

```

The `getMetricsViewName` operation retrieves the names of the configured enabled and disabled views. The `enableMetricsView` and `disableMetricsView` allow to enable and disable a specific view. Calling those methods is equivalent to setting the view `Disabled` property to 1 or 0. The `getMetricsView` operation returns the metrics for the given view. The `getMapMetricsFailures` and `getMetricsFailures` operations retrieve the metrics failures for a given map or metrics id.

Obtaining the Local Metrics Facet

We [already showed](#) how to obtain a proxy for a remote administrative facet, but suppose you want to interact with the facet in your local address space. The code below shows the necessary steps:

C++

```

Ice::ObjectPtr obj = communicator->findAdminFacet("Metrics");
if(obj) { // May be nil if the facet is not enabled
    Ice::MetricsAdminPtr facet = Ice::MetricsAdminPtr::dynamicCast(obj);
    ...
}

```

As shown here, the facet is registered with the name `Metrics` and a regular language cast is used to downcast the base object type to the `MetricsAdmin` interface.

Metrics Attributes

Metrics views are configured with `IceMX Metrics` properties.

The `GroupBy`, `Accept` and `Reject` properties are specified using attributes that are specific to each metrics map. The table below describes the attributes supported by the Ice run time's metrics maps.

Name	Maps	Description
id	All	A unique identifier to select the instrumented object or operation.
parent	All	The parent of the instrumented object or operation.
none	All	The none attribute is a special attribute that evaluates to the empty string.
endpoint	Connection, Dispatch, Remote, ConnectionEstablishment, EndpointLookup	The stringified endpoint.
endpointType	Connection, Dispatch, Remote, ConnectionEstablishment, EndpointLookup	The endpoint numerical type as defined in <code>Ice/Endpoint.ice</code> .
endpointIsDatagram	Connection, Dispatch, Remote, ConnectionEstablishment, EndpointLookup	A boolean indicating if the endpoint is a datagram endpoint.
endpointIsSecure	Connection, Dispatch, Remote, ConnectionEstablishment, EndpointLookup	A boolean indicating if the endpoint is secure.
endpointTimeout	Connection, Dispatch, Remote, ConnectionEstablishment, EndpointLookup	The endpoint timeout.
endpointCompress	Connection, Dispatch, Remote, ConnectionEstablishment, EndpointLookup	A boolean indicating if the endpoint requires compression.
endpointHost	Connection, Dispatch, Remote, ConnectionEstablishment, EndpointLookup	The endpoint host.
endpointPort	Connection, Dispatch, Remote, ConnectionEstablishment, EndpointLookup	The endpoint port.
connection	Dispatch	The connection description.
incoming	Connection, Dispatch, Remote	A boolean where true indicates an incoming (server) connection and false an outgoing (client) connection.
adapterName	Connection, Dispatch, Remote	If the connection is a server connection, <code>adapterName</code> returns the name of the adapter that created the connection, otherwise it is the empty string.
connectionId	Connection, Dispatch, Remote	The ID of the connection if one is set, otherwise it is the empty string.
localAddress	Connection, Dispatch, Remote	The connection's local address.
localPort	Connection, Dispatch, Remote	The connection's local port.
remoteAddress	Connection, Dispatch, Remote	The connection's remote address.
remotePort	Connection, Dispatch, Remote	The connection's remote port.
mcastAddress	Connection, Dispatch, Remote	The connection's multicast address.
mcastPort	Connection, Dispatch, Remote	The connection's multicast port.
state	Connection	The state of the connection.
operation	Dispatch, Invocation	The dispatched or invoked operation name.
identity	Dispatch, Invocation	The identity of the Ice object used for the dispatch or invocation.
facet	Dispatch, Invocation	The facet of the Ice object used for the dispatch or invocation.
mode	Dispatch, Invocation	The dispatch or invocation mode.
context.key	Dispatch, Invocation	The value of the dispatch or invocation context with the given key.

proxy	Invocation	The proxy used for the invocation.
encoding	Invocation	The proxy encoding.

The `id`, `parent` and `none` attributes are supported by all maps.

The value of the `parent` attribute depends on the map. For the `Connection`, `Dispatch` and `Remote` maps, the `parent` will either be "Communicator" if the connection is a client connection, or the object adapter name if it's a server connection. For the `Invocation`, `EndpointLookup`, and `ConnectionEstablishment` maps, it will always be "Communicator". The `parent` attribute enables the filtering of metrics based on the object adapter. When used with the `GroupBy` property it also allows you to obtain metrics at the object adapter level. For instance, the following configuration does not monitor any metrics for the `Ice.Admin` object adapter and it groups all the metrics based on the object adapter or communicator:

```
IceMX.Metrics.MyView.GroupBy=parent
IceMX.Metrics.MyView.Reject.parent=Ice\.Admin # Escape the dot in
Ice.Admin
```

This configuration enables the communicator to get metrics on a per object adapter or communicator basis.

You can also use the `none` attribute to get metrics for the communicator including the metrics from object adapters, e.g., `IceMX.Metrics.MyView.GroupBy=none`. This provides the lowest possible level of detail as all the statistics will be recorded by a single metrics object.

The `id` attribute allows you to get a higher level of detail by recording metrics on a per instrumented object or operation basis. If you specify `IceMX.Metrics.MyView.GroupBy=id`, the `Metrics` facet will record metrics for each individual object or operation.

- [Creating the admin Object](#)
- [Ice.Admin.*](#)

Filtering Administrative Facets

The Ice run time enables all of its built-in [administrative facets](#) by default, and an application may install its own [custom facets](#). You can control which facets the Ice run time enables using the `Ice.Admin.Facets` property. For example, the following property definition enables the `Properties` facet and leaves the `Process` facet (and any application-defined facets) disabled:

```
Ice.Admin.Facets=Properties
```

To specify more than one facet, separate them with a comma or white space. A facet whose name contains white space must be enclosed in single or double quotes.

The Ice run time creates only the built-in administrative facets that are enabled. Disabled built-in facets are not created at all. In Ice releases prior to Ice 3.6, the built-in facets were always created, whether enabled or disabled through `Ice.Admin.Facets`.

- [Ice.Admin.*](#)

Custom Administrative Facets

An application can add and remove administrative facets using the `Communicator` operations shown below:

Slice

```

module Ice {
  local interface Communicator {
    // ...
    void addAdminFacet(Object servant, string facet);
    Object removeAdminFacet(string facet);
  };
};

```

The `addAdminFacet` operation installs a new facet with the given name, or raises `AlreadyRegisteredException` if a facet already exists with the same name. The `removeAdminFacet` operation removes (and returns) the facet with the given name, or raises `NotRegisteredException` if no matching facet is found.

The mechanism for [filtering administrative facets](#) also applies to application-defined facets. If you call `addAdminFacet` while a filter is in effect, and the name of your custom facet does not match the filter, the Ice run time will not expose your facet but instead keeps a reference to it so that a subsequent call to `removeAdminFacet` is possible.

We provide an example of using these communicator operations in our discussion of the [Process](#) facet.

See Also

- [Filtering Administrative Facets](#)
- [The Process Facet](#)

Security Considerations for Administrative Facets

Exposing administrative functionality naturally makes a program vulnerable, therefore it is important that proper precautions are taken. With respect to the default functionality, the [Properties](#) facet could expose sensitive configuration information, and the [Process](#) facet supports a `shutdown` operation that opens the door for a denial-of-service attack. Developers should carefully consider the security implications of any additional administrative facets that an application installs.

There are several approaches you can take to mitigate the possibility of abuse:

- Disable the administrative facility

The administrative facility is disabled by default, and remains disabled as long as its [prerequisites](#) are not met. Note that [IceGrid](#) enables the facility in servers that it activates for the following reasons:

- The [Process](#) facet allows the IceGrid node to gracefully terminate the process.
- The [Properties](#) facet enables IceGrid administrative clients to obtain configuration information about activated servers.
- The [Logger](#) facet enables IceGrid administrative clients to attach remote loggers to the [Loggers](#) of activated servers.

You could disable a facet using filtering, but doing so may disrupt IceGrid's normal operation.

- Select a proper endpoint

If you host the admin object in the `Ice.Admin` object adapter, a reasonably secure value for the `Ice.Admin.Endpoints` property is one that uses the local host interface (`-h 127.0.0.1`), which restricts access to clients that run on the same host. Incidentally, this is the default value that IceGrid defines for its servers, although you can override that if you like. Note that using a local host endpoint does not preclude [remote administration](#) for IceGrid servers because IceGrid transparently routes requests on `admin` objects to the appropriate server via its node. If your application must support administration from non-local hosts, we recommend the use of [SSL](#) and certificate-based access control.

- Filter the facets

After choosing a suitable endpoint, you can minimize risks by filtering the facets to enable only the functionality that is required. For example, if you are not using IceGrid's [server activation](#) feature and do not require the ability to remotely terminate a program, you should disable the [Process](#) facet using the [filtering mechanism](#).

- Consider the object's identity

The default [identity](#) of an [admin object](#) created during communicator initialization (or with `getAdmin`) has a UUID for its category, which makes it difficult for a hostile client to guess. Depending on your requirements, the use of a UUID may be an advantage or a disadvantage. For example, in a trusted environment, the use of a UUID may create additional work, such as the need to add an interface that an administrative client can use to obtain the identity or proxy of a remote `admin` object. An obscure identity might be more of a hindrance in this situation, and therefore specifying a static category via the `Ice.Admin.InstanceName` property is a reasonable alternative. In general, however, we recommend using the default behavior.

Logger Facility

Depending on the setting of [various properties](#), the Ice run time produces trace, warning, or error messages. These messages are written via the `Ice::Logger` interface:

Slice
<pre> module Ice { local interface Logger { void print(string message); void trace(string category, string message); void warning(string message); void error(string message); string getPrefix(); Logger cloneWithPrefix(string prefix); }; }; </pre>

The `cloneWithPrefix` operation returns a new logger that logs to the same destination but with a different prefix. (The prefix is used to, for example, provide the name of the process writing the log messages.)

See Also

- [Properties and Configuration](#)

The Default Logger

A default `logger` is instantiated when you create a communicator. The default logger writes its messages to the standard error output. The `trace` operation accepts a `category` parameter in addition to the error message; this allows you to separate trace output from different subsystems by sending the output through a filter.

You can obtain the logger that is attached to a communicator using the `getLogger` operation:

```

Slice

```
module Ice {
 local interface Communicator {
 Logger getLogger();
 // ...
 };
};
```

```

On Windows, when the default C++ logger outputs a log message to the console, it converts this message from your narrow string encoding (as defined by narrow string converter you installed, if any) to your console code page. This conversion is disabled if you redirect standard error to a file with `Ice.StdErr`, or if you set `Ice.LogStdErr.Convert` to 0.

See Also

- [Logger Facility](#)
- [C++ Strings and Character Encoding](#)

Custom Loggers

You have several options if you wish to install a logger other than the default one:

- Select one of the other [built-in loggers](#), which allow you to log to a file, to the `syslog` on Unix, and to the Windows event log
- Supply your own logger implementation in an [InitializationData](#) parameter when you create a communicator
- Load a logger implementation dynamically via the [Ice plug-in facility](#)

Changing the `Logger` object that is attached to a communicator allows you to integrate Ice messages into your own message handling system. For example, for a complex application, you might have an existing logging framework. To integrate Ice messages into that framework, you can create your own `Logger` implementation that logs messages to the existing framework.

When you destroy a communicator, its logger is *not* destroyed. This means that you can safely use a logger even beyond the lifetime of its communicator.

Built-in Loggers

Ice provides a file-based logger as well as Unix- and Windows-specific logger implementations. For .NET, the default Ice logger uses a `TraceListener` and so can be customized at run time via configuration.

On this page:

- [File Logger](#)
- [Syslog Logger](#)
- [Windows Logger](#)
- [.NET Logger](#)

File Logger

The file-based logger is enabled via the `Ice.LogFile` property. This logger is available for all supported languages and platforms.

Syslog Logger

You can activate a logger that logs via the Unix `syslog` implementation by setting the `Ice.UseSyslog` property. This logger is available in Ice for C++, Java, and C#, as well as for scripting languages based on Ice for C++.

Windows Logger

On Windows, subclasses of `Ice::Service` use the Windows application event log by default. The event log implementation is available for C++ applications.

.NET Logger

The default logger in Ice for .NET writes its messages using the `System.Diagnostics.Trace` facility. By default, the Ice run time registers a `ConsoleTraceListener` that writes to `stderr`. You can disable the logging of messages via this trace listener by setting the property `Ice.ConsoleListener` to zero.

You can change the trace listener for your application via the application's configuration file. For example:

```
<configuration>
  <system.diagnostics>
    <trace autoflush="false" indentsize="4">
      <listeners>
        <add name="myListener"
              type="System.Diagnostics.EventLogTraceListener"
              initializeData="TraceListenerLog" />
      </listeners>
    </trace>
  </system.diagnostics>
</configuration>
```

This configuration installs a trace listener that logs to the Windows event log using the source name `TraceListenerLog`.

The `EventLogTraceListener` creates a new event source if no match is found for the source name defined by `initializeData`, and creating a new event source requires that you run the application with administrative privileges. Alternatively, you can create the event source in advance using an administrative tool. For more information, search MSDN for "EventLog Component".

Logger Plug-ins

Installing a [custom logger](#) using the Ice plug-in facility has several advantages. Because the logger plug-in is specified by a configuration property and loaded dynamically by the Ice run time, an application requires no code changes in order to utilize a custom logger implementation. Furthermore, a logger plug-in takes precedence over the [per-process logger](#) and the logger supplied in the `InitializationData` argument during [communicator initialization](#), meaning you can use a logger plug-in to override the logger that an application installs by default.

On this page:

- [Installing a C++ Logger Plug-in](#)
- [Installing a Java Logger Plug-in](#)
- [Installing a C# Logger Plug-in](#)

Installing a C++ Logger Plug-in

To install a logger plug-in in C++, you must first define a subclass of `Ice::Logger`:

C++

```
class MyLoggerI : public Ice::Logger {
public:

    virtual void print(const std::string& message);
    virtual void trace(const std::string& category,
const std::string& message);
    virtual void warning(const std::string& message);
    virtual void error(const std::string& message);
    virtual std::string getPrefix();
    virtual LoggerPtr cloneWithPrefix(const string& prefix);

    // ...
};
```

Next, supply a factory function that installs your custom logger by returning an instance of `Ice::LoggerPlugin`:

C++

```
extern "C"
{

ICE_DECLSPEC_EXPORT Ice::Plugin*
createLogger(const Ice::CommunicatorPtr& communicator,
             const std::string& name,
             const Ice::StringSeq& args)
{
    Ice::LoggerPtr logger = new MyLoggerI;
    return new Ice::LoggerPlugin(communicator, logger);
}

}
```

The factory function can have any name you wish; we used `createLogger` in this example. Refer to the [plug-in API](#) for more information on plug-in factories.

The definition of `LoggerPlugin` is shown below:

C++

```
namespace Ice {
class LoggerPlugin {
public:
    LoggerPlugin(const CommunicatorPtr&, const LoggerPtr&);

    virtual void initialize();
    virtual void destroy();
};
}
```

The constructor installs your logger into the given communicator. The `initialize` and `destroy` methods are empty, but you can subclass `LoggerPlugin` and override these methods if necessary.

Finally, define a [configuration property](#) that loads your plug-in into an application:

```
Ice.Plugin.MyLogger=mylogger:createLogger
```

The plug-in's name in this example is `MyLogger`; again, you can use any name you wish. The value of the property represents the plug-in's entry point, in which `mylogger` is the abbreviated form of its shared library or DLL, and `createLogger` is the name of the factory function.

If the configuration file containing this property is shared by programs in multiple implementation languages, you can use an alternate syntax that is loaded only by the Ice for C++ run time:

```
Ice.Plugin.MyLogger.cpp=mylogger:createLogger
```

Installing a Java Logger Plug-in

To install a logger plug-in in Java, you must first define a subclass of `Ice.Logger`:

```

Java

public class MyLoggerI implements Ice.Logger {

    public void print(String message) { ... }
    public void trace(String category, String message) { ... }
    public void warning(String message) { ... }
    public void error(String message) { ... }
    public String getPrefix() { ... }
    public Logger cloneWithPrefix(String prefix) { ... }

    // ...
}

```

Next, define a factory class that installs your custom logger by returning an instance of `Ice.LoggerPlugin`:

```

Java

public class MyLoggerPluginFactoryI implements Ice.PluginFactory {
    public Ice.Plugin create(Ice.Communicator communicator,
                            String name, String[] args)
    {
        Ice.Logger logger = new MyLoggerI();
        return new Ice.LoggerPlugin(communicator, logger);
    }
}

```

The factory class can have any name you wish; in this example, we used `MyLoggerPluginFactoryI`. Refer to the [plug-in API](#) for more information on plug-in factories.

The definition of `LoggerPlugin` is shown below:

Java

```

package Ice;

public class LoggerPlugin implements Plugin {
    public LoggerPlugin(Communicator communicator, Logger logger)
    {
        // ...
    }

    public void initialize() { }

    public void destroy() { }
}

```

The constructor installs your logger into the given communicator. The `initialize` and `destroy` methods are empty, but you can subclass `LoggerPlugin` and override these methods if necessary.

Finally, define a [configuration property](#) that loads your plug-in into an application:

```
Ice.Plugin.MyLogger=MyLoggerPluginFactoryI
```

The plug-in's name in this example is `MyLogger`; again, you can use any name you wish. The value of the property is the name of the factory class.

If the configuration file containing this property is shared by programs in multiple implementation languages, you can use an alternate syntax that is loaded only by the Ice for Java run time:

```
Ice.Plugin.MyLogger.java=MyLoggerPluginFactoryI
```

Installing a C# Logger Plug-in

To install a logger plug-in in .NET, you must first define a subclass of `Ice.Logger`:

C#

```

public class MyLoggerI : Ice.Logger {

    public void print(string message) { ... }
    public void trace(string category, string message) { ... }
    public void warning(string message) { ... }
    public void error(string message) { ... }
    public string getPrefix() { ... }
    public Logger cloneWithPrefix(string prefix) { ... }

    // ...
}

```

Next, define a factory class that installs your custom logger by returning an instance of `Ice.LoggerPlugin`:

C#

```

public class MyLoggerPluginFactoryI : Ice.PluginFactory {
    public Ice.Plugin create(Ice.Communicator communicator,
                            string name, string[] args)
    {
        Ice.Logger logger = new MyLoggerI();
        return new Ice.LoggerPlugin(communicator, logger);
    }
}

```

The factory class can have any name you wish; in this example, we used `MyLoggerPluginFactoryI`. Refer to the [plug-in API](#) for more information on plug-in factories. Typically the logger implementation and the factory are compiled into a single assembly.

The definition of `LoggerPlugin` is shown below:

C#

```

namespace Ice {
public partial class LoggerPlugin : Plugin {
    public LoggerPlugin(Communicator communicator, Logger logger)
    {
        // ...
    }

    public void initialize() { }

    public void destroy() { }
}
}

```

The constructor installs your logger into the given communicator. The `initialize` and `destroy` methods are empty, but you can subclass `LoggerPlugin` and override these methods if necessary.

Finally, define a [configuration property](#) that loads your plug-in into an application:

```
Ice.Plugin.MyLogger=mylogger.dll:MyLoggerPluginFactoryI
```

The plug-in's name in this example is `MyLogger`; again, you can use any name you wish. The value of the property is the entry point for the factory, consisting of an assembly name followed by the name of the factory class.

If the configuration file containing this property is shared by programs in multiple implementation languages, you can use an alternate syntax that is loaded only by the Ice for .NET run time:

```
Ice.Plugin.MyLogger.clr=mylogger.dll:MyLoggerPluginFactoryI
```

The Per-Process Logger

Ice allows you to install a per-process [custom logger](#). This logger is used by all communicators that do not have their own specific logger established at the time a [communicator is created](#).

You can set a per-process logger in C++ by calling `Ice::setProcessLogger`, and you can retrieve the per-process logger by calling `Ice::getProcessLogger`:

C++

```
LoggerPtr getProcessLogger();  
void setProcessLogger(const LoggerPtr&);
```

If you call `getProcessLogger` without having called `setProcessLogger` first, the Ice run time installs a default per-process logger. Note that if you call `setProcessLogger`, only communicators created after that point will use this per-process logger; communicators created earlier use the logger that was in effect at the time they were created. (This also means that you can call `setProcessLogger` multiple times; communicators created after that point will use whatever logger was established by the last call to `setProcessLogger`.)

`getProcessLogger` and `setProcessLogger` are language-specific APIs that are not defined in Slice. Therefore, for Java and C#, these methods appear in the `Ice.Util` class.

For applications that use the `Application` or `Service` convenience classes and do not explicitly configure a logger, these classes set a default per-process logger that uses the `Ice.ProgramName` property as a prefix for log messages. The `Application` class is described in the server-side language mapping chapters; more information on the `Service` class can be found in [The `Ice::Service` Class](#).

- [The Server-Side main Function in C++](#)

C++ Logger Utility Classes

The Ice run time supplies a collection of utility classes that make use of the [logger facility](#) simpler and more convenient. Each of the `Logger` interface's four operations has a corresponding helper class:

C++
<pre> namespace Ice { class Print { public: Print(const LoggerPtr&); void flush(); ... }; class Trace { public: Trace(const LoggerPtr&, const std::string&); void flush(); ... }; class Warning { public: Warning(const LoggerPtr&); void flush(); ... }; class Error { public: Error(const LoggerPtr&); void flush(); ... }; } </pre>

The only notable difference among these classes is the extra argument to the `Trace` constructor; this argument represents the trace category.

To use one of the helper classes in your application, you simply instantiate it and compose your message:

C++
<pre> if (errorCondition) { Error err(communicator->getLogger()); err << "encountered error condition: " << errorCondition; } </pre>

The Ice run time defines the necessary stream insertion operators so that you can treat an instance of a helper class as if it were a standard C++ output stream. When the helper object is destroyed, its destructor logs the message you have composed. If you want to log more than

one message using the same helper object, invoke the `flush` method on the object to log what you have composed so far and reset the object for a new message.

The helper classes also supply insertion operators to simplify the task of logging an exception. The operators accept instances of `std::exception` (from which all Ice exceptions derive) and log the string returned by the `what` method. On some platforms, you can also enable the configuration property `Ice.PrintStackTraces`, which causes the helper classes to log the stack trace of the exception in addition to the value of `what`.

- [Logger Facility](#)

Instrumentation Facility

The Ice run time can be instrumented using observer interfaces that monitor many aspects of the run time's internal objects and activities, including connections, threads, servant dispatching, proxy invocations, endpoint lookups and connection establishment. We refer to these internal objects and activities as "instrumented objects" in the discussion below. The application is responsible for implementing the instrumentation observer interfaces. Note however that an implementation of these interfaces is provided by the [Metrics Facet](#), so most applications do not need to implement them and can instead collect metrics through the `MetricsAdmin` facet. The definition of the instrumentation interfaces can be found in the `Ice/Instrumentation.ice` Slice file.

The Ice run time uses the `Ice::Instrumentation::CommunicatorObserver` interface to obtain observers for instrumented objects created by the run time:

```

Slice
module Ice {
  module Instrumentation {
    local interface CommunicatorObserver {
      Observer getConnectionEstablishmentObserver(Endpoint endpt,
string connector);
      Observer getEndpointLookupObserver(Endpoint endpt);
      ConnectionObserver getConnectionObserver(ConnectionInfo c,
Endpoint e,
                                                    ConnectionState s,
ConnectionObserver o);
      ThreadObserver getThreadObserver(string parent, string id,
ThreadState s,
                                                    ThreadObserver o);
      InvocationObserver getInvocationObserver(Object* prx, string
operation, Context ctx);
      DispatchObserver getDispatchObserver(Current c);
      void setObserverUpdater(ObserverUpdater updater);
    };
  };
  local interface Communicator {
    Ice::Instrumentation::CommunicatorObserver getObserver();
    // ...
  };
};

```

The Ice run time calls the appropriate `get...Observer` operation each time a new instrumented object is created. The implementation of these methods should return an observer, or `nil` if the implementation does not want to monitor the instrumented object. This observer is associated with the instrumented object and receives notifications of any changes to its attributes or state. All observer interfaces derive from the `Ice::Instrumentation::Observer` base interface:

```

Slice
local interface Observer {
  void attach();
  void detach();
  void failed(string exceptionName);
};

```

The `attach` operation is called upon association of the observer with the new instrumented object. The `detach` operation is called when the object is destroyed. The `failed` operation is called to report any failures that might occur during the lifetime of the instrumented object. Observer specializations provide additional operations for monitoring other attributes. For example, here is the `Ice::Instrumentation::ConnectionObserver` interface:

Slice

```
local interface ConnectionObserver extends Observer {
    void sentBytes(int num);
    void receivedBytes(int num);
};
```

The `sentBytes` and `receivedBytes` methods are called by the Ice connection when new bytes are received or sent over the connection.

Shown below is an implementation of the communicator and connection observer interfaces to record sent and received bytes on a per-connection basis. The observer dumps how many bytes were received and sent for the connection when it is detached:

C++

```
class ConnectionObserverImpl : public
Ice::Instrumentation::ConnectionObserver {
public:
    ConnectionObserverImpl(const Ice::ConnectionInfoPtr& connInfo) :
        info(connInfo), sentBytes(0), receivedBytes(0)
    {
    }

    void attach() {}

    void detach()
    {
        cerr << info->remoteHost << ":" << info->remotePort << ": sent
bytes = "
                << sentBytes << ", received bytes = " << receivedBytes <<
endl;
    }

    void sentBytes(int num)
    {
        sentBytes += num;
    }

    void receivedBytes(int num)
    {
        receivedBytes += num;
    }

    void failed(const std::string&)
    {
    }
};
```

```
private:

    Ice::ConnectionInfoPtr info;
    long sentBytes;
    long receivedBytes;
};

class CommunicatorObserverImpl : public
Ice::Instrumentation::CommunicatorObserver {
public:

    Ice::Instrumentation::ConnectionObserverPtr
    getConnectionObserver(const Ice::ConnectionInfoPtr& c, const
Ice::EndpointPtr& e,
                        Ice::Instrumentation::ConnectionState s,
                        const
Ice::Instrumentation::ConnectionObserverPtr& previous)
    {
        return new ConnectionObserverImpl(c);
    }
};
```

```

    }
};

```

For brevity we have omitted the implementation of the other `get...Observer` methods; they all return 0 as we are only interested in instrumenting connections.

To register your implementation, you must pass it in an `InitializationData` parameter when you initialize a communicator:

C++

```

Ice::InitializationData id;
id.observer = new CommunicatorObserverImpl();
Ice::CommunicatorPtr ic = Ice::initialize(id);

```

You can install a `CommunicatorObserver` object on either the client or the server side (or both). Here is some example output produced by installing our `CommunicatorObserver` and `ConnectionObserver` object implementations in a simple server:

```

127.0.0.1:3487: sent bytes = 14, received bytes = 32
127.0.0.1:3487: sent bytes = 33, received bytes = 14
127.0.0.1:3490: sent bytes = 14, received bytes = 14
...

```

In addition to the operations for retrieving observers, the `CommunicatorObserver` interface also defines a `setObserverUpdater` operation that is called by the Ice run time on initialization to provide an updater object to the `CommunicatorObserver` implementation. This updater object can be used to "refresh" some of the created observers. The updater object provided by the Ice run time implements the following interface:

Slice

```

local interface ObserverUpdater {
    void updateConnectionObservers();
    void updateThreadObservers();
};

```

The `CommunicatorObserver` implementation can call these operations to update the observers associated with Ice connections or threads. When one of these operations is called, the Ice run time calls the matching `get...Observer` method on the `CommunicatorObserver` interface for each of the instrumented objects. For example, if you call `updateConnectionObservers`, your implementation of `getConnectionObserver` will be called again for each Ice connection in the communicator. The `previous` parameter to `getConnectionObserver` represents the observer that is currently associated with the connection.

This mechanism can be used to re-configure the observers associated with instrumented objects. For instance, the application might not wish to instrument connections all the time but only when needed. It can use the observer updater to enable or disable the instrumentation. Here is the example above modified to provide this functionality:

C++

```

class CommunicatorObserverImpl : public
Ice::Instrumentation::CommunicatorObserver,
                                private IceUtil::Mutex {
public:

    Ice::Instrumentation::ConnectionObserverPtr
    getConnectionObserver(const Ice::ConnectionInfoPtr& c, const
Ice::EndpointPtr& e,
                                Ice::Instrumentation::ConnectionState s,
                                const
Ice::Instrumentation::ConnectionObserverPtr& previous)
    {
        Lock sync(*this);
        return enabled ? new ConnectionObserverImpl(c) : 0;
    }

    void setEnabled(bool enabled)
    {
        {
            Lock sync(*this);
            if(this->enabled == enabled)
                return;
            this->enabled = enabled;
        }
        updater->updateConnections();
    }

    void setObserverUpdater(const
Ice::Instrumentation::ObserverUpdaterPtr& updater)
    {
        this->updater = updater;
    }

    const Ice::Instrumentation::ObserverUpdaterPtr updater;
    bool enabled;
};

```

As you can see in the example above, special care needs to be taken with respect to synchronization. The Ice run time can call observers with Ice internal locks held to guarantee consistency of the information passed to the `get...Observer` methods. It is therefore important that the implementation of your observers performs quickly and does not create deadlocks. Your observers should not make remote invocations or call Ice APIs that require acquiring locks on instrumented objects.

IceBox

IceBox is an easy-to-use framework for Ice application services. The Service Configurator pattern [1] is a useful technique for configuring services and centralizing their administration. In practical terms, this means services are developed as dynamically-loadable components that can be configured into a general purpose "super server" in whatever combinations are necessary. IceBox is an implementation of the Service Configurator pattern for Ice services.

A generic IceBox server replaces the typical monolithic Ice server you normally write. The IceBox server is configured via properties with the application-specific services it is responsible for loading and managing, and it can be administered remotely. There are several advantages in using this architecture:

- Services loaded by the same IceBox server can be configured to take advantage of Ice's [collocation optimizations](#). For example, if one service is a client of another service, and those services reside in the same IceBox server, then invocations between them can be optimized.
- Composing an application consisting of various services is done by configuration, not by compiling and linking. This decouples the service from the server, allowing services to be combined or separated as needed.
- Multiple Java services can be active in a single instance of a Java Virtual Machine (JVM). This conserves operating system resources when compared to running several monolithic servers, each in its own JVM.
- Services implement an IceBox service interface, providing a common framework for developers and a centralized administrative facility.
- IceBox support is [integrated into IceGrid](#), the server activation and deployment service.

IceBox offers a refreshing change of perspective: developers focus on writing services, not applications. The definition of an application changes as well; using IceBox, an application becomes a collection of discrete services whose composition is determined dynamically by configuration, rather than statically by the linker.

The IceBox Service Interface

Writing an IceBox service requires implementing the `IceBox::Service` interface:

Slice
<pre> module IceBox { local interface Service { void start(string name, Ice::Communicator communicator, Ice::StringSeq args); void stop(); }; }; </pre>

As you can see, a service needs to implement only two operations, `start` and `stop`. These operations are invoked by the server; `start` is called after the service is loaded, and `stop` is called when the IceBox server is shutting down.

The `start` operation is the service's opportunity to initialize itself; this typically includes creating an object adapter and servants. The `name` and `args` parameters supply information from the service's [configuration](#), and the `communicator` parameter is an `Ice::Communicator` object created by the server for use by the service. Depending on the service configuration, this communicator instance may be [shared by other services](#) in the same IceBox server, therefore care should be taken to ensure that items such as object adapters are given unique names.

The `stop` operation must reclaim any resources used by the service. Generally, a service deactivates its object adapter, and may also need to invoke `waitForDeactivate` on the object adapter in order to ensure that all pending requests have been completed before the clean up process can proceed. The server is responsible for destroying the communicator instance that was passed to `start`.

Whether the service's implementation of `stop` should explicitly destroy its object adapter depends on other factors. For example, the adapter should be destroyed if the service uses a shared communicator, especially if the service could eventually be restarted. In other circumstances, the service can allow its adapter to be destroyed as part of the communicator's destruction.

These interfaces are declared as `local` for a reason: they represent a contract between the server and the service, and are not intended to be used by remote clients. Any interaction the service has with remote clients is done via servants created by the service.

IceBox Service Example in C++

The example we present here is taken from the `IceBox/hello` sample program provided in the Ice distribution.

The class definition for our service is quite straightforward:

C++

```

#include <IceBox/IceBox.h>

class HelloServiceI : public IceBox::Service {
public:
    virtual void start(const std::string&,
                      const Ice::CommunicatorPtr&,
                      const Ice::StringSeq&);
    virtual void stop();

private:
    Ice::ObjectAdapterPtr _adapter;
};

```

The member definitions are equally straightforward:

C++

```

#include <Ice/Ice.h>
#include <HelloServiceI.h>
#include <HelloI.h>

using namespace std;

void
HelloServiceI::start(
    const string& name,
    const Ice::CommunicatorPtr& communicator,
    const Ice::StringSeq& args)
{
    _adapter = communicator->createObjectAdapter(name);
    Ice::ObjectPtr object = new HelloI(communicator);
    _adapter->add(object, communicator->stringToIdentity("hello"));
    _adapter->activate();
}

void
HelloServiceI::stop()
{
    _adapter->deactivate();
}

```

The `start` method creates an object adapter with the same name as the service, activates a single servant of type `HelloI` (not shown), and activates the object adapter. The `stop` method simply deactivates the object adapter.

C++ Service Entry Point

The last piece of the puzzle is the *entry point* function, which the IceBox server calls to obtain an instance of the service:

```
C++
```

```
extern "C" {
    ICE_DECLSPEC_EXPORT IceBox::Service*
    create(Ice::CommunicatorPtr communicator)
    {
        return new HelloServiceI;
    }
}
```

In this example, the `create` function returns a new instance of the `Hello` service. The name of the function is not important, but it must have the signature shown above. In particular, the function must have C linkage, accept a single parameter of type `Ice::CommunicatorPtr`, and return a native pointer to `IceBox::Service`.

[Configuring IceBox Services](#) provides more information on entry points and describes how to configure your service into an IceBox server.

IceBox Service Example in Java

As with the C++ example presented in the previous section, the complete source for the Java example can be found in the `IceBox/hello` directory of the Ice distribution. The class definition for our service looks as follows:

```
Java
```

```
public class HelloServiceI implements IceBox.Service
{
    public void
    start(String name, Ice.Communicator communicator, String[] args)
    {
        _adapter = communicator.createObjectAdapter(name);
        Ice.Object object = new HelloI(communicator);
        _adapter.add(object, communicator.stringToIdentity("hello"));
        _adapter.activate();
    }

    public void
    stop()
    {
        _adapter.deactivate();
    }

    private Ice.ObjectAdapter _adapter;
}
```

The `start` method creates an object adapter with the same name as the service, activates a single servant of type `HelloI` (not shown), and activates the object adapter. The `stop` method simply deactivates the object adapter.

The server requires a service implementation to have a default constructor. This is the *entry point* for a Java IceBox service; that is, the server dynamically loads the service implementation class and invokes the default constructor to obtain an instance of the service.

This example is a trivial service, and yours will likely be much more interesting, but this does demonstrate how easy it is to write an IceBox

service. After compiling the service implementation class, it can be configured into an IceBox server as described in [Configuring IceBox Services](#).

IceBox Service Example in C#

The complete source for the C# example can be found in the `IceBox/hello` directory of the Ice distribution. The class definition for our service looks as follows:

```

C#

class HelloServiceI : IceBox.Service
{
    public void
    start(string name, Ice.Communicator communicator, string[] args)
    {
        _adapter = communicator.createObjectAdapter(name);
        _adapter.add(new HelloI(),
communicator.stringToIdentity("hello"));
        _adapter.activate();
    }

    public void
    stop()
    {
        _adapter.deactivate();
    }

    private Ice.ObjectAdapter _adapter;
}

```

The `start` method creates an object adapter with the same name as the service, activates a single servant of type `HelloI` (not shown), and activates the object adapter. The `stop` method simply deactivates the object adapter.

The server requires a service implementation to have a default constructor. This is the entry point for a C# IceBox service; that is, the server dynamically loads the service implementation class from an assembly and invokes the default constructor to obtain an instance of the service.

This example is a trivial service, and yours will likely be much more interesting, but this does demonstrate how easy it is to write an IceBox service. After compiling the service implementation class, it can be configured into an IceBox server as described in [Configuring IceBox Services](#).

IceBox Service Failures

An exception raised by a service's implementation of its entry point, `start`, or `stop` methods causes IceBox to log a message. An exception that occurs during server startup also results in [server termination](#).

A service implementation can indicate a failure by raising `IceBox::FailureException`:

Slice

```
module IceBox {  
  local exception FailureException {  
    string reason;  
  };  
};
```

Note that, as a local exception, C++ users must instantiate `FailureException` with file and line number information:

C++

```
throw IceBox::FailureException(__FILE__, __LINE__, "my error message");
```

- [Inheriting Properties from the IceBox Server](#)
- [Logging Considerations for IceBox Services](#)

Installing an IceBox Service

A service is configured into an IceBox server using a single `IceBox.Service` property. This property serves several purposes: it defines the name of the service, it provides the server with the service entry point, and it defines properties and arguments for the service.

The format of the property is shown below:

```
IceBox.Service.name=entry_point [args]
```

The *name* component of the property key is the service name (IceStorm, in this example). This name is passed to the service's `start` operation, and must be unique among all services configured in the same IceBox server. It is possible, though rarely necessary, to load two or more instances of the same service under different names.

The first argument in the property value is the entry point specification. Any arguments following the entry point specification are examined. If an argument has the form `--name=value`, then it is interpreted as a property definition that appears in the property set of the communicator passed to the service `start` operation. These arguments are removed, and any remaining arguments are passed to the `start` operation in the `args` parameter.

IceBox Service Configuration in C++

For a C++ service, the [entry point](#) must have the form `library[.version]:symbol`, where *library* is the simple name of the service's shared library or DLL, and *symbol* is the name of the entry point function. A "simple name" is one without any platform-specific prefixes or extensions; the server adds appropriate decorations depending on the platform. The simple name may include a leading path, and the version is optional. If specified, the version is embedded in the library name.

As an example, here is how we could configure `IceStorm`, which is implemented as an IceBox service in C++:

```
IceBox.Service.IceStorm=IceStormService,36:createIceStorm
```

IceBox uses the information provided in the entry point specification to compose a library name. For the `IceStorm` example shown above, IceBox on Windows would compose the library name `IceStormService36.dll`. If IceBox is compiled with debug information, it appends a `d` to the library name, so the name becomes `IceStormService36d.dll` instead.

The exact name of the library that is loaded depends on the naming conventions of the platform IceBox executes on. For example, on an OS X machine, the library name is `libIceStormService36.dylib`.

If the simple name does not include a leading path, the shared library or DLL must reside in a directory that appears in `PATH` on Windows or the shared library search path (such as `LD_LIBRARY_PATH`) on POSIX systems.

The entry point function, *symbol*, must have the signature that we originally presented in our [example](#):

C++

```
extern "C" IceBox::Service* function(Ice::CommunicatorPtr);
```

The communicator instance passed to this function is the IceBox server's communicator and should only be used for administrative purposes. For example, the entry point function could use this communicator's logger to display log messages. For a service's normal operations, it must use the communicator that it receives as an argument to its `start` method.

Here is a sample configuration for our C++ service:

```
IceBox.Service.Hello=HelloService:create --Ice.Trace.Network=1 hello
there
```

This configuration results in the creation of a service named `Hello`. The service is expected to reside in `HelloService.dll` on Windows or `libHelloService.so` on Linux, and the entry point function `create` is invoked to create an instance of the service. The argument `--Ice.Trace.Network=1` is converted into a property definition, and the arguments `hello` and `there` become the two elements in the `args` sequence parameter that is passed to the `start` method.

IceBox Service Configuration in Java

For a Java service, the [entry point](#) is typically the class name (including any package) of the service implementation class, but may also include a leading path to a class directory or JAR file. The class must define a public constructor.

To instantiate the service, the IceBox server first checks to see if the service defines a constructor taking an argument of type `Ice.Communicator`. If so, the service invokes this constructor and passes the server's communicator, which should only be used for administrative purposes. For example, the constructor could use this communicator's logger to display log messages. For a service's normal operations, it must use the communicator that it receives as an argument to its `start` method.

If the service does not define a constructor taking an `Ice.Communicator` argument, the server invokes the service's default constructor.

Here is a sample configuration for our [Java example](#):

```
IceBox.Service.Hello=HelloServiceI --Ice.Trace.Network=1 hello there
```

This configuration results in the creation of a service named `Hello`. The service is expected to reside in the class `HelloServiceI`. The argument `--Ice.Trace.Network=1` is converted into a property definition, and the arguments `hello` and `there` become the two elements in the `args` sequence parameter that is passed to the `start` method.

IceBox Service Configuration in C#

The [entry point](#) of a .NET service has the form `assembly:class`. The `assembly` component can be a partially or fully qualified assembly name, such as `hello,Version=0.0.0.0,Culture=neutral`, or an assembly DLL name such as `hello.dll` that may optionally include a leading relative or absolute path name.

The locations that are searched for the assembly depend on how you define the `assembly` component:

Value for <i>assembly</i>	Example	Semantics
---------------------------	---------	-----------

Fully-qualified assembly name (strong-named assembly)	<code>hello,Version=...,Culture=neutral,publicKeyToken=...</code>	<ol style="list-style-type: none"> 1. Checks assemblies that have already been loaded 2. Searches the Global Assembly Cache (GAC) 3. Searches the directory containing the <code>iceboxnet</code> executable
Partially-qualified assembly name	<code>hello</code>	<ol style="list-style-type: none"> 1. Checks assemblies that have already been loaded 2. Searches the directory containing the <code>iceboxnet</code> executable
Relative path name	<code>services\MyService.dll</code>	Path name is relative to <code>iceboxnet</code> 's current working directory. Be sure to include the <code>.dll</code> extension in the path name.
Absolute path name	<code>C:\services\MyService.dll</code>	Assembly must reside at the specified path name. Be sure to include the <code>.dll</code> extension in the path name.

See MSDN for more information on [how the CLR locates assemblies](#).

The `class` component is the complete class name of the service implementation class, which must define a public constructor.

To instantiate the service, the IceBox server first checks to see if the service defines a constructor taking an argument of type `Ice.Communicator`. If so, the service invokes this constructor and passes the server's communicator, which should only be used for administrative purposes. For example, the constructor could use this communicator's logger to display log messages. For a service's normal operations, it must use the communicator that it receives as an argument to its `start` method.

If the service does not define a constructor taking an `Ice.Communicator` argument, the server invokes the service's default constructor.

Here is a sample configuration for our [C# example](#):

```
IceBox.Service.Hello=helloservice.dll:HelloServiceI
--Ice.Trace.Network=1 hello there
```

This configuration results in the creation of a service named `Hello`. The service is expected to reside in the assembly named `helloservice.dll`, implemented by the class `HelloServiceI`. The argument `--Ice.Trace.Network=1` is converted into a property definition, and the arguments `hello` and `there` become the two elements in the `args` sequence parameter that is passed to the `start` method.

Load Order for IceBox Services

By default, the server loads the configured services in an undefined order, meaning services in the same IceBox server should not depend on one another. If services must be loaded in a particular order, the `IceBox.LoadOrder` property can be used:

```
IceBox.LoadOrder=Service1,Service2
```

In this example, `Service1` is loaded first, followed by `Service2`. Any remaining services are loaded after `Service2`, in an undefined order. Each service mentioned in `IceBox.LoadOrder` must have a matching `IceBox.Service` property.

During shutdown, services are stopped in the reverse of the order in which they were loaded.

Using a Shared Communicator

IceBox creates a separate communicator instance for each service by default in order to minimize the chances of accidental conflicts among services. You can optionally specify that certain services use a shared communicator instead by setting `IceBox.UseSharedCommunicator.r.name` properties in the server's configuration:

```
IceBox.Service.Hello=...
IceBox.Service.Printer=...
IceBox.UseSharedCommunicator.Hello=1
IceBox.UseSharedCommunicator.Printer=1
```

A common use case for sharing a communicator between two or more services is enabling the use of [collocation optimizations](#) for invocations among those services. This optimization is not possible with the default behavior that creates a new communicator for each service.

IceBox prepares the property set of this shared communicator as follows:

- If services [inherit the server's properties](#), the property set initially contains the server's properties (excluding `Ice.Admin.Endpoint`s), otherwise the property set starts out empty.
- For each service that uses the shared communicator:
 - Merge its properties into the shared property set, overwriting any existing properties with the same names
 - Remove any properties from the shared property set that the service explicitly clears. For example, the definition `Ice.Trace.Network=` clears any existing setting of `Ice.Trace.Network` in the shared property set.
 - Translate service-specific command-line settings into properties (e.g., `--Hello.Debug=1`)

Service properties are merged in the same order as the [services are loaded](#). As a result, the final value of a property that is defined by multiple services depends on the order in which those services are loaded. Let's expand our example to demonstrate this behavior:

```
# File: server.cfg
IceBox.Service.Hello=... --Ice.Config=hello.cfg --Hello.Debug=1
IceBox.Service.Printer=... --Ice.Config=printer.cfg
IceBox.UseSharedCommunicator.Hello=1
IceBox.UseSharedCommunicator.Printer=1
IceBox.InheritProperties=1
IceBox.LoadOrder=Hello,Printer
Ice.Trace.Network=1

# File: hello.cfg
Ice.Trace.Network=2

# File: printer.cfg
Ice.Trace.Network=3
```

The two services `Hello` and `Printer` use the shared communicator, and all services inherit the server's properties. As IceBox prepares the shared property set, the initial value of `Ice.Trace.Network` is 1 as defined in the (inherited) server's configuration. The `IceBox.LoadOrder` property specifies that the `Hello` service should be loaded first, therefore the `Ice.Trace.Network` property momentarily has the value 2 but ultimately has the value 3 after the properties for the `Printer` service are merged.

If we change the value of `IceBox.LoadOrder` so that IceBox loads `Printer` first, the value for `Ice.Trace.Network` in the shared communicator will be 2 instead because the setting in `hello.cfg` overrides all previous values.

Inheriting Properties from the IceBox Server

By default, a service does not inherit the IceBox server's configuration properties. For example, consider the following server configuration:

```
IceBox.Service.Weather=... --Ice.Config=svc.cfg
Ice.Trace.Network=1
```

The `Weather` service only receives the properties that are defined in its `IceBox.Service` property. In the example above, the service's communicator is initialized with the properties from the file `svc.cfg`.

If services need to inherit the IceBox server's configuration properties, define the `IceBox.InheritProperties` property in the IceBox server's configuration:

```
IceBox.Service.Weather=... --Ice.Config=svc.cfg
Ice.Trace.Network=1
IceBox.InheritProperties=1
```

All services inherit the server's properties when `IceBox.InheritProperties` is set to a non-zero value. The service inherits all the properties of the IceBox servers, with the exception of properties whose names start with `Ice.Admin`.

The properties of the [shared communicator](#) are also affected by this setting.

Logging Considerations for IceBox Services

In Ice 3.4 and earlier, the IceBox server configures a variation of its own logger in the communicator that it creates for each service (the only difference being a service-specific logging prefix), therefore the logging scheme you configure for the IceBox server must be appropriate for all of its services. The only way a service can configure a different logger is by using a [logger plug-in](#).

As of Ice 3.5, the IceBox server only configures a logger for a service if that service has not already specified its own logger via the `Ice.LogFile` or `Ice.UseSyslog` properties.

Starting the IceBox Server

Incorporating everything we discussed previously, we can now configure and start IceBox servers.

On this page:

- [Starting the C++ IceBox Server](#)
- [Starting the Java IceBox Server](#)
- [Starting the C# IceBox Server](#)
- [IceBox Server Failures](#)

Starting the C++ IceBox Server

The configuration file for our example C++ service is shown below:

```
IceBox.Service.Hello=HelloService:create
Hello.Endpoints=tcp -p 10001
```

Notice that we define an endpoint for the object adapter created by the `Hello` service.

Assuming these properties reside in a configuration file named `config`, we can usually start the C++ IceBox server as follows:

```
$ icebox --Ice.Config=config
```

Additional command line options are supported, including those that allow the server to run as a [Windows service](#) or [Unix daemon](#).

Windows Notes

Several versions of the `icebox` executable are included in the binary distribution for Windows. In the table below, `<installdir>` represents the directory in which you installed the Ice binary distribution.

Executable	Notes
<code><installdir>\bin\icebox</code>	Loads 32-bit IceBox services compiled with Visual Studio 2013
<code><installdir>\bin\iceboxd</code>	Loads 32-bit debug IceBox services compiled with Visual Studio 2013
<code><installdir>\bin\x64\icebox</code>	Loads 64-bit IceBox services compiled with Visual Studio 2013
<code><installdir>\bin\x64\iceboxd</code>	Loads 64-bit debug IceBox services compiled with Visual Studio 2013
<code><installdir>\bin\vc1xx\icebox</code>	Loads 32-bit IceBox services compiled with vc1xx
<code><installdir>\bin\vc1xx\iceboxd</code>	Loads 32-bit debug IceBox services compiled with vc1xx
<code><installdir>\bin\vc1xx\x64\icebox</code>	Loads 64-bit IceBox services compiled with vc1xx
<code><installdir>\bin\vc1xx\x64\iceboxd</code>	Loads 64-bit debug IceBox services compiled with vc1xx

vc1xx corresponds to the following versions of Visual Studio:

Compiler Name	Visual Studio Version	Notes
vc140	Visual Studio 2015	
vc120	Visual Studio 2013	The default version for Ice 3.6, uses <code>bin</code> and <code>bin\x64</code> with no subdirectory
vc110	Visual Studio 2012	

vc100	Visual Studio 2010
-------	--------------------

Linux Notes

Several versions of the `icebox` executable are included in the binary distributions for Linux platforms:

Executable	Notes
<code>icebox</code>	Loads 64-bit IceBox services; only available on 64-bit architectures
<code>icebox++11</code>	Loads 64-bit IceBox services compiled in C++11 or C++14 mode; only available on 64-bit architectures
<code>icebox32</code>	Loads 32-bit IceBox services
<code>icebox32++11</code>	Loads 32-bit IceBox services compiled in C++11 or C++14 mode

Starting the Java IceBox Server

Our Java configuration is nearly identical to the C++ version, except for the entry point specification:

```
IceBox.Service.Hello=HelloServiceI
Hello.Endpoints=tcp -p 10001
```

Notice that we define an endpoint for the object adapter created by the `Hello` service.

Assuming these properties reside in a configuration file named `config`, we can start the Java IceBox server as follows:

```
$ java IceBox.Server --Ice.Config=config
```

Starting the C# IceBox Server

The configuration file for our example C# service is shown below:

```
IceBox.Service.Hello=helloservice.dll:HelloService
Hello.Endpoints=tcp -p 10001
```

Notice that we define an endpoint for the object adapter created by the `Hello` service.

Assuming these properties reside in a configuration file named `config`, we can start the C# IceBox server as follows:

```
$ iceboxnet --Ice.Config=config
```

IceBox Server Failures

At startup, an IceBox server inspects its configuration for all properties having the prefix `IceBox.Service` and initializes each service. If initialization fails for a service, the IceBox server invokes the `stop` operation on any initialized services, reports an error, and terminates.

See Also

- [The Server-Side main Function in C++](#)
- [IceBox.*](#)

IceBox Administration

An IceBox server internally creates an object called the service manager that is responsible for loading and initializing the configured services. You can optionally expose this object to remote clients, such as the IceBox and IceGrid administrative utilities, so that they can execute certain administrative tasks.

On this page:

- [IceBox Administrative Slice Interfaces](#)
 - [The IceBox ServiceManager Interface](#)
 - [The IceBox ServiceObserver Interface](#)
- [Enabling the Service Manager](#)
- [IceBox Admin Facets](#)
- [IceBox Administrative Client Configuration](#)
- [IceBox Administrative Utility](#)

IceBox Administrative Slice Interfaces

The Slice definitions shown below comprise the IceBox administrative interface:

Slice
<pre> module IceBox { exception AlreadyStartedException {}; exception AlreadyStoppedException {}; exception NoSuchServiceException {}; interface ServiceObserver { void servicesStarted(Ice::StringSeq services); void servicesStopped(Ice::StringSeq services); }; interface ServiceManager { idempotent Ice::SliceChecksumDict getSliceChecksums(); void startService(string service) throws AlreadyStartedException, NoSuchServiceException; void stopService(string service) throws AlreadyStoppedException, NoSuchServiceException; void addObserver(ServiceObserver* observer); void shutdown(); }; }; </pre>

The IceBox ServiceManager Interface

The `ServiceManager` interface provides access to the service manager object of an IceBox server. It defines the following operations:

- `getSliceChecksums`
Returns a dictionary of `checksums` that allows a client to verify that it is using the same Slice definitions as the server.
- `startService`
Starts a pre-configured service that is currently inactive. This operation cannot be used to add new services at run time, nor will it

cause an inactive service's implementation to be reloaded. If no matching service is found, the operation raises `NoSuchServiceException`. If the service is already active, the operation raises `AlreadyStartedException`.

- `stopService`
Stops an active service but does not unload its implementation. The operation raises `NoSuchServiceException` if no matching service is found, and `AlreadyStoppedException` if the service is stopped at the time `stopService` is invoked.
- `addObserver`
Adds an observer that is called when `IceBox` services are started or stopped. The service manager ignores operations that supply a null proxy, or a proxy that has already been registered.
- `shutdown`
Terminates the services and shuts down the `IceBox` server.

The `IceBox` `ServiceObserver` Interface

An administrative client that is interested in receiving callbacks when `IceBox` services are started or stopped must implement the `ServiceObserver` interface and register the callback object's proxy with the service manager using its `addObserver` operation. The `ServiceObserver` interface defines two operations:

- `servicesStarted`
Invoked immediately upon registration to supply the current list of active services, and thereafter each time a service is started.
- `servicesStopped`
Invoked whenever a service is stopped, and when the `IceBox` server is shutting down.

The `IceBox` server unregisters an observer if the invocation of either operation causes an exception.

Our discussion of `IceGrid` includes an example that demonstrates how to register a `ServiceObserver` callback with an `IceBox` server deployed with `IceGrid`.

Enabling the Service Manager

`IceBox`'s administrative functionality is disabled by default. You can enable it using the `Ice` [administrative facility](#) by defining endpoints for the `Ice.Admin` object adapter with the property `Ice.Admin.Endpoints`.

The `Ice.Admin` object adapter is enabled automatically in an `IceBox` server that is [deployed by IceGrid](#).

With the administrative facility enabled, `IceBox` registers an administrative facet with the name `IceBox.ServiceManager`. We discuss the [identity](#) of the `admin` object below.

Exposing the service manager makes an `IceBox` server vulnerable to denial-of-service attacks from malicious clients. Consequently, you should [choose the endpoints and transports carefully](#).

IceBox Admin Facets

When you [enable the service manager](#), `IceBox` adds it as a facet of the server's `admin` object. As a result, the identity of the service manager is the same as that of the `admin` object, and the name of its facet is `IceBox.ServiceManager`.

The identity of the `admin` object uses either a UUID or a statically-configured value for its category, and the value `admin` for its name. For example, consider the following property definitions:

```
Ice.Admin.Endpoints=tcp -h 127.0.0.1 -p 10001
Ice.Admin.InstanceName=IceBox
```

In this case, the identity of the `admin` object is `IceBox/admin`.

IceBox also creates in each service communicator ([shared communicator](#) and per-service communicator) all the built-in facets enabled on its main communicator, and adds all these facets, except the `Process` facet, to its admin object. These facets are named `IceBox.Service.service-name.facet-name`, where *service-name* corresponds to the service name (for example `Hello` or `IceStorm`), and *facet-name* is the name of the built-in facet (for example `Properties` or `Logger`).

You can instruct IceBox to skip the admin facets for a specific service by setting the property `Ice.Admin.Enabled` to a numeric value (typically 0) in the configuration for that service.

IceBox Administrative Client Configuration

A client requiring administrative access to the service manager must first obtain (or be able to construct) a proxy for the `admin` object. The default identity of the `admin` object uses a UUID for its category, which means the client cannot predict the identity and therefore will be unable to construct the proxy itself. If the IceBox server is deployed with IceGrid, the client can use the technique described in our discussion of [IceGrid](#) to access its `admin` object.

In the absence of IceGrid, the IceBox server should set the `Ice.Admin.InstanceName` property if remote administration is required. In so doing, the identity of the `admin` object becomes well-known, and a client can construct the proxy on its own. For example, let's assume that the IceBox server defines the following property:

```
Ice.Admin.InstanceName=IceBox
```

A client can define the proxy for the `admin` object in a configuration property as follows:

```
ServiceManager.Proxy=IceBox/admin -f IceBox.ServiceManager -h 127.0.0.1
-p 10001
```

The `proxy option` `-f IceBox.ServiceManager` specifies the name of the service manager's administrative facet.

IceBox Administrative Utility

IceBox includes C++ and Java implementations of an administrative utility. The utilities have the same usage:

```

Usage: iceboxadmin [options] [command...]
Options:
-h, --help           Show this message.
-v, --version        Display the Ice version.

Commands:
start SERVICE        Start a service.
stop SERVICE         Stop a service.
shutdown             Shutdown the server.

```

The C++ utility is named `iceboxadmin`, while the Java utility is represented by the class `IceBox.Admin`.

The `start` command is equivalent to invoking `startService` on the service manager interface. Its purpose is to start a pre-configured service; it cannot be used to add new services at run time. Note that this command does not cause the service's implementation to be reloaded.

Similarly, the `stop` command stops the requested service but does not cause the IceBox server to unload the service's implementation.

The `shutdown` command stops all active services and shuts down the IceBox server.

The C++ and Java utilities obtain the service manager's proxy from the property `IceBoxAdmin.ServiceManager.Proxy`, therefore this proxy must be defined in the program's configuration file or on the command line, and the proxy's contents depend on the server's configuration. If the IceBox server is deployed with IceGrid, we recommend using the IceGrid [administrative utilities](#) instead, which provide equivalent commands for administering an IceBox server. Otherwise, the proxy should have the [endpoints](#) and [identity](#) configured for the server.

IceDiscovery

IceDiscovery provides a location service using UDP multicast that enables Ice applications to discover objects and object adapters.

On this page:

- [IceDiscovery Overview](#)
 - [IceDiscovery Concepts](#)
 - [IceDiscovery vs. IceGrid](#)
- [Installing IceDiscovery](#)

 - [Configuring IceDiscovery in Servers](#)
 - [Configuring a Locator Proxy](#)
- [Using IceDiscovery](#)
 - [IceDiscovery Design Decisions](#)
 - [IceDiscovery Sample Programs](#)

IceDiscovery Overview

IceDiscovery is an [Ice plug-in](#) that must be installed in all of the clients and servers in your application. Once installed, IceDiscovery enables a client to dynamically locate objects using [indirect proxies](#), which avoids the need for the client to statically configure the endpoints of the objects it uses. In a server, IceDiscovery makes objects and object adapters available for discovery with minimal additional effort.

IceDiscovery Concepts

This section reviews some concepts that will help you as you learn more about IceDiscovery.

Indirect Proxies

[Indirect proxies](#) have two formats:

- `identityOnly`
This format uses only the object's identity.
- `identity@adapterId`
This format combines the object identity and an adapter identifier. This identifier can either refer to a specific object adapter or a replica group.

Notice that neither format includes any endpoints, such as `tcp -h somehost -p 10000`. The ability to resolve an indirect proxy using only symbolic information, much like a DNS lookup, helps to loosen the coupling between clients and servers.

The Ice core delegates the resolution of indirect proxies to a standardized [locator facility](#). This architecture offers a significant advantage: Ice applications can change locator settings via external configuration without requiring any changes to the application code.

Plug-in Facility

In addition to the locator facility, Ice also defines a standard plug-in facility through which applications can modify the functionality of the Ice core or add new capabilities, again using only external configuration.

IceDiscovery combines these two facilities: it's installed as a standard Ice plug-in via configuration, and this plug-in installs a custom locator implementation that enables discovery using UDP multicast.

We'll describe later how to install IceDiscovery in your clients and servers.

Replication

The locator facility includes support for replicated object adapters. For example, if `Adapter1` and `Adapter2` both participate in a replicate group identified as `TheGroup`, then the indirect proxy `someObject@TheGroup` could resolve to either `someObject@Adapter1` or `someObject@Adapter2`. Although there are two adapters that host `someObject` at the implementation level, both object adapters incarnate the

same logical object. The application is responsible for ensuring that any persistent state is properly synchronized between the servers that host replicated object adapters.

Requests and Replies

In general terms, here's what happens when a client uses an indirect proxy for the first time:

- The client's IceDiscovery plug-in transparently broadcasts a "lookup" request via multicast
- The lookup request includes the identity of the target object, the object adapter identifier (if any), and a proxy that the target server's IceDiscovery plug-in can use to communicate directly with the client's IceDiscovery plug-in
- Every program that installs the plug-in and uses the same addressing information receives the client's multicast lookup request; only the server that hosts the target object sends a reply
- The client plug-in waits for a reply using a configurable timeout period; if it doesn't receive a reply, it tries again a configurable number of times before giving up
- The target server's IceDiscovery plug-in sends a reply including a proxy for the target object, which the client's plug-in receives and returns to the client's application code
- At this point, the client's application code uses the returned proxy's endpoints to communicate directly with the target object using whichever transports its object adapter supports

Only the initial lookup request occurs over multicast. The reply from the server plug-in to the client plug-in occurs using UDP unicast (by default). All subsequent communication between the client and the target object proceed directly without intervention by the IceDiscovery plug-in.

IceDiscovery Domains

Nothing prevents two unrelated IceDiscovery applications from using the same multicast address and port, which means a plug-in from Application A can receive lookup requests from a client in Application B for objects and object adapters that might coincidentally match those of Application A. To avoid this situation, the applications should configure unique *domain identifiers*. The client plug-in includes its domain identifier in each lookup request it sends so that a server plug-in can ignore any requests that don't match its own domain identifier.

IceDiscovery vs. IceGrid

IceDiscovery and IceGrid both provide a location service but it helps to understand their differences when deciding which one to use in an application. Use IceDiscovery when your application needs a lightweight, transient location service. IceGrid's location service is backed by a persistent database and represents just one of the features that IceGrid offers, along with remote administration, on-demand server activation, and many others. If you need a location service but aren't yet ready to dive into IceGrid, start out using IceDiscovery; migrating to IceGrid later won't be difficult.

We provide a plug-in similar to IceDiscovery called [IceLocatorDiscovery](#) that integrates with IceGrid.

Installing IceDiscovery

The IceDiscovery plug-in must be installed in every client that needs to locate objects and in all of the servers that host those objects.

You can use the `Ice.Plugin` property to load and install the plug-in at runtime; the property value depends on the language mapping you're using:

```
# C++, Python, PHP, Ruby
Ice.Plugin.IceDiscovery=IceDiscovery:createIceDiscovery

# Java
Ice.Plugin.IceDiscovery=IceDiscovery:IceDiscovery.PluginFactory

# .NET
Ice.Plugin.IceDiscovery=IceDiscovery:IceDiscovery.PluginFactory
```

If using C++, instead of dynamically loading the plug-in at runtime your application can explicitly link with and register the plug-in. To register the plug-in, you must call the `Ice::registerIceDiscovery(bool loadOnInitialize = true)` function before the communicator initialization. The `loadOnInitialize` parameter specifies if the plug-in is installed when the communicator is initialized. If set to `false`, you will need to enable the plugin by setting the `Ice.Plugin.IceDiscovery` property to 1.

`Ice::registerIceDiscovery` is a simple helper function that calls `Ice::registerPluginFactory`.

Refer to the next section for information on configuring the plug-in.

Configuring IceDiscovery

Applications configure the `IceDiscovery` plug-in using configuration properties; the plug-in does not provide a local API.

IceDiscovery Property Overview

The `IceDiscovery` plug-in supports a number of [configuration properties](#), most of which affect the endpoints that the plug-in uses to communicate with its peers:

- **Lookup endpoint**
This is the multicast endpoint on which all lookup queries are broadcast. It must use an IPv4 or IPv6 address in the multicast range with a fixed port.
- **Reply endpoint**
This is the endpoint on which a client receives replies from servers. In general, this endpoint should not use a fixed port.

The plug-in uses sensible default values for all of its configuration properties, such that it's often unnecessary to define any of the plug-in's properties. However, it's still important to understand how the plug-in derives its endpoint information.

`IceDiscovery` creates several object adapters in each communicator in which it's installed, including the object adapters `IceDiscovery.Multicast` and `IceDiscovery.Reply`. These object adapters correspond to the Lookup and Reply endpoints mentioned above, respectively. You can configure the endpoints of these object adapters directly by defining the properties `IceDiscovery.Multicast.Endpoints` and `IceDiscovery.Reply.Endpoints`. If you don't define an endpoint for an object adapter, the plug-in computes it as follows:

- `IceDiscovery.Multicast.Endpoints=udp -h address -p port [--interface interface]`
- `IceDiscovery.Reply.Endpoints=udp [--interface interface]`

where

- `address` is the value of `IceDiscovery.Address` - defaults to `239.255.0.1` if IPv4 is enabled or `ff15::1` if IPv4 is disabled
- `port` is the value of `IceDiscovery.Port` - defaults to `4061`
- `interface` is the value of `IceDiscovery.Interface`

Consequently, if you don't define any of these properties, the plug-in uses the following endpoints by default (assuming IPv4):

- `IceDiscovery.Multicast.Endpoints=udp -h 239.255.0.1 -p 4061`
- `IceDiscovery.Reply.Endpoints=udp`

Finally, you can also override the default endpoint that a client uses to broadcast its lookup queries by defining `IceDiscovery.Lookup`, otherwise the plug-in computes this endpoint as follows:

- `IceDiscovery.Lookup=udp -h address -p port [--interface interface]`

This endpoint must use the same address and port as `IceDiscovery.Multicast.Endpoints`.

As you can see, the properties `IceDiscovery.Address`, `IceDiscovery.Port` and `IceDiscovery.Interface` are simply used as convenient shortcuts for customizing the details of the plug-in's endpoints. For example, suppose we want to use a different multicast address and port:

```
IceDiscovery.Address=239.255.0.99
IceDiscovery.Port=8000
```

The plug-in derives the following properties from these settings:

```
IceDiscovery.Multicast.Endpoints=udp -h 239.255.0.99 -p 8000
IceDiscovery.Lookup=udp -h 239.255.0.99 -p 8000
```

All of the clients and servers comprising an application must use the same values for `IceDiscovery.Address` and `IceDiscovery.Port`. You should also consider defining `IceDiscovery.DomainId` to avoid any potential collisions from unrelated applications that happen to use the same address and port.

Configuring IceDiscovery in Clients

Aside from [installing the plug-in](#) and optionally [configuring its addressing information](#), no other configuration steps are required for an IceDiscovery client.

Configuring IceDiscovery in Servers

In addition to [installing the plug-in](#) and optionally [configuring its addressing information](#), you also need to configure an identifier for each of a server's object adapters that hosts well-known (discoverable) objects. For example, suppose a server creates an object adapter named `Hello` and we want its objects to be discoverable. We can configure the object adapter's `AdapterId` property as follows:

```
Hello.AdapterId=HelloAdapter
```

The identifier you select must be globally unique among the servers sharing the same address and domain settings.

To use object adapter replication, you'll need to include the `ReplicaGroupId` property for each replicated object adapter:

```
Hello.AdapterId=Hello1
Hello.ReplicaGroupId=HelloAdapter
```

The indirect proxy `someObject@Hello1` refers to an object in this particular object adapter, whereas the indirect proxy `someObject@HelloAdapter` could refer to any object having the identity `someObject` in any of the object adapters participating in the replica group `HelloAdapter`.

Configuring a Locator Proxy

The IceDiscovery plug-in calls `setDefaultLocator` on its communicator at startup, therefore it's not necessary for you to configure a locator proxy.

Using IceDiscovery

As its name implies, the IceDiscovery plug-in enables clients to locate objects at run time, as long as the servers hosting those objects are actively running and using the same configuration settings for address, port, domain, and so on. Since IceDiscovery relies on UDP multicast to broadcast the lookup requests, you'll need to ensure that your network supports this transport.

IceDiscovery Design Decisions

From a design perspective, incorporating IceDiscovery into your application requires answering the following questions:

- What is the set of well-known objects that will be available for discovery?
Applications typically don't need to make *every* object available for discovery. Rather, designs often only make "bootstrap" or "factory" objects available for discovery, while proxies for other objects can be obtained by invoking operations on these initial objects.
- How should clients refer to these well-known objects?
As we explained [earlier](#), proxies for well-known objects can take two forms: an identity by itself, or an identity with an adapter identifier, such as `factory` and `factory@AccountAdapter`, respectively. Clearly, using only identities places a greater burden on the application to ensure that they are globally unique among all of the clients and servers sharing the same address and domain settings. Including an object adapter identifier can help to further partition the object namespace, so that `factory@AccountAdapter` and `factory@AdminAdapter` represent distinct objects without requiring artificially unique identities such as `accountFactory` and `adminFactory`.
- Can unrelated applications share the same multicast address and port?
If so, select unique domain identifiers for the applications and configure `IceDiscovery.DomainId` properties to avoid the potential for subtle bugs.
- Do you need replicated objects?
Replicated object adapters can improve the fault tolerance of your application by allowing independent server processes to implement the same logical objects. Configure your servers as described above, and ensure your clients resolve indirect proxies using the replica group identifiers.

IceDiscovery provides enough flexibility to support a wide variety of application architectures. If you need additional functionality, consider using IceGrid instead. Note also that IceGrid supports its own version of IceDiscovery, so that migrating an existing IceDiscovery application should be straightforward.

IceDiscovery Sample Programs

The Ice distribution includes two IceDiscovery sample programs:

- `hello` - A basic client/server application
- `replication` - An application that demonstrates the use of object adapter replication

Refer to the `README` files in the demo source directories for more information on these examples.

IceLocatorDiscovery

This page describes IceLocatorDiscovery, an Ice plug-in that enables the discovery of IceGrid and custom locators via UDP multicast.

On this page:

- [IceLocatorDiscovery Overview](#)
- [Installing IceLocatorDiscovery](#)
- [Configuring IceLocatorDiscovery](#)
 - [IceLocatorDiscovery Property Overview](#)
 - [Configuring IceLocatorDiscovery in User Applications](#)
 - [Configuring IceLocatorDiscovery in IceGrid Administrative Clients](#)
 - [Configuring IceLocatorDiscovery in an IceGrid Registry](#)
 - [Configuring IceLocatorDiscovery in an IceGrid Node](#)

IceLocatorDiscovery Overview

IceLocatorDiscovery is an [Ice plug-in](#) introduced in Ice 3.6 that discovers IceGrid and custom [locators](#) on a network using UDP multicast. Once installed, the plug-in automatically and transparently issues a multicast query in an attempt to find one or more locators, collects the responses, and configures the Ice run time accordingly. The primary advantage of using IceLocatorDiscovery is that it eliminates the need to manually configure and maintain the `Ice.Default.Locator` property that has traditionally been necessary in prior Ice releases. It's even more helpful in a [replicated IceGrid deployment](#) consisting of a master replica and one or more slave replicas, where the `Ice.Default.Locator` property would normally include endpoints for some or all of the replicas. Avoiding the need to statically configure the locator endpoints relieves some of the administrative burden, simplifies deployment and configuration tasks, and adds more flexibility to your application designs.

You can think of IceLocatorDiscovery as an application-specific version of [IceDiscovery](#) geared primarily toward IceGrid users.

Installing IceLocatorDiscovery

The IceLocatorDiscovery plug-in must be installed in every client that needs to locate objects; you can optionally install it in IceGrid nodes and registry replicas.

You can use the `Ice.Plugin` property to install the plug-in; the property value depends on the language mapping you're using:

```
# C++, Python, PHP, Ruby
Ice.Plugin.IceLocatorDiscovery=IceLocatorDiscovery:createIceLocatorDiscovery

# Java
Ice.Plugin.IceLocatorDiscovery=IceLocatorDiscovery:IceLocatorDiscovery.PluginFactory

# .NET
Ice.Plugin.IceLocatorDiscovery=IceLocatorDiscovery:IceLocatorDiscovery.PluginFactory
```

If using C++, instead of dynamically loading the plug-in at runtime your application can explicitly link with and register the plug-in. To register the plug-in, you must call the `Ice::registerIceLocatorDiscovery(bool loadOnInitialize = true)` function before the communicator initialization. The `loadOnInitialize` parameter specifies if the plug-in is installed when the communicator is initialized. If set to `false`, you will need to enable the plugin by setting the `Ice.Plugin.IceLocatorDiscovery` property to 1.

`Ice::registerIceLocatorDiscovery` is a simple helper function that calls `Ice::registerPluginFactory`.

Refer to the next section for information on configuring the plug-in.

Configuring IceLocatorDiscovery

Applications configure the IceLocatorDiscovery plug-in using configuration properties; the plug-in does not provide a local API.

IceLocatorDiscovery Property Overview

The IceDiscovery plug-in supports a number of [configuration properties](#), many of which affect the endpoints that the plug-in uses for its queries:

- **Lookup endpoint**
This is the multicast endpoint on which all lookup queries are broadcast. It must use an IPv4 or IPv6 address in the multicast range with a fixed port.
- **Reply endpoint**
This is the endpoint on which the plug-in receives replies from locators (an IceGrid registry is the most common example of a locator). In general, this endpoint should not use a fixed port.

The plug-in uses sensible default values for all of its configuration properties, such that it's often unnecessary to define any of the plug-in's properties. However, it's still important to understand how the plug-in derives its endpoint information.

First, you can override the default endpoint that the plug-in uses to broadcast its queries by defining `IceLocatorDiscovery.Lookup`, otherwise the plug-in computes this endpoint as follows:

```
IceLocatorDiscovery.Lookup=udp -h address -p port [--interface interface]
```

where

- `address` is the value of `IceLocatorDiscovery.Address` - defaults to `239.255.0.1` if IPv4 is enabled or `ff15::1` if IPv4 is disabled
- `port` is the value of `IceLocatorDiscovery.Port` - defaults to `4061`
- `interface` is the value of `IceLocatorDiscovery.Interface`

For IceGrid users, the lookup endpoint must use the same multicast address and port as `IceGrid.Registry.Discovery.Endpoints` in the registry configuration.

IceLocatorDiscovery also creates object adapters in each communicator in which it's installed, including the object adapter `IceLocatorDiscovery.Reply`. This object adapter corresponds to the Reply endpoint mentioned above.

As you can see, the properties `IceLocatorDiscovery.Address`, `IceLocatorDiscovery.Port` and `IceLocatorDiscovery.Interface` are simply used as convenient shortcuts for customizing the details of the plug-in's endpoints. For example, suppose we want to use a different multicast address and port:

```
IceLocatorDiscovery.Address=239.255.0.99
IceLocatorDiscovery.Port=8000
```

The plug-in derives the following property from these settings:

```
IceLocatorDiscovery.Lookup=udp -h 239.255.0.99 -p 8000
```

All of the components of an IceGrid application must use the same multicast address and port. You should also consider defining `IceLocatorDiscovery.InstanceName` to avoid any potential collisions from unrelated IceGrid applications that happen to use the same address and port.

Configuring IceLocatorDiscovery in User Applications

For a client application, remove any existing definition of `Ice.Default.Locator`, then [install the plug-in](#) and optionally [configuring its addressing information](#).

For a server deployed with IceGrid, you normally don't need to install the IceLocatorDiscovery plug-in.

Configuring IceLocatorDiscovery in IceGrid Administrative Clients

Support for multicast discovery is built into the [command-line](#) and [graphical](#) IceGrid administrative utilities, therefore you don't need to install the plug-in. Both utilities support [configuration properties](#) similar to the ones we described above for defining the multicast address and port.

Configuring IceLocatorDiscovery in an IceGrid Registry

An IceGrid registry does not need the plug-in if it's the master replica or the only registry in a deployment, although there's no harm in installing it. The plug-in is useful for slave replicas because it allows them to locate the current master without statically configuring the master's endpoints. Configure the plug-in for slave replicas just like you would for any C++ client.

IceGrid registries listen for multicast discovery queries by default, but you can disable this feature by setting `IceGrid.Registry.Discovery.Enabled` to zero.

If you've changed the default multicast address or port for IceLocatorDiscovery, you must also make corresponding changes to the configuration of each registry. The registry supports properties similar to those of IceLocatorDiscovery:

- `IceGrid.Registry.Discovery.Address`
- `IceGrid.Registry.Discovery.Port`
- `IceGrid.Registry.Discovery.Interface`

These properties influence the endpoint on which the registry listens for multicast discovery queries. If you don't override the endpoint by setting `IceGrid.Registry.Discovery.Endpoints`, the registry uses these properties to compute its endpoint as follows:

```
IceGrid.Registry.Discovery.Endpoints=udp -h address -p port [--interface interface]
```

You don't need to define any `IceGrid.Registry.Discovery.*` properties if you want the registry to listen for discovery queries on its default multicast address and port.

Configuring IceLocatorDiscovery in an IceGrid Node

The plug-in is useful for IceGrid nodes because it allows them to locate the registry without statically configuring the registry's endpoints. Configure nodes just like you would for any C++ client.

IceSSL

Security is an important consideration for many distributed applications, both within corporate intranets as well as over untrusted networks, such as the Internet. The ability to protect sensitive information, ensure its integrity, and verify the identities of the communicating parties is essential for developing secure applications. With those goals in mind, Ice includes the IceSSL *plug-in* that provides these capabilities using the Secure Socket Layer (SSL) protocol.

Although security is an optional component of Ice, it is not an afterthought. The IceSSL plug-in integrates easily into existing Ice applications, in most cases requiring nothing more than configuration changes. Naturally, some additional effort is required to create the necessary security infrastructure for an application, but in many enterprises this work will have already been done.

IceSSL is available for C++, Java and .NET applications. Python, PHP and Ruby applications can use IceSSL for C++ via configuration.

On this page:

- [Overview of SSL](#)
- [Public Key Infrastructure](#)
- [Requirements](#)

Overview of SSL

The Secure Socket Layer (SSL) protocol is the de facto standard for secure network communication. Its support for authentication, non-repudiation, data integrity, and strong encryption makes it the logical choice for securing Ice applications.

SSL is the protocol [1] that enables Web browsers to conduct secure transactions and therefore is one of the most commonly used protocols for secure network communication. You do not need to know the technical details of the SSL protocol in order to use IceSSL successfully (and those details are outside the scope of this text). However, it would be helpful to have a high-level understanding of how the protocol works and the infrastructure required to support it.

SSL provides a secure environment for communication (without sacrificing too much performance) by combining a number of cryptographic techniques:

- public key encryption
- symmetric (shared key) encryption
- message authentication codes
- digital certificates

When a client establishes an SSL connection to a server, a *handshake* is performed. During a typical handshake, digital certificates that identify the communicating parties are validated, and symmetric keys are exchanged for encrypting the session traffic. Public key encryption, which is too slow to be used for the bulk of a session's data transfer, is used heavily during the handshaking phase. Once the handshake is complete, SSL uses message authentication codes to ensure data integrity, allowing the client and server to communicate at will with reasonable assurance that their messages are secure.

Public Key Infrastructure

Security requires trust, and public key cryptography by itself does nothing to establish trust. SSL addresses the issue of trust using Public Key Infrastructure (PKI) [2], which binds public keys to identities using certificates. A certificate *issuer* creates a certificate for an entity, called the *subject*. The subject is often a person, but it may also be a computer or a specific application. The subject's identity is represented by a *distinguished name*, which includes information such as the subject's name, organization and location. A certificate alone is not sufficient to establish the subject's identity, however, as anyone can create a certificate for a particular distinguished name.

In order to authenticate a certificate, we need a third-party to guarantee that the certificate belongs to the subject described by the distinguished name. This third party, called a Certificate Authority (CA), expresses this guarantee by using its own private key to sign the subject's certificate. Combining the CA's certificate with the subject's certificate forms a *certificate chain* that provides SSL with most of the information it needs to authenticate the remote peer. In many cases, the chain contains only the aforementioned two certificates, but it is also possible for the chain to be longer when the *root* CA issues a certificate that the subject may use to sign other certificates. Regardless of the length of the chain, this scheme can only work if we trust that the root CA has sufficiently verified the identity of the subject before issuing the certificate.

An implementation of the SSL protocol also needs to know which root CAs we trust. An application supplies that information as a list of certificates representing the trusted root CAs. With that list in hand, the SSL implementation authenticates a peer by obtaining the peer's certificate chain and examining it carefully for validity. If we view the chain as a hierarchy with the root CA certificate at the top and the peer's certificate at the bottom, we can describe SSL's validation activities as follows:

- The root CA certificate must be self-signed and be present among the application's trusted CA certificates.
- All other certificates in the chain must be signed by the one immediately preceding it.
- The certificates must not be expired or revoked.

These tests certify that the chain is valid, but applications often require the chain to undergo more intensive scrutiny to determine whether the chain is [trustworthy](#).

Commercial CAs exist to supply organizations with a reliable source of certificates, but in many cases a private CA is completely sufficient. You can create and manage your CA using freely-available tools, and in fact Ice includes a [collection of utilities](#) that simplify this process.

Depending on your implementation language, it may also possible to avoid the use of certificates altogether; encryption is still used to obscure the session traffic, but the benefits of authentication are sacrificed in favor of reduced complexity and administration.

Requirements

Integrating IceSSL into your application often requires no changes to your source code, but does involve the following administrative tasks:

- creating a public key infrastructure (if necessary)
- configuring the IceSSL plug-in
- modifying your application's configuration to install the IceSSL plug-in and use secure connections

The remainder of this discussion concentrates on plug-in configuration and programming.

Using IceSSL

Incorporating IceSSL into your application requires installing the plug-in, configuring it according to your security requirements, and creating SSL endpoints.

On this page:

- [Installing IceSSL](#)
 - [C++ Applications](#)
 - [Java Applications](#)
 - [.NET Applications](#)
 - [Ice Touch Applications](#)
- [Creating SSL Endpoints](#)
- [Endpoint Security Considerations](#)

Installing IceSSL

Ice supports a generic [plug-in facility](#) that allows extensions (such as IceSSL) to be installed dynamically without changing the application source code. The `Ice.Plugin` property provides language-specific information that enables the Ice run time to install a plug-in.

C++ Applications

The executable code for the IceSSL C++ plug-in resides in a shared library on Unix and a dynamic link library (DLL) on Windows. The format for the `Ice.Plugin` property is shown below:

```
Ice.Plugin.IceSSL=IceSSL:createIceSSL
```

The last component of the property name (`IceSSL`) becomes the plug-in's official identifier for configuration purposes, but the IceSSL plug-in requires its identifier to be `IceSSL`. The property value `IceSSL:createIceSSL` is sufficient to allow the Ice run time to locate the IceSSL library (on both Unix and Windows) and initialize the plug-in. The only requirement is that the library reside in a directory that appears in the shared library path (`LD_LIBRARY_PATH` on most Unix platforms, `PATH` on Windows).

Instead of dynamically loading the plug-in at runtime your application can also explicitly link with and register the plug-in. To register the plug-in, you must call the `Ice::registerIceSSL(bool loadOnInitialize = true)` function before the communicator initialization. The `loadOnInitialize` parameter specifies if the plug-in is installed when the communicator is initialized. If set to `false`, you will need to enable the plugin by setting the `Ice.Plugin.IceSSL` property to 1.

Additional [configuration properties](#) are usually necessary as well.

```
Ice::registerIceSSL is a simple helper function that calls Ice::registerPluginFactory.
```

Java Applications

The format for the `Ice.Plugin` property is shown below:

```
Ice.Plugin.IceSSL=IceSSL.PluginFactory
```

The last component of the property name (`IceSSL`) becomes the plug-in's official identifier for configuration purposes, but the IceSSL plug-in requires its identifier to be `IceSSL`. The property value `IceSSL.PluginFactory` is the name of a class that allows the Ice run time to initialize the plug-in. The IceSSL classes are included in `Ice.jar`, therefore no other changes to your `CLASSPATH` are necessary.

Additional [configuration properties](#) are usually necessary as well.

.NET Applications

The format for the `Ice.Plugin` property is shown below:

```
Ice.Plugin.IceSSL=C:/Ice/bin/IceSSL.dll:IceSSL.PluginFactory
```

The last component of the property name (`IceSSL`) becomes the plug-in's official identifier for configuration purposes, but the `IceSSL` plug-in requires its identifier to be `IceSSL`. The property value contains the file name of the `IceSSL` assembly as well as the name of a class, `IceSSL.PluginFactory`, that allows the Ice run time to initialize the plug-in.

You may also specify a partially or fully qualified assembly name instead of the file name in an `Ice.Plugin` property. For example, you can use the following configuration to load the plug-in from the release version of the assembly provided in ZeroC's binary distribution:

```
Ice.Plugin.IceSSL=IceSSL,Version=3.6.0.0,Culture=neutral,PublicKeyToken
=cdd571ade22f2f16:IceSSL.PluginFactory
```

Alternatively, if you have built the Ice source code yourself, you can load the development version of the assembly as shown below:

```
Ice.Plugin.IceSSL=IceSSL,Version=3.6.0.0,Culture=neutral,PublicKeyToken
=1f998c50fec78381:IceSSL.PluginFactory
```

You *must* use a fully qualified assembly name to load the `IceSSL` plug-in from the Global Assembly Cache.

Additional [configuration properties](#) are usually necessary as well.

Ice Touch Applications

The `IceSSL` plug-in is included in the Ice Touch run time and installed automatically, therefore it is not necessary to explicitly load it. However, [configuration properties](#) are usually necessary.

Creating SSL Endpoints

Installing the `IceSSL` plug-in enables you to use a new protocol, `ssl`, in your endpoints. For example, the following [adapter endpoint](#) list creates a TCP endpoint, an SSL endpoint, and a UDP endpoint:

```
MyAdapter.Endpoints=tcp -p 4063:ssl -p 4064:udp -p 4063
```

As this example demonstrates, it is possible for a UDP endpoint to use the same port number as a TCP or SSL endpoint, because UDP is a different protocol and therefore has an independent set of ports. It is not possible for a TCP endpoint and an SSL endpoint to use the same port number, because SSL is essentially a layer over TCP.

Using SSL in [proxy endpoints](#) is equally straightforward:

```
MyProxy=MyObject:tcp -p 4063:ssl -p 4064:udp -p 4063
```

Endpoint Security Considerations

Defining an object adapter's endpoints to use multiple protocols, [as shown above](#), has obvious security implications. If your intent is to use SSL to protect session traffic and/or restrict access to the server, then you should only define SSL endpoints.

There can be situations, however, in which insecure endpoint protocols are advantageous. The figure below illustrates an environment in which TCP endpoints are allowed behind the firewall, but external clients are required to use SSL:

An application of multiple protocol endpoints.

The firewall in the illustration is configured to block external access to TCP port 4063 and to forward connections to port 4064 to the server machine.

One reason for using TCP behind the firewall is that it is more efficient than SSL and requires less administrative work. Of course, this scenario assumes that internal clients can be trusted, which is not true in many environments.

For more information on using SSL in complex network architectures, refer to our discussion of the [Glacier2 router](#).

Configuring IceSSL

After installing IceSSL, an application typically needs to define a handful of additional [properties](#) to configure settings such as the location of certificate and key files. This page provides an introduction to configuring the plug-in for each of the supported language mappings.

Configuring IceSSL for C++ and .NET on Windows

IceSSL for .NET and C++ supports loading certificates, keys, and trusted CA certificates from regular files. You can also make use of Windows certificate stores.

The ability to load trusted CA certificates from a file in .NET is a new feature added in Ice 3.6.

Using Certificate Files

Our first example demonstrates how to configure IceSSL with certificate files:

```
# For .NET:
Ice.Plugin.IceSSL=IceSSL.dll:IceSSL.PluginFactory
# For C++:
Ice.Plugin.IceSSL=IceSSL:createIceSSL

IceSSL.DefaultDir=/opt/certs
IceSSL.CAs=cacert.pem
IceSSL.CertFile=cert.pfx
IceSSL.Password=password
```

Notice that the value for `Ice.Plugin.IceSSL` differs depending on the language mapping you're using. The `Ice.Plugin` properties also support an alternate syntax that allows you to define both variations in the same configuration file if desired.

The `IceSSL.DefaultDir` property is a convenient way to specify the default location of your certificate files. The two subsequent properties identify the files containing the trusted CA certificate and the certificate with private key, respectively. When these properties specify a relative path name, as shown here, IceSSL attempts to find these files in the directory defined by `IceSSL.DefaultDir`. The file specified in `IceSSL.CAs` should normally be in the Privacy Enhanced Mail (PEM) format, whereas the file in `IceSSL.CertFile` must use the Personal Information Exchange (PFX, also known as PKCS#12) format and contain both a certificate and its corresponding private key. The `IceSSL.Password` property specifies the password used to secure the file.

It is a security risk to define a password in a plain text file, such as an Ice configuration file, because anyone who can gain read access to your configuration file can obtain your password. IceSSL also supports [alternate ways](#) to supply a password.

Using Certificate Stores

Windows uses certificate stores as the persistent repositories of certificates and keys. Furthermore, there are two distinct sets of certificate stores, one for the current user and another for the local machine.

Managing Certificates with the Microsoft Management Console

On Windows, you can use the Microsoft Management Console (MMC) to browse the contents of the various certificate stores. To start the console, run `MMC.EXE` from a command window, or choose Run from the Start menu and enter `MMC.EXE`.

Once the console is running, you need to install the Certificates "snap-in" by choosing Add/Remove Snap-in from the File menu. Click the Add button, choose Certificates in the popup window and click Add. If you wish to manage certificates for the current user, select My Current Account and click Finish. To manage certificates for the local computer, select Computer Account and click Next, then select Local Computer and click Finish.

When you have finished adding snap-ins, close the Add Standalone Snap-in window and click OK on the Add/Remove Snap-in window. Your Console Root window now contains a tree structure that you can expand to view the available certificate stores. If you have a certificate in a file that you want to add to a store, click on the desired store, then open the Action menu and select All Tasks/Import.

Configuring IceSSL using Certificate Stores

If the program's certificate and private key are already installed in a certificate store, you can select it using the `IceSSL.FindCert` configuration property as shown in the following example:

```
Ice.Plugin.IceSSL=. . .
IceSSL.FindCert=subject:"Quote Server"
IceSSL.CertStore=My
IceSSL.CertStoreLocation=LocalMachine
```

An `IceSSL.FindCert` property executes a query in a particular certificate store and selects all of the certificates that match the given criteria. In the example above, the location of the certificate store is `LocalMachine` (as defined by `IceSSL.CertStoreLocation`) and the store's name is `My` (as defined by `IceSSL.CertStore`). When using MMC to browse the certificate stores, this is equivalent to the store "Personal" in the location "Certificates (Local Computer)."

The other legal value for `IceSSL.CertStoreLocation` is `CurrentUser`. The following table shows the valid values for `IceSSL.CertStore` and their equivalents in MMC:

Property Value	MMC Name
<code>AddressBook</code>	Other People
<code>AuthRoot</code>	Third-Party Root Certification Authorities
<code>CertificateAuthority</code>	Intermediate Certification Authorities
<code>Disallowed</code>	Untrusted Certificates
<code>My</code>	Personal
<code>Root</code>	Trusted Root Certification Authorities

TrustedPeople	Trusted People
TrustedPublisher	Trusted Publishers

The search criteria consists of *name:value* pairs that perform case-insensitive comparisons against the fields of each certificate in the specified store, and the special property value `*` selects every certificate in the store. Typically, however, the criteria should select a single certificate. In a server, IceSSL must supply Windows with the certificate that represents the server's identity; if a configuration matches several certificates, IceSSL chooses one (in an undefined manner) and logs a warning to notify you of the situation.

Selecting a certificate from a store is more secure than using a certificate file via the `IceSSL.CertFile` property because it is not necessary to specify a plain-text password. MMC prompts you for the password when initially importing a certificate into a store, so the password is not required when an application uses that certificate to identify itself.

Trusted CA Certificates

We made no mention of trusted CA certificates in the configuration above. For a program to be able to successfully authenticate a certificate it receives from a peer, all trusted CA certificates must either be loaded via the `IceSSL.CAs` property or already be present in the appropriate certificate stores.

When installing a trusted CA certificate, authentication succeeds only when the certificate is installed into one of the following stores:

- Local Computer / Trusted Root Certification Authorities
- Local Computer / Third-Party Root Certification Authorities
- Current User / Trusted Root Certification Authorities

Note that administrative privileges are required when installing a certificate into a Local Computer store.

Configuring IceSSL for C++ on OS X

Our first example shows the properties that are sufficient in many situations:

```
Ice.Plugin.IceSSL=IceSSL:createIceSSL
IceSSL.DefaultDir=/opt/certs
IceSSL.CertFile=cert.pfx
IceSSL.CAs=ca.pem
IceSSL.Password=password
```

The `IceSSL.DefaultDir` property is a convenient way to specify the default location of your certificate files. The properties that follow it define the files containing the program's certificate with private key, and trusted CA certificate, respectively. Finally, the `IceSSL.Password` property specifies the password necessary to open `cert.pfx`.

It is a security risk to define a password in a plain text file, such as an Ice configuration file, because anyone who can gain read access to your configuration file can obtain your password. IceSSL also supports [alternate ways](#) to supply a password.

Keychain Examples for OS X

IceSSL imports the certificate specified by `IceSSL.CertFile` into a keychain. IceSSL uses the user's default keychain unless you choose a different one by defining the `IceSSL.Keychain` property:

```
IceSSL.Keychain=Test Keychain
```

If the specified keychain file does not exist, IceSSL will create it. The file name is opened relative to the user's current working directory unless an absolute path name is provided.

The user's default keychain is normally unlocked after logging into the system, so IceSSL doesn't usually require a password to import a certificate into this keychain. However, if your keychain is not unlocked automatically, or if you've selected a different keychain, you can

supply a password using the `IceSSL.KeychainPassword` property:

```
IceSSL.KeychainPassword=password
```

It is a security risk to define a password in a plain text file, such as an Ice configuration file, because anyone who can gain read access to your configuration file can obtain your password.

If you don't define `IceSSL.KeychainPassword` and a password is required to open the keychain, OS X will prompt the user for the password.

To use a certificate that's already in a keychain, you can omit the `IceSSL.CertFile` and `IceSSL.Password` properties and use `IceSSL.FindCert` instead:

```
Ice.Plugin.IceSSL=IceSSL:createIceSSL
IceSSL.DefaultDir=/opt/certs
IceSSL.CAs=ca.pem
IceSSL.FindCert=Label:Client
```

Here we've instructed IceSSL to locate the certificate in the default keychain labeled `Client` and use that as the program's identity.

ADH Example for OS X

The following example uses ADH (the Anonymous Diffie-Hellman cipher). ADH is not a good choice in most cases because, as its name implies, there is no authentication of the communicating parties, and it is vulnerable to man-in-the-middle attacks. However, it still provides encryption of the session traffic and requires very little administration and therefore may be useful in certain situations. The configuration properties shown below demonstrate how to use ADH:

```
Ice.Plugin.IceSSL=IceSSL:createIceSSL
IceSSL.Ciphers=(DH_anon*)
IceSSL.DHParams=dhparams.der
IceSSL.VerifyPeer=0
```

The `IceSSL.Ciphers` property enables support for ADH. We also recommend setting `IceSSL.DHParams` with the name of a DER-encoded file containing pre-generated DH parameters.

The `IceSSL.VerifyPeer` property changes the plug-in's default behavior with respect to certificate verification. Without this setting, IceSSL rejects a connection if the peer does not supply a certificate (as is the case with ADH).

Configuring IceSSL for C++ on Linux

Our first example shows the properties that are sufficient in many situations:

```
Ice.Plugin.IceSSL=IceSSL:createIceSSL
IceSSL.DefaultDir=/opt/certs
IceSSL.CertFile=cert.pfx
IceSSL.CAs=ca.pem
IceSSL.Password=password
```

The `IceSSL.DefaultDir` property is a convenient way to specify the default location of your certificate and key files. The two properties

that follow it define the files containing the program's certificate with private key and trusted CA certificate, respectively. This example assumes the files contain RSA keys, and IceSSL requires the files to use the Privacy Enhanced Mail (PEM) encoding. Finally, the `IceSSL.Password` property specifies the password of the private key.

It is a security risk to define a password in a plain text file, such as an Ice configuration file, because anyone who can gain read access to your configuration file can obtain your password. IceSSL also supports [alternate ways](#) to supply a password.

DSA Example for C++

If you used DSA to generate your keys, one additional property is necessary:

```
Ice.Plugin.IceSSL=IceSSL:createIceSSL
IceSSL.DefaultDir=/opt/certs
IceSSL.CertFile=cert_dsa.pfx
IceSSL.CAs=ca.pem
IceSSL.Password=password
IceSSL.Ciphers=DEFAULT:DSS
```

The `IceSSL.Ciphers` property adds support for DSS authentication to the plug-in's default set of ciphersuites.

RSA and DSA Example for C++

It is also possible to specify certificates and keys for both RSA and DSA by including two filenames in the `IceSSL.CertFile` property. The file names must be separated using the platform's path separator. The example below demonstrates the configuration:

```
Ice.Plugin.IceSSL=IceSSL:createIceSSL
IceSSL.DefaultDir=/opt/certs
IceSSL.CertFile=cert_rsa.pfx:cert_dsa.pfx
IceSSL.CAs=ca.pem
IceSSL.Password=password
IceSSL.Ciphers=DEFAULT:DSS
```

ADH Example for C++

The following example uses ADH (the Anonymous Diffie-Hellman cipher). ADH is not a good choice in most cases because, as its name implies, there is no authentication of the communicating parties, and it is vulnerable to man-in-the-middle attacks. However, it still provides encryption of the session traffic and requires very little administration and therefore may be useful in certain situations. The configuration properties shown below demonstrate how to use ADH:

```
Ice.Plugin.IceSSL=IceSSL:createIceSSL
IceSSL.Ciphers=ADH:!LOW:!MD5:!EXP:!3DES:@STRENGTH
IceSSL.VerifyPeer=0
```

The `IceSSL.Ciphers` property enables support for ADH (which is disabled by default) and eliminates low-strength ciphersuites.

The `IceSSL.VerifyPeer` property changes the plug-in's default behavior with respect to certificate verification. Without this setting, IceSSL rejects a connection if the peer does not supply a certificate (as is the case with ADH).

Configuring IceSSL for Java

IceSSL uses Java's native format for storing keys and certificates: the keystore.

A keystore is represented as a file containing key pairs and associated certificates, and is usually administered using the `keytool` utility supplied with the Java run time. Keystores serve two roles in Java's SSL architecture:

1. A keystore containing a key pair identifies the peer and is usually closely guarded.
2. A keystore containing public certificates represents the identities of trusted peers and can be freely shared. These keystores are also referred to as "truststores" when they are used to store only trusted certificate chains.

A single keystore file can fulfill both of these purposes.

Java supports a pluggable architecture for keystore implementations in which a system property selects a particular implementation as the default keystore type. IceSSL uses the default keystore type unless otherwise specified.

A password is assigned to each key pair in a keystore, as well as to the keystore itself. IceSSL must be provided with the password for the key pair, but the keystore password is optional. If a keystore password is specified, it is used only to verify the keystore's integrity. IceSSL requires that all of the key pairs in a keystore have the same password.

Our first example shows the properties that are sufficient in many situations:

```
Ice.Plugin.IceSSL=IceSSL.PluginFactory
IceSSL.DefaultDir=/opt/certs
IceSSL.Keystore=keys.jks
IceSSL.Truststore=ca.jks
IceSSL.Password=password
```

IceSSL resolves the filenames defined in its configuration properties as follows:

1. Attempt to open the file as a class loader resource. This is especially useful for deploying applications with special security restrictions, such as applets.
2. Attempt to open the file in the local file system.
3. If `IceSSL.DefaultDir` is defined, prepend its value and try steps 1 and 2 again. The `IceSSL.DefaultDir` property is a convenient way to specify the default location of your keystore and truststore files.

The `IceSSL.Password` property specifies the password of the key pair.

It is a security risk to define a password in a plain text file, such as an Ice configuration file, because anyone who can gain read access to your configuration file can obtain your password. IceSSL also supports [alternate ways](#) to supply a password.

DSA Example for Java

Java supports both RSA and DSA keys. No additional properties are necessary to use DSA:

```
Ice.Plugin.IceSSL=IceSSL.PluginFactory
IceSSL.DefaultDir=/opt/certs
IceSSL.Keystore=dsakeys.jks
IceSSL.Truststore=ca.jks
IceSSL.Password=password
```

ADH Example for Java

The following example uses ADH (the Anonymous Diffie-Hellman cipher). ADH is not a good choice in most cases because, as its name implies, there is no authentication of the communicating parties, and it is vulnerable to man-in-the-middle attacks. However, it still provides encryption of the session traffic and requires very little administration and therefore may be useful in certain situations. The configuration properties shown below demonstrate how to use ADH:

```
Ice.Plugin.IceSSL=IceSSL.PluginFactory
IceSSL.DefaultDir=/opt/certs
IceSSL.Ciphers=NONE (DH_anon.*AES)
IceSSL.VerifyPeer=0
```

The `IceSSL.Ciphers` property enables support for ADH, which is disabled by default. Furthermore, this setting enables only those ADH ciphersuites that support AES encryption and eliminates other, lower-strength ciphersuites that may not be supported by recent JVMs.

The `IceSSL.VerifyPeer` property changes the plug-in's default behavior with respect to certificate verification. Without this setting, IceSSL rejects a connection if the peer does not supply a certificate (as is the case with ADH).

Configuring IceSSL for Ice Touch

In Ice Touch, certificate files are loaded from the application's resource bundle. If the application's target platform is OS X, certificate files can also be loaded directly from the file system. Consider the following properties:

```
IceSSL.DefaultDir=certs
IceSSL.CAs=cacert.der
IceSSL.CertFile=cert.pfx
IceSSL.Password=password
```

The `IceSSL.DefaultDir` property is a convenient way to specify the location of your certificate files. Defining `IceSSL.DefaultDir` means IceSSL searches for certificate files relative to the specified directory. For the properties in the example above, IceSSL composes the pathnames `certs/cacert.der` and `certs/cert.pfx`. If `IceSSL.DefaultDir` is not defined, IceSSL uses the certificate file pathnames exactly as they are supplied.

As mentioned earlier, IceSSL has different semantics for locating certificate files depending on the target platform. For the iPhone and iPhone simulator, IceSSL attempts to open a certificate file in the application's resource bundle as `Resources/DefaultDir/file` if `IceSSL.DefaultDir` is defined, or as simply `Resources/file` otherwise. If the target platform is OS X and the certificate file cannot be found in the resource bundle, IceSSL also attempts to open the file in the file system as `DefaultDir/file` if a default directory is specified, or as simply `file` otherwise.

IceSSL requires that the CA certificate file specified by `IceSSL.CAs` use the DER format. The certificate file in `IceSSL.CertFile` must use the Personal Information Exchange (PEM, also known as PKCS#12) format and contain both a certificate and its corresponding private key. The `IceSSL.Password` property specifies the password used to secure the certificate file.

Keychains

IceSSL imports the certificate specified by `IceSSL.CertFile` into a keychain. IceSSL uses the `login` keychain by default unless you choose a different one by defining the `IceSSL.Keychain` property:

```
IceSSL.Keychain=Test Keychain
```

The `login` keychain is the user's default keychain, which is normally unlocked after logging into the system. IceSSL does not usually require a password to import a certificate into the `login` keychain. However, if your `login` keychain is not unlocked automatically, or if you have selected a different keychain, you can supply a password using the `IceSSL.KeychainPassword` property:

```
IceSSL.KeychainPassword=password
```

Configuring Ciphersuites

A ciphersuite represents a particular combination of encryption, authentication and hashing algorithms. The IceSSL plug-ins for C++ and Java allow you to configure the ciphersuites that their underlying SSL engines are allowed to negotiate during handshaking with a peer. By default, IceSSL uses the underlying engine's default ciphersuites, but you can define a property to customize the list as we demonstrated above with the ADH examples. Normally the default configuration is chosen to eliminate relatively insecure ciphersuites such as ADH, which is the reason it must be explicitly enabled.

Configuring Ciphersuites in C++

The value of the `IceSSL.Ciphers` property is given directly to the platform's native SSL implementation, which determines the allowable ciphersuites.

On Linux, the list of ciphersuites supported by OpenSSL depends on how the OpenSSL distribution was compiled. You can obtain a complete list of the supported ciphersuites using the `openssl ciphers` command:

```
$ openssl ciphers
```

This command will likely generate a long list.

In general, we recommend setting `IceSSL.Trace.Security=1` when experimenting with ciphersuite configurations. When executing your program, pay special attention to the log output to verify the ciphersuites that IceSSL has enabled.

Refer to the platform notes in the `IceSSL.Ciphers` property description for the details about your platform.

Configuring Ciphersuites in Java

IceSSL for Java interprets the value of `IceSSL.Ciphers` as a sequence of expressions that filter the selected ciphersuites using name and pattern matching. If the property is not defined, the Java security provider's default ciphersuites are used. The following table defines the valid expressions that may appear in the property value.

Expression	Description
NONE	Disables all ciphersuites. If specified, it must appear first.
ALL	Enables all supported ciphersuites. If specified, it must appear first. This expression should be used with caution, as it may enable low-security ciphersuites.
NAME	Enables the ciphersuite matching the given name.
!NAME	Disables the ciphersuite matching the given name.
(EXP)	Enables ciphersuites whose names contain the regular expression <i>EXP</i> .
!(EXP)	Disables ciphersuites whose names contain the regular expression <i>EXP</i> .

To determine the set of enabled ciphersuites, the plug-in begins with a list of ciphersuite names containing the default set as determined by the security provider. The expressions in the property value add and remove ciphersuites from this list and are evaluated in the order of appearance. For example, consider the following property definition:

```
IceSSL.Ciphers=NONE (RSA.*AES) !(EXPORT)
```

The expressions in this property have the following effects:

- `NONE` clears the list of enabled ciphersuites.
- `(RSA.*AES)` is a regular expression that enables ciphersuites whose names contain the string "RSA" followed by "AES", meaning ciphersuites using RSA authentication and AES encryption.
- `!(EXPORT)` is a regular expression that disables any of the selected ciphersuites whose names contain the string "EXPORT", meaning ciphersuites having export-quality strength.

As another example, this property adds anonymous Diffie-Hellman to the default set of ciphersuites and disables export ciphersuites:

```
IceSSL.Client.Ciphers=(DH_anon) !(EXPORT)
```

Finally, this example selects only one ciphersuite:

```
IceSSL.Client.Ciphers=NONE SSL_RSA_WITH_RC4_128_SHA
```

Configuring Trust Relationships

Declaring that you [trust a certificate authority](#) implies that you trust any peer whose certificate was signed directly or indirectly by that certificate authority. It is necessary to use this broad definition of trust in some applications, such as a public Web server. In more controlled environments, it is a good idea to restrict access as much as possible, and IceSSL provides a number of ways for you to do that.

Trusted Peers

After the low-level SSL engine has completed its authentication process, IceSSL can be configured to take additional steps to verify whether a peer should be trusted. The [IceSSL.TrustOnly](#) family of properties defines a collection of acceptance and rejection filters that IceSSL applies to the distinguished name of a peer's certificate in order to determine whether to allow the connection to proceed. IceSSL permits the connection if the peer's distinguished name matches any of the acceptance filters and does not match any of the rejection filters.

A distinguished name uniquely identifies a person or entity and is generally represented in the following textual form:

```
C=US, ST=Florida, L=Palm Beach Gardens, O="ZeroC, Inc.", OU=Servers,
CN=Quote Server
```

Suppose we are configuring a client to communicate with the server whose distinguished name is shown above. If we know that the client is allowed to communicate only with this server, we can enforce this rule using the following property:

```
IceSSL.TrustOnly=O="ZeroC, Inc.", OU=Servers, CN=Quote Server
```

With this property in place, IceSSL allows a connection to proceed only if the distinguished name in the server's certificate matches this filter. The property may contain multiple filters, separated by semicolons, if the client needs to communicate with more than one server. Additional variations of the property are also supported.

If the [IceSSL.TrustOnly](#) properties do not provide the selectivity you require, the next step is to install a [custom certificate verifier](#).

Verification Depth

In order to authenticate a peer, SSL obtains the peer's certificate chain, which includes the peer's certificate as well as that of the root CA. SSL verifies that each certificate in the chain is valid, but there still remains a subtle security risk. Suppose that we have identified a trusted root CA (via its certificate), and a peer has supplied a valid certificate chain signed by our trusted root CA. It is possible for an attacker to obtain a special signing certificate that is signed by our root CA and therefore trusted implicitly. The attacker can use this certificate to sign fraudulent certificates with the goal of masquerading as a trusted peer, presumably for some nefarious purpose.

We could use the [IceSSL.TrustOnly](#) properties described above in an attempt to defend against such an attack. However, the attacker could easily manufacture a certificate containing a distinguished name that satisfies the trust properties.

If you know that all trusted peers present certificate chains of a certain length, set the property [IceSSL.VerifyDepthMax](#) so that IceSSL automatically rejects longer chains. The default value of this property is three, therefore you may need to set it to a larger value if you expect peers to present longer chains.

In situations where you cannot make assumptions about the length of a peer's certificate chain, yet you still want to examine the chain before allowing the connection, you should install a [custom certificate verifier](#).

Configuring Secure Proxies

Proxies may contain any combination of secure and insecure endpoints. An application that requires secure communication can guarantee that proxies it manufactures itself, such as those created by calling `stringToProxy`, contain only secure endpoints. However, the application cannot make the same assumption about proxies received as the result of a remote invocation.

The simplest way to guarantee that all proxies use only secure endpoints is to define the `Ice.Override.Secure` configuration property:

```
Ice.Override.Secure=1
```

Setting this property is equivalent to invoking the `proxy method` `ice_secure(true)` on every proxy. When enabled, attempting to establish a connection using a proxy that does not contain a secure endpoint results in `NoEndpointException`.

If you want the default behavior of proxies to give precedence to secure endpoints, you can set this property instead:

```
Ice.Default.PreferSecure=1
```

Note that proxies may still attempt to establish connections to insecure endpoints, but they try all secure endpoints first. This is equivalent to invoking `ice_preferSecure(true)` on a proxy.

IceSSL Diagnostics

You can use two configuration properties to obtain more information about the plug-in's activities. Setting `IceSSL.Trace.Security=1` enables the plug-in's diagnostic output, which includes a variety of messages regarding events such as ciphersuite selection, peer verification and trust evaluation. The other property, `Ice.Trace.Network`, determines how much information is logged about network events such as connections and packets. Note that the output generated by `Ice.Trace.Network` also includes other transports such as TCP and UDP.

System Logging in Java

In Java, you can use a system property that displays a great deal of information about SSL certificates and connections, including the ciphersuite that is selected for use by each connection. For example, the following command sets the system property that activates the diagnostics:

```
$ java -Djavax.net.debug=ssl MyProgram
```

System Logging in .NET

Enabling additional tracing output in .NET requires the creation of an XML file such as the one shown below:

XML

```

<?xml version="1.0" encoding="UTF-8" ?>
<configuration>
  <system.diagnostics>
    <trace autoflush="true"/>
    <sources>
      <source name="System.Net">
        <listeners>
          <add name="System.Net"/>
        </listeners>
      </source>
      <source name="System.Net.Sockets">
        <listeners>
          <add name="System.Net"/>
        </listeners>
      </source>
      <source name="System.Net.Cache">
        <listeners>
          <add name="System.Net"/>
        </listeners>
      </source>
    </sources>
    <sharedListeners>
      <add
        name="System.Net"
        type="System.Diagnostics.TextWriterTraceListener"
        initializeData="trace.txt"
      />
    </sharedListeners>
    <switches>
      <add name="System.Net" value="Verbose"/>
      <add name="System.Net.Sockets" value="Verbose"/>

      <add name="System.Net.Cache" value="Verbose"/>
    </switches>
  </system.diagnostics>
</configuration>

```

In this example, the output is stored in the file `trace.txt`. To activate tracing, give the XML file the same name as your executable with a `.config` extension (such as `server.exe.config`), and place it in the same directory as the executable.

System Logging on OS X

OS X 10.10 (Yosemite) includes a TLS logging facility. To enable it, run the following command in Terminal:

```
$ sudo defaults write /Library/Preferences/com.apple.security
SSLDebugScope -bool true
```

To see the log entries you must enable logging for warnings in syslog:

```
$ sudo syslog -c 0 -w
```

Then run syslog in 'wait' mode:

```
$ syslog -w
```

Programming IceSSL

The IceSSL [configuration properties](#) are flexible enough to satisfy the requirements of many applications, and IceSSL supports a public API that offers even more functionality for those applications that need it.

Programming IceSSL in CPP

This page describes the C++ API for the IceSSL plug-in.

On this page:

- [The IceSSL Plugin Interface in C++](#)
- [Obtaining SSL Connection Information in C++](#)
- [Installing a Certificate Verifier in C++](#)
- [Using Certificates in C++](#)
- [Using Distinguished Names in C++](#)

The IceSSL Plugin Interface in C++

Applications can interact directly with the IceSSL plug-in using the native C++ class `IceSSL::Plugin`. A reference to a `Plugin` object must be obtained from the communicator in which the plug-in is installed:

```

C++

Ice::CommunicatorPtr communicator = // ...
Ice::PluginManagerPtr pluginMgr = communicator->getPluginManager();
Ice::PluginPtr plugin = pluginMgr->getPlugin("IceSSL");
IceSSL::PluginPtr sslPlugin = IceSSL::PluginPtr::dynamicCast(plugin);
```

The `Plugin` class supports the following methods:

```

C++

namespace IceSSL
{
class Plugin : public Ice::Plugin
{
public:
    virtual void setCertificateVerifier(const CertificateVerifierPtr&
= 0;

    virtual void setPasswordPrompt(const PasswordPromptPtr&) = 0;

    virtual void setContext(SSL_CTX*) = 0;
    virtual SSL_CTX* getContext() = 0;
};
typedef IceUtil::Handle<Plugin> PluginPtr;
}
```

The `setCertificateVerifier` method installs a custom certificate verifier object that the plug-in invokes for each new connection. The `setPasswordPrompt` method provides an alternate way to supply IceSSL with passwords. We discuss certificate verifiers below and revisit the other methods in our discussion of [advanced IceSSL programming](#).

The `setContext` and `getContext` methods are only available on platforms that use OpenSSL and are rarely used in practice. The `IceSSL.InitOpenSSL` property is typically used in conjunction with `setContext`.

Obtaining SSL Connection Information in C++

You can obtain information about any SSL connection using the `getInfo` operation on a `Connection` object. The most-derived type of the object returned by `getInfo` varies depending on the transport being used. IceSSL defines two base types in Slice:

Slice

```

module Ice {
    local class ConnectionInfo {
        bool incoming;
        string adapterName;
    };

    local class IPConnectionInfo extends ConnectionInfo {
        string localAddress;
        int localPort;
        string remoteAddress;
        int remotePort;
    };
};

module IceSSL {
    local class ConnectionInfo extends Ice::IPConnectionInfo {
        string cipher;
        Ice::StringSeq certs;
        bool verified;
    };

    local class WSSConnectioninfo extends ConnectionInfo {
        Ice::HeaderDict headers;
    };
};

```

The `cipher` member is a description of the ciphersuite that SSL negotiated for this connection. The local and remote address information is provided in `localAddress` and `remoteAddress`, respectively. The `verified` member indicates whether IceSSL was able to successfully verify the peer's certificate.

The inherited `incoming` member indicates whether the connection is inbound (a server connection) or outbound (a client connection). Finally, if `incoming` is true, the `adapterName` member supplies the name of the object adapter that hosts the endpoint.

The `Ice::ConnectionInfo` object can be narrowed to either `IceSSL::ConnectionInfo` for an SSL endpoint or `IceSSL::WSSConnectionInfo` for a WSS (secure WebSocket) endpoint. Furthermore, IceSSL defines two native C++ subclasses as follows:

C++

```

namespace IceSSL {
class NativeConnectionInfo : public ConnectionInfo {
public:
    std::vector<CertificatePtr> nativeCerts;
};
typedef IceUtil::Handle<NativeConnectionInfo> NativeConnectionInfoPtr;

class WSSNativeConnectionInfo : public WSSConnectionInfo {
public:
    std::vector<CertificatePtr> nativeCerts;
};
typedef IceUtil::Handle<WSSNativeConnectionInfo>
WSSNativeConnectionInfoPtr;
}

```

The `nativeCerts` member is a vector of certificates representing the peer's certificate chain. The vector is structured so that the first element is the peer's certificate, followed by its signing certificates in the order they appear in the chain, with the root CA certificate as the last element. The vector is empty if the peer did not present a certificate chain.

Installing a Certificate Verifier in C++

A new connection undergoes a series of verification steps before an application is allowed to use it. The low-level SSL engine executes [certificate validation procedures](#) and, assuming the certificate chain is successfully validated, IceSSL performs [additional verification](#) as directed by its configuration properties. Finally, if a certificate verifier is installed, IceSSL invokes it to provide the application with an opportunity to decide whether to allow the connection to proceed.

The `CertificateVerifier` interface has only one method:

C++

```

namespace IceSSL
{
class CertificateVerifier : public IceUtil::Shared
{
public:

    virtual bool verify(const NativeConnectionInfoPtr&) = 0;
};
typedef IceUtil::Handle<CertificateVerifier> CertificateVerifierPtr;
}

```

IceSSL rejects the connection if `verify` returns `false`, and allows it to proceed if the method returns `true`. The `verify` method receives a `NativeConnectionInfo` object that describes the connection's attributes.

The following class is a simple implementation of a certificate verifier:

C++

```

class Verifier : public IceSSL::CertificateVerifier
{
public:

    bool verify(const IceSSL::NativeConnectionInfo& info)
    {
        if (!info.nativeCerts.empty())
        {
            string dn = info.nativeCerts[0].getIssuerDN();
            transform(dn.begin(), dn.end(), dn.begin(), ::tolower);
            if (dn.find("zeroc") != string::npos)
            {
                return true;
            }
        }
        return false;
    }
}

```

In this example, the verifier rejects the connection unless the string `zeroc` is present in the issuer's distinguished name of the peer's certificate. In a more realistic implementation, the application is likely to perform detailed inspection of the certificate chain.

Installing the verifier is a simple matter of calling `setCertificateVerifier` on the plug-in interface:

C++

```

IceSSL::PluginPtr sslPlugin = // ...
sslPlugin->setCertificateVerifier(new Verifier);

```

You should install the verifier before any SSL connections are established.

You can also install a certificate verifier [using a custom plug-in](#) to avoid making changes to the code of an existing application.

The Ice run time calls the `verify` method during the connection-establishment process, therefore delays in the `verify` implementation have a direct impact on the performance of the application. Do not make remote invocations from your implementation of `verify`.

Using Certificates in C++

The `ConnectionInfo` class contains a vector of `Certificate` objects representing the peer's certificate chain. `Certificate` is a reference-counted convenience class that hides the complexity of the platform's native SSL API. Its methods are inspired by the Java class `x509Certificate`:

C++

```

namespace IceSSL
{
class Certificate : public IceUtil::Shared
{
public:

    Certificate(X509CertificateRef);

    static CertificatePtr load(const string&);
    static CertificatePtr decode(const string&);

    bool operator==(const Certificate&) const;
    bool operator!=(const Certificate&) const;

    PublicKeyPtr getPublicKey() const;

    bool verify(const CertificatePtr&) const;

    string encode() const;

    bool checkValidity() const;
    bool checkValidity(const IceUtil::Time&) const;

    IceUtil::Time getNotAfter() const;
    IceUtil::Time getNotBefore() const;

    string getSerialNumber() const;

    DistinguishedName getIssuerDN() const;
    vector<pair<int, string> > getIssuerAlternativeNames();

    DistinguishedName getSubjectDN() const;
    vector<pair<int, string> > getSubjectAlternativeNames();

    int getVersion() const;

    string toString() const;

    X509CertificateRef getCert() const;
};
typedef IceUtil::Handle<Certificate> CertificatePtr;
}

```

The more commonly-used methods are described below; refer to the documentation in `IceSSL/Plugin.h` for information on the methods that are not covered.

The static method `load` creates a certificate from the contents of a certificate file. If an error occurs, the function raises `IceSSL::CertificateReadException`; the reason member provides a description of the problem.

Use `decode` to obtain a certificate from a PEM-encoded string representing a certificate. The caller must be prepared to catch `IceSSL::CertificateEncodingException` if `decode` fails; the `reason` member provides a description of the problem.

The `encode` method creates a PEM-encoded string that represents the certificate. The return value can later be passed to `decode` to recreate the certificate.

The `checkValidity` methods determine whether the certificate is valid. The overloading with no arguments returns true if the certificate is valid at the current time; the other overloading accepts an `IceUtil::Time` object and returns true if the certificate is valid at the given time.

The `getNotAfter` and `getNotBefore` methods return instances of `IceUtil::Time` that define the certificate's valid period.

The methods `getIssuerDN` and `getSubjectDN` supply the distinguished names of the certificate's issuer (i.e., the CA that signed the certificate) and subject (i.e., the person or entity to which the certificate was issued). The methods return instances of the class `IceSSL::DistinguishedName`, another convenience class that is described below.

Finally, the `toString` method returns a human-readable string describing the certificate.

Using Distinguished Names in C++

X.509 certificates use a distinguished name to identify a person or entity. The name is an ordered sequence of relative distinguished names that supply values for fields such as common name, organization, state, and country. Distinguished names are commonly displayed in stringified form according to the rules specified by RFC 2253, as shown in the following example:

```
C=US, ST=Florida, L=Palm Beach Gardens, O="ZeroC, Inc.", OU=Servers,
CN=Quote Server
```

`DistinguishedName` is a convenience class provided by `IceSSL` to simplify the tasks of parsing, formatting and comparing distinguished names.

```
C++
```

```
namespace IceSSL
{
class DistinguishedName
{
public:

    DistinguishedName(const std::string&);
    DistinguishedName(const std::list<std::pair<std::string, std::string>>&);

    bool operator==(const DistinguishedName&) const;
    bool operator!=(const DistinguishedName&) const;
    bool operator<(const DistinguishedName&) const;

    bool match(const DistinguishedName&) const;

    operator std::string() const;
};
}
```

The first overloaded constructor accepts a string argument representing a distinguished name encoded using the rules set forth in RFC 2253. The new `DistinguishedName` instance preserves the order of the relative distinguished names in the string. The caller must be prepared to catch `IceSSL::ParseException` if an error occurs during parsing.

The second overloaded constructor requires a list of type-value pairs representing the relative distinguished names. The new `DistinguishedName` instance preserves the order of the relative distinguished names in the list.

The overloaded operator functions `operator==`, `operator!=`, and `operator<` perform an exact match of distinguished names in which the order of the relative distinguished names is important. For two distinguished names to be equal, they must have the same relative distinguished names in the same order.

The `match` function performs a partial comparison that does not consider the order of relative distinguished names. If `N1` and `N2` are instances of `DistinguishedName`, `N1.match(N2)` returns true if all of the relative distinguished names in `N2` are present in `N1`.

Finally, the string conversion operator encodes the distinguished name in the format described by RFC 2253.

Programming IceSSL in Java

This page describes the Java API for the IceSSL plug-in.

On this page:

- [The IceSSL Plugin Interface in Java](#)
- [Obtaining SSL Connection Information in Java](#)
- [Installing a Certificate Verifier in Java](#)
- [Converting Certificates in Java](#)

The IceSSL Plugin Interface in Java

Applications can interact directly with the IceSSL plug-in using the native Java interface `IceSSL.Plugin`. A reference to a `Plugin` object must be obtained from the communicator in which the plug-in is installed:

Java

```
Ice.Communicator comm = // ...
Ice.PluginManager pluginMgr = comm.getPluginManager();
Ice.Plugin plugin = pluginMgr.getPlugin("IceSSL");
IceSSL.Plugin sslPlugin = (IceSSL.Plugin)plugin;
```

The `Plugin` interface supports the following methods:

Java

```
package IceSSL;

public interface Plugin extends Ice.Plugin
{
    void setContext(javax.net.ssl.SSLContext context);
    javax.net.ssl.SSLContext getContext();

    void setCertificateVerifier(CertificateVerifier verifier);
    CertificateVerifier getCertificateVerifier();

    void setPasswordCallback>PasswordCallback callback);
    PasswordCallback getPasswordCallback();

    void setKeystoreStream(java.io.InputStream stream);

    void setTruststoreStream(java.io.InputStream stream);

    void addSeedStream(java.io.InputStream stream);
}
```

The methods are summarized below:

- `setContext`
- `getContext`

These methods are for [advanced use cases](#) and rarely used in practice.

- `setCertificateVerifier`
`getCertificateVerifier`
These methods install and retrieve a custom certificate verifier object that the plug-in invokes for each new connection. `getCertificateVerifier` returns null if a verifier has not been set.
- `setPasswordCallback`
`getPasswordCallback`
These methods install and retrieve a password callback object that supplies IceSSL with passwords. `getPasswordCallback` returns null if a callback has not been set. Using `setPasswordCallback` is a [more secure alternative](#) to setting passwords in clear-text configuration files.
- `setKeystoreStream`
Supplies an input stream for a keystore containing the key pair. The `IceSSL.Keystore` property is ignored if this method is called with a non-null value. You may supply the same input stream object to this method and to `setTruststoreStream` if your keystore contains your key pair as well as your trusted CA certificates.
- `setTruststoreStream`
Supplies an input stream for a truststore containing your trusted CA certificates. The `IceSSL.Truststore` property is ignored if this method is called with a non-null value. You may supply the same input stream object to this method and to `setKeystoreStream` if your keystore contains your key pair as well as your trusted CA certificates.
- `addSeedStream`
Adds an input stream that supplies seed data for the random number generator. You may call this method multiple times if necessary.

Obtaining SSL Connection Information in Java

You can obtain information about any SSL connection using the `getInfo` operation on a [Connection object](#). The most-derived type of the object returned by `getInfo` varies depending on the transport being used. IceSSL defines two base types in Slice:

Slice

```

module Ice {
    local class ConnectionInfo {
        bool incoming;
        string adapterName;
    };

    local class IPConnectionInfo extends ConnectionInfo {
        string localAddress;
        int localPort;
        string remoteAddress;
        int remotePort;
    };
};

module IceSSL {
    local class ConnectionInfo extends Ice::IPConnectionInfo {
        string cipher;
        Ice::StringSeq certs;
        bool verified;
    };

    local class WSSConnectionInfo extends ConnectionInfo {
        Ice::HeaderDict headers;
    };
};

```

The `cipher` member is a description of the ciphersuite that SSL negotiated for this connection. The local and remote address information is provided in `localAddress` and `remoteAddress`, respectively. The `verified` member indicates whether IceSSL was able to successfully verify the peer's certificate.

The inherited `incoming` member indicates whether the connection is inbound (a server connection) or outbound (a client connection). Finally, if `incoming` is true, the `adapterName` member supplies the name of the object adapter that hosts the endpoint.

The `Ice::ConnectionInfo` object can be narrowed to either `IceSSL::ConnectionInfo` for an SSL endpoint or `IceSSL::WSSConnectionInfo` for a WSS (secure WebSocket) endpoint. Furthermore, IceSSL defines two native Java subclasses as follows:

Java

```

package IceSSL;

public class NativeConnectionInfo extends ConnectionInfo
{
    public java.security.cert.Certificate[] nativeCerts;
}

public class WSSNativeConnectionInfo extends WSSConnectionInfo
{
    public java.security.cert.Certificate[] nativeCerts;
}

```

The `nativeCerts` member is an array of certificates representing the peer's certificate chain. The array is structured so that the first element is the peer's certificate, followed by its signing certificates in the order they appear in the chain, with the root CA certificate as the last element. The array is empty if the peer did not present a certificate chain.

Installing a Certificate Verifier in Java

A new connection undergoes a series of verification steps before an application is allowed to use it. The low-level SSL engine executes [certificate validation procedures](#) and, assuming the certificate chain is successfully validated, IceSSL performs [additional verification](#) as directed by its configuration properties. Finally, if a certificate verifier is installed, IceSSL invokes it to provide the application with an opportunity to decide whether to allow the connection to proceed.

The `CertificateVerifier` interface has only one method:

Java

```

package IceSSL;

public interface CertificateVerifier
{
    boolean verify(NativeConnectionInfo info);
}

```

IceSSL rejects the connection if `verify` returns `false`, and allows it to proceed if the method returns `true`. The `verify` method receives a `NativeConnectionInfo` object that describes the connection's attributes.

The following class is a simple implementation of a certificate verifier:

Java

```
import java.security.cert.X509Certificate;
import javax.security.auth.x500.X500Principal;

class Verifier implements IceSSL.CertificateVerifier
{
    public boolean
    verify(IceSSL.NativeConnectionInfo info)
    {
        if (info.nativeCerts != null)
        {
            X509Certificate cert = (X509Certificate)info.nativeCerts[0];
            X500Principal p = cert.getIssuerX500Principal();
            if (p.getName().toLowerCase().indexOf("zeroc") != -1)
            {
                return true;
            }
        }
        return false;
    }
}
```

In this example, the verifier rejects the connection unless the string `zeroc` is present in the issuer's distinguished name of the peer's certificate. In a more realistic implementation, the application is likely to perform detailed inspection of the certificate chain.

Installing the verifier is a simple matter of calling `setCertificateVerifier` on the plug-in interface:

Java

```
IceSSL.Plugin sslPlugin = // ...
sslPlugin.setCertificateVerifier(new Verifier());
```

You should install the verifier before any SSL connections are established. An alternate way of installing the verifier is to define the `IceSSL.CertVerifier` property with the class name of your verifier implementation. IceSSL instantiates the class using its default constructor.

You can also install a certificate verifier using a [custom plug-in](#) to avoid making changes to the code of an existing application.

The Ice run time calls the `verify` method during the connection-establishment process, therefore delays in the `verify` implementation have a direct impact on the performance of the application. Do not make remote invocations from your implementation of `verify`.

Converting Certificates in Java

Java does not provide a simple way to create a certificate object from a PEM-encoded string, therefore IceSSL offers the following convenience method:

Java

```
package IceSSL;

public final class Util
{
    // ...

    public static java.security.cert.X509Certificate
    createCertificate(String certPEM)
        throws java.security.cert.CertificateException;
}
```

Given a string in the PEM format, `createCertificate` returns the equivalent `X509Certificate` object.

The IceSSL Plugin Interface in C#

Applications can interact directly with the IceSSL plug-in using the native C# interface `IceSSL.Plugin`. A reference to a `Plugin` object must be obtained from the communicator in which the plug-in is installed:

```

C#

Ice.Communicator comm = // ...  
Ice.PluginManager pluginMgr = comm.getPluginManager();  
Ice.Plugin plugin = pluginMgr.getPlugin("IceSSL");  
IceSSL.Plugin sslPlugin = (IceSSL.Plugin)plugin;
```

The `Plugin` interface supports the following methods:

C#

```

namespace IceSSL
{
    using System.Security.Cryptography.X509Certificates;

    abstract public class Plugin : Ice.Plugin
    {
        abstract public void
        setCertificates(X509Certificate2Collection certs);

        abstract public void
        setCACertificates(X509Certificate2Collection certs);
        abstract public void
        setCertificateVerifier(CertificateVerifier verifier);

        abstract public CertificateVerifier
        getCertificateVerifier();

        abstract public void
        setPasswordCallback>PasswordCallback callback);

        abstract public PasswordCallback
        getPasswordCallback();
    }
}

```

The methods are summarized below:

- `setCertificates`
`setCACertificates`
These methods are for [advanced use cases](#) and rarely used in practice.
- `setCertificateVerifier`
`getCertificateVerifier`
These methods install and retrieve a custom certificate verifier object that the plug-in invokes for each new connection. `getCertificateVerifier` returns null if a verifier has not been set.
- `setPasswordCallback`
`getPasswordCallback`
These methods install and retrieve a password callback object that supplies IceSSL with passwords. `getPasswordCallback` returns null if a callback has not been set. Using `setPasswordCallback` is a [more secure alternative](#) to setting passwords in clear-text configuration files.

Obtaining SSL Connection Information in C#

You can obtain information about any SSL connection using the `getInfo` operation on a [Connection object](#). The most-derived type of the object returned by `getInfo` varies depending on the transport being used. IceSSL defines two base types in Slice:

Slice

```

module Ice {
    local class ConnectionInfo {
        bool incoming;
        string adapterName;
    };

    local class IPConnectionInfo extends ConnectionInfo {
        string localAddress;
        int localPort;
        string remoteAddress;
        int remotePort;
    };
};

module IceSSL {
    local class ConnectionInfo extends Ice::IPConnectionInfo {
        string cipher;
        Ice::StringSeq certs;
        bool verified;
    };

    local class WSSConnectionInfo extends ConnectionInfo {
        Ice::HeaderDict headers;
    };
};

```

The `cipher` member is a description of the ciphersuite that SSL negotiated for this connection. The local and remote address information is provided in `localAddress` and `remoteAddress`, respectively. The `verified` member indicates whether IceSSL was able to successfully verify the peer's certificate.

The inherited `incoming` member indicates whether the connection is inbound (a server connection) or outbound (a client connection). Finally, if `incoming` is true, the `adapterName` member supplies the name of the object adapter that hosts the endpoint.

The `Ice::ConnectionInfo` object can be narrowed to either `IceSSL::ConnectionInfo` for an SSL endpoint or `IceSSL::WSSConnectionInfo` for a WSS (secure WebSocket) endpoint. Furthermore, IceSSL defines two native C# subclasses as follows:

C#

```

namespace IceSSL
{
    public sealed class NativeConnectionInfo : ConnectionInfo
    {
        public System.Security.Cryptography.X509Certificates.X509Certificate2[]
        nativeCerts;
    }

    public sealed class WSSNativeConnectionInfo : WSSConnectionInfo
    {
        public
        System.Security.Cryptography.X509Certificates.X509Certificate2[]
        nativeCerts;
    }
}

```

The `nativeCerts` member is an array of certificates representing the peer's certificate chain. The array is structured so that the first element is the peer's certificate, followed by its signing certificates in the order they appear in the chain, with the root CA certificate as the last element. The array is empty if the peer did not present a certificate chain.

Installing a Certificate Verifier in C#

A new connection undergoes a series of verification steps before an application is allowed to use it. The low-level SSL engine executes [certificate validation procedures](#) and, assuming the certificate chain is successfully validated, IceSSL performs [additional verification](#) as directed by its configuration properties. Finally, if a certificate verifier is installed, IceSSL invokes it to provide the application with an opportunity to decide whether to allow the connection to proceed.

The `CertificateVerifier` interface has only one method:

C#

```

namespace IceSSL
{
    public interface CertificateVerifier
    {
        bool verify(NativeConnectionInfo info);
    }
}

```

IceSSL rejects the connection if `verify` returns `false`, and allows it to proceed if the method returns `true`. The `verify` method receives a `NativeConnectionInfo` object that describes the connection's attributes.

The following class is a simple implementation of a certificate verifier:

C#

```

using System.Security.Cryptography.X509Certificates;

class Verifier : IceSSL.CertificateVerifier
{
    public boolean
    verify(IceSSL.NativeConnectionInfo info)
    {
        if (info.nativeCerts != null)
        {
            X500DistinguishedName dn = info.nativeCerts[0].IssuerName;
            if (dn.Name.ToLower().Contains("zeroc"))
            {
                return true;
            }
        }
        return false;
    }
}

```

In this example, the verifier rejects the connection unless the string `zeroc` is present in the issuer's distinguished name of the peer's certificate. In a more realistic implementation, the application is likely to perform detailed inspection of the certificate chain.

Installing the verifier is a simple matter of calling `setCertificateVerifier` on the plug-in interface:

C#

```

IceSSL.Plugin sslPlugin = // ...
sslPlugin.setCertificateVerifier(new Verifier());

```

You should install the verifier before any SSL connections are established. An alternate way of installing the verifier is to define the `IceSSL.CertVerifier` property with the class name of your verifier implementation. IceSSL instantiates the class using its default constructor.

You can also install a certificate verifier using a [custom plug-in](#) to avoid making changes to the code of an existing application.

The Ice run time calls the `verify` method during the connection-establishment process, therefore delays in the `verify` implementation have a direct impact on the performance of the application. Do not make remote invocations from your implementation of `verify`.

Converting Certificates in C#

IceSSL offers the following convenience method to create a certificate object from a PEM-encoded string:

C#

```
namespace IceSSL
{
    using System.Security.Cryptography.X509Certificates;

    public sealed class Util
    {
        // ...

        public static X509Certificate2
        createCertificate(string certPEM);
    }
}
```

Given a string in the PEM format, `createCertificate` returns the equivalent `X509Certificate2` object.

Managing Certificate Passwords

IceSSL may need to obtain a password if it loads a file that contains secure data, such as an encrypted private key. An application can supply a plain-text password in a [configuration property](#), but doing so is a potential security risk. For example, if you define the property on the application's command-line, it may be possible for other users on the same host to see the password simply by obtaining a list of active processes. If you define the property in a configuration file, the password is only as secure as the file in which it is defined.

In highly secure environments where access to a host is tightly restricted, a password can safely be supplied as a plain-text configuration property, or the need for the password can be eliminated altogether by using unsecured key files.

In situations where password security is a concern, the application generally needs to take additional action.

Dynamic Properties

A common technique is to prompt the user for a password and transfer the user's input to a configuration property that the application defines dynamically, as shown below:

C++

```
string password = // ...
Ice::InitializationData initData;
initData.properties = Ice::createProperties(argc, argv);
initData.properties->setProperty("IceSSL.Password", password);
Ice::CommunicatorPtr comm = Ice::initialize(initData);
```

The password must be present in the property set before the communicator is initialized, since IceSSL needs the password during its initialization, and the communicator initializes plug-ins automatically by default.

Password Callbacks in C++

If a password is required but the application has not configured one, IceSSL prompts the user at the terminal during the plug-in's initialization. This behavior is not suitable for some types of applications, such as a program that runs automatically at system startup as a [UNIX daemon](#) or [Windows service](#).

A terminal prompt is equally undesirable for graphical applications, which would generally prefer to prompt the user in an application window. The dynamic property technique described in the previous section is usually appropriate in this situation.

If your application must supply a password, and you do not want to use a configuration property or a terminal prompt, your remaining option is to install a `PasswordPrompt` object in the plug-in using the `setPasswordPrompt` method. The `PasswordPrompt` class is defined as follows:

C++

```

namespace IceSSL
{
class PasswordPrompt : public IceUtil::Shared
{
public:

    virtual std::string getPassword() = 0;
};
typedef IceUtil::Handle<PasswordPrompt> PasswordPromptPtr;
}

```

IceSSL invokes `getPassword` on the object when a password is required. If the object returns an incorrect password, IceSSL tries again, up to the limit defined by the `IceSSL.PasswordRetryMax` property.

Note that you must delay the initialization of the IceSSL plug-in until after the `PasswordPrompt` object is installed. To illustrate this point, consider the following example:

C++

```

Ice::CommunicatorPtr communicator = // ...
Ice::PluginManagerPtr pluginMgr = communicator->getPluginManager();
Ice::PluginPtr plugin = pluginMgr->getPlugin("IceSSL");
IceSSL::PluginPtr sslPlugin = IceSSL::PluginPtr::dynamicCast(plugin);
sslPlugin->setPasswordPrompt(new Prompt); // OOPS!

```

This code is incorrect because the `PasswordPrompt` object is installed too late: the communicator is already initialized, which means IceSSL has already attempted to load the file that required a password.

The correct approach is to define the `Ice.InitPlugins` configuration property:

```
Ice.InitPlugins=0
```

This setting causes the communicator to install, but not initialize, its configured plug-ins. The application becomes responsible for initializing the plug-ins, as shown below:

C++

```
Ice::CommunicatorPtr communicator = // ...
Ice::PluginManagerPtr pluginMgr = communicator->getPluginManager();
Ice::PluginPtr plugin = pluginMgr->getPlugin("IceSSL");
IceSSL::PluginPtr sslPlugin = IceSSL::PluginPtr::dynamicCast(plugin);
sslPlugin->setPasswordPrompt(new Prompt);
pluginMgr->initializePlugins();
```

We assume the communicator was initialized with `Ice.InitPlugins=0`. After installing the `PasswordPrompt` object, the application invokes `initializePlugins` on the plug-in manager to complete the plug-in initialization process.

Password Callbacks in Java

If you do not want to use configuration properties to define passwords, you can install a `PasswordCallback` object in the plug-in using a configuration property, or using the `setPasswordCallback` method. The `PasswordCallback` interface has the following definition:

Java

```
public interface PasswordCallback
{
    char[] getPassword(String alias);
    char[] getTruststorePassword();
    char[] getKeystorePassword();
}
```

The methods are described below:

- `getPassword`
Supplies the password for the key with the given alias. The return value must not be null.
- `getTruststorePassword`
Supplies the password for a truststore. The method may return null, in which case the integrity of the truststore is not verified.
- `getKeystorePassword` to obtain the password for a keystore.
Supplies the password for a keystore. The method may return null, in which case the integrity of the keystore is not verified.

For each of these methods, `IceSSL` clears the contents of the returned array as soon as possible.

The simplest way to install the callback is by defining the configuration property `IceSSL.PasswordCallback`. The property's value is the name of your callback implementation class. `IceSSL` instantiates the class using its default constructor.

To install the callback manually, you must delay the initialization of the `IceSSL` plug-in until after the `PasswordCallback` object is installed. To illustrate this point, consider the following example:

Java

```
Ice.Communicator communicator = // ...
Ice.PluginManager pluginMgr = communicator.getPluginManager();
Ice.Plugin plugin = pluginMgr.getPlugin("IceSSL");
IceSSL.Plugin sslPlugin = (IceSSL.Plugin)plugin;
sslPlugin.setPasswordCallback(new CallbackI()); // OOPS!
```

This code is incorrect because the `PasswordCallback` object is installed too late: the communicator is already initialized, which means `IceSSL` has already attempted to retrieve the certificate that required a password.

The correct approach is to define the `Ice.InitPlugins` configuration property:

```
Ice.InitPlugins=0
```

This setting causes the communicator to install, but not initialize, its configured plug-ins. The application becomes responsible for initializing the plug-ins, as shown below:

Java

```
Ice.Communicator communicator = // ...
Ice.PluginManager pluginMgr = communicator.getPluginManager();
Ice.Plugin plugin = pluginMgr.getPlugin("IceSSL");
IceSSL.Plugin sslPlugin = (IceSSL.Plugin)plugin;
sslPlugin.setPasswordCallback(new CallbackI());
pluginMgr.initializePlugins();
```

We assume the communicator was initialized with `Ice.InitPlugins=0`. After installing the `PasswordCallback` object, the application invokes `initializePlugins` on the plug-in manager to complete the plug-in initialization process.

Password Callbacks in .NET

If you do not want to use configuration properties to define passwords, you can install a `PasswordCallback` object in the plug-in using a configuration property, or using the `setPasswordCallback` method. The `PasswordCallback` interface has the following definition:

C#

```
using System.Security;

public interface PasswordCallback
{
    SecureString getPassword(string file);
    SecureString getImportPassword(string file);
}
```

The methods are described below:

- `getPassword`
Supplies the password for the given file. The method may return null if no password is required.
- `getImportPassword`
Supplies the password for a file from which certificates are imported into the certificate store. The method may return null if no password is required.

The simplest way to install the callback is by defining the configuration property `IceSSL.PasswordCallback`. The property's value is the name of your callback implementation class. IceSSL instantiates the class using its default constructor.

To install the callback manually, you must delay the initialization of the IceSSL plug-in until after the `PasswordCallback` object is installed. To illustrate this point, consider the following example:

C#

```
Ice.Communicator communicator = // ...
Ice.PluginManager pluginMgr = communicator.getPluginManager();
Ice.Plugin plugin = pluginMgr.getPlugin("IceSSL");
IceSSL.Plugin sslPlugin = (IceSSL.Plugin)plugin;
sslPlugin.setPasswordCallback(new CallbackI()); // OOPS!
```

This code is incorrect because the `PasswordCallback` object is installed too late: the communicator is already initialized, which means IceSSL has already attempted to retrieve the certificate that required a password.

The correct approach is to define the `Ice.InitPlugins` configuration property:

```
Ice.InitPlugins=0
```

This setting causes the communicator to install, but not initialize, its configured plug-ins. The application becomes responsible for initializing the plug-ins, as shown below:

C#

```
Ice.Communicator communicator = // ...
Ice.PluginManager pluginMgr = communicator.getPluginManager();
Ice.Plugin plugin = pluginMgr.getPlugin("IceSSL");
IceSSL.Plugin sslPlugin = (IceSSL.Plugin)plugin;
sslPlugin.setPasswordCallback(new CallbackI());
pluginMgr.initializePlugins();
```

We assume the communicator was initialized with `Ice.InitPlugins=0`. After installing the `PasswordCallback` object, the application invokes `initializePlugins` on the plug-in manager to complete the plug-in initialization process.

Manually Configuring IceSSL

The [Plugin interface](#) supports a method in each of the supported language mappings that provides an application with more control over the plug-in's configuration.

In C++ with OpenSSL and in Java, an application can call the `setContext` method to supply a pre-configured "context" object used by the underlying SSL engines. In .NET, the `setCertificates` method accepts a collection of certificates that the plug-in should use. In all cases, using one of these methods causes IceSSL to ignore (at a minimum) the configuration properties related to certificates and keys. The application is responsible for accumulating its certificates and keys, and must also deal with any password requirements.

Describing the use of these plug-in methods in detail is outside the scope of this manual, however it is important to understand their prerequisites. In particular, the application needs to have the communicator load the plug-in but not actually initialize it until after the application has had a chance to interact directly with it. (The previous section showed examples of this technique.) The application must define the `Ice.InitPlugins` configuration property:

```
Ice.InitPlugins=0
```

With this setting, the application becomes responsible for completing the plug-in initialization process by invoking `initializePlugins` on the `PluginManager`. The C# example below demonstrates the proper steps:

C#

```
Ice.Communicator comm = // ...
Ice.PluginManager pluginMgr = comm.getPluginManager();
Ice.Plugin plugin = pluginMgr.getPlugin("IceSSL");
IceSSL.Plugin sslPlugin = (IceSSL.Plugin)plugin;
X509Certificate2Collection certs = // ...
sslPlugin.setCertificates(certs);
pluginMgr.initializePlugins();
```

Using Custom Plug-ins with IceSSL

The Ice [plug-in facility](#) is not restricted to protocol implementations. Ice only requires that a plug-in implement the `Ice::Plugin` interface and support the language-specific mechanism for dynamic loading.

The customization options of the IceSSL plug-in make it possible for you to install an application-specific implementation of a certificate

verifier in an existing program. For example, you could install a custom certificate verifier in a Glacier2 router without the need to modify Glacier2's source code or rebuild the executable. You would have to write a C++ plug-in to accomplish this, since Glacier2 is written in C++. In short, your plug-in must interact with the IceSSL plug-in and install a certificate verifier.

For this technique to work, it is important that the plug-ins be loaded in a particular order. Specifically, the IceSSL plug-in must be loaded first, followed by the certificate verifier plug-in. By default, Ice loads plug-ins in an undefined order, but you can use the property `Ice.PluginLoadOrder` to specify a particular order.

As an example, let's write a plug-in that installs our simple C++ certificate verifier. Here is the definition of our plug-in class:

```

C++

class VerifierPlugin : public Ice::Plugin
{
public:
    VerifierPlugin(const Ice::CommunicatorPtr & comm) :
        _comm(comm)
    {
    }

    virtual void initialize()
    {
        Ice::PluginManagerPtr pluginMgr = _comm->getPluginManager();
        Ice::PluginPtr plugin = pluginMgr->getPlugin("IceSSL");
        IceSSL::PluginPtr sslPlugin =
        IceSSL::PluginPtr::dynamicCast(plugin);
        sslPlugin->setCertificateVerifier(new Verifier);
    }

    virtual void destroy()
    {
    }

private:
    Ice::CommunicatorPtr _comm;
};

```

The class implements the two operations in the `Plugin` interface, `initialize` and `destroy`. The code in `initialize` installs the certificate verifier object, while nothing needs to be done in `destroy`.

The next step is to write the plug-in's factory function, which the communicator invokes to obtain an instance of the plug-in:

C++

```
extern "C"
{

Ice::Plugin*
createVerifierPlugin(
    const Ice::CommunicatorPtr & communicator,
    const string & name,
    const Ice::StringSeq & args)
{
    return new VerifierPlugin(communicator);
}

}
```

We can give the function any name; in this example, we chose `createVerifierPlugin`.

Finally, to install the plug-in we need to define the following properties:

C++

```
Ice.PluginLoadOrder=IceSSL,Verifier
Ice.Plugin.IceSSL=IceSSL:createIceSSL
Ice.Plugin.Verifier=Verifier:createVerifierPlugin
```

The value of `Ice.PluginLoadOrder` guarantees that `IceSSL` is loaded first. The plug-in specification `Verifier:createVerifierPlugin` identifies the name of the shared library or DLL and the name of the registration function.

There are a few more details you must attend to, such as ensuring that the factory function is exported properly and building the shared library or DLL that contains the new plug-in. Our discussion of the [plug-in facility](#) provides more information on developing a plug-in.

Setting up a Certificate Authority

During development, it is convenient to have a simple way of creating new certificates. OpenSSL includes all of the necessary infrastructure for setting up your own certificate authority (CA), but it requires getting more familiar with OpenSSL than is really necessary. To simplify the process, the `zeroc-icecertutils` PyPi package provides a Python library and an `iceca` script that allows you to quickly perform the essential tasks:

- initializing a new root CA
- generating new certificates
- converting certificates to match platform-specific requirements.

You are not obligated to use this package; IceSSL accepts certificates from any source as long as they are provided in the appropriate formats. However, you may find this tool sufficient for your development needs, and possibly even for your deployed application as well.

You will find more information on the `IceCertUtils` package and the `iceca` utility on the `zeroc-icecertutils` PyPi page. You can also take a look at the `makecerts.py` scripts in the `certs` and `cpp/IceGrid/secure` directories from the Ice demos repository for examples on how to use the `IceCertUtils` Python library.

Using Plugins with Static Libraries

When an Ice plug-in is packaged in a static library, you need to link your application with the plug-in's static library and call a `register` function from your application to ensure the corresponding code gets correctly included.

Linux Only

You need to call these `register` functions when linking with static libraries on Linux. On other platforms, all Ice plug-ins included in the Ice static library are registered automatically.

Ice provides the following plug-in registration functions:

```
C++
```

```
namespace Ice
{
    void registerIceDiscovery(bool loadOnInitialize = true);
    void registerIceLocatorDiscovery(bool loadOnInitialize = true);
    void registerIceSSL(bool loadOnInitialize = true);
    void registerIceStringConverter(bool loadOnInitialize = true);
}
```

For example, if you are using a static IceSSL plug-in, link your application with `libIce.a` and call `Ice::registerIceSSL` from your application. All Ice plug-ins (IceDiscovery, IceLocatorDiscovery and IceSSL) are included in the Ice static library (`libIce.a`).

When the `bool` parameter is `true` (the default), the plug-in is always loaded (created) during communicator initialization, even if `Ice.Plugin.name` is not set. When `false`, the plug-in is loaded (created) during communication initialization only if `Ice.Plugin.name` is set to a non-empty value (e.g., `Ice.Plugin.IceSSL=1`).

The table below summarizes the registration functions:

Plug-in Name	Functionality	Function
IceStringConverter	convert native string encoding to/from UTF-8	<code>Ice::registerIceStringConverter</code>
IceSSL	icessl transport	<code>Ice::registerIceSSL</code>
IceDiscovery	Location service implemented using UDP multicast	<code>Ice::registerIceDiscovery</code>
IceLocatorDiscovery	Location service implemented using UDP multicast	<code>Ice::registerIceLocatorDiscovery</code>

If you are developing your own plug-in, you will also need to register your plug-in factory function using `Ice::registerPluginFactory`. Refer to the [Plug-in API](#) for more information on this function.

Ice Services

Freeze

Freeze is a collection of services that simplify the use of persistence in Ice applications, as shown below:

Layer diagram for Freeze persistence services.

The [Freeze map](#) is an associative container mapping any Slice key and value types, providing a convenient and familiar interface to a persistent map. [Freeze evictors](#) are an especially powerful facility for supporting persistent Ice objects in a highly-scalable implementation.

The Freeze persistence services comprise:

- [Freeze evictor](#)
A highly-scalable implementation of an Ice [servant locator](#) that provides automatic persistence and eviction of servants with only minimal application code.
- [Freeze map](#)
A generic associative container. Code generators are provided that produce type-specific maps for Slice key and value types. Applications interact with a Freeze map just like any other associative container, except the keys and values of a Freeze map are persistent.

As you will see from the examples in this discussion, integrating a Freeze map or evictor into your Ice application is quite straightforward: once you define your persistent data in Slice, Freeze manages the mundane details of persistence.

Freeze is implemented using Berkeley DB, a compact and high-performance embedded database. The Freeze map and evictor APIs insulate applications from the Berkeley DB API, but do not prevent applications from interacting directly with Berkeley DB if necessary.

Freeze Evictors

Freeze evictors combine persistence and scalability features into a single facility that is easily incorporated into Ice applications.

As an implementation of a [servant locator](#), a Freeze evictor takes advantage of the fundamental separation between Ice object and servant to activate servants on demand from persistent storage, and to deactivate them again using customized eviction constraints. Although an application may have thousands of Ice objects in its database, it is not practical to have servants for all of those Ice objects resident in memory simultaneously. The application can conserve resources and gain greater scalability by setting an upper limit on the number of active servants, and letting a Freeze evictor handle the details of servant activation, persistence, and deactivation.

Describing Persistent State for an Evictor

The persistent state of servants managed by a Freeze evictor must be described in Slice. Specifically, every servant must implement a [Slice class](#), and a Freeze evictor automatically stores and retrieves all the (Slice-defined) data members of these Slice classes. Data members that are not specified in Slice are not persistent.

A Freeze evictor relies on the Ice object factory facility to load persistent servants from disk: the evictor creates a brand new servant using the registered factory and then restores the servant's data members. Therefore, for every persistent servant class you define, you need to register a corresponding object factory with the Ice communicator. (For more details on object factories, refer to the [C++ mapping](#) or the [Java mapping](#).)

Evictor Servant Semantics

With a Freeze evictor, each `<object identity, facet>` pair is associated with its own dedicated persistent object (servant). Such a persistent object cannot serve several identities or facets. Each servant is loaded and saved independently of other servants; in particular, there is no special grouping for the servants that serve the facets of a given Ice object.

Similar to the way you [activate servants with an object adapter](#), the Freeze evictor provides operations named `add`, `addFacet`, `remove`, and `removeFacet`. They have the same signature and semantics, except that with the Freeze evictor, the mapping and the state of the mapped servants is stored in a database.

Evictor Types

Freeze provides two types of evictors with different storage characteristics. The [background save evictor](#) records state changes to the database in a background thread, while the [transactional evictor](#) records all state changes immediately within the context of a transaction. You can choose the evictor that best fits the persistence requirements of your application.

Eviction Strategy

Both types of evictors associate a queue with their servant map and manage this queue using a "least recently used" eviction algorithm: if the queue is full, the least recently used servant is evicted to make room for a new servant.

Here is the sequence of events for activating a servant as shown in the figure below. Let us assume that we have configured the evictor with a size of five, that the queue is full, and that a request has arrived for a servant that is not currently active. (With a transactional evictor, we also assume this request does not change any persistent state.)

1. A client invokes an operation.
2. The object adapter invokes on the evictor to locate the servant.
3. The evictor first checks its servant map and fails to find the servant, so it instantiates the servant and restores its persistent state from the database.
4. The evictor adds an item for the servant (servant 1) at the head of the queue.
5. The queue's length now exceeds the configured maximum, so the evictor removes servant 6 from the queue as soon as it is eligible for eviction. With a background save evictor, this occurs once there are no outstanding requests pending on servant 6, and once the servant's state has been safely stored in the database. With a transactional save, the servant is removed from the queue immediately.
6. The object adapter dispatches the request to the new servant.

An evictor queue after restoring servant 1 and evicting servant 6.

Detecting Updates to Persistent State

A Freeze evictor considers that a servant's persistent state has been modified when a read-write operation on this servant completes. To indicate whether an operation is read-only or read-write, you add metadata directives to the Slice definitions of the objects:

- The ["freeze:write"] directive informs the evictor that an operation modifies the persistent state of the target servant.
- The ["freeze:read"] directive informs the evictor that an operation does not modify the persistent state of the target.

If no metadata directive is present, an operation is assumed to not modify its target.

Here is how you could mark the operations on an interface with these metadata directives:

Slice

```
interface Example {
    ["freeze:read"]  string readonlyOp();
    ["freeze:write"] void  writeOp();
};
```

This marks `readonlyOp` as an operation that does not modify its target, and marks `writeOp` as an operation that does modify its target. Because, without any directive, an operation is assumed to not modify its target, the preceding definition can also be written as follows:

Slice

```
interface Example {
    string readonlyOp(); // ["freeze:read"] implied
    ["freeze:write"] void writeOp();
};
```

The metadata directives can also be applied to an interface or a class to establish a default. This allows you to mark an interface as ["freeze:write"] and to only add a ["freeze:read"] directive to those operations that are read-only, for example:

Slice

```
["freeze:write"]
interface Example {
    ["freeze:read"] string readonlyOp();
    void writeOp1();
    void writeOp2();
    void writeOp3();
};
```

This marks `writeOp1`, `writeOp2`, and `writeOp3` as read-write operations, and `readonlyOp` as a read-only operation.

Note that it is important to correctly mark read-write operations with a ["freeze:write"] metadata directive — without the directive, Freeze will not know when an object has been modified and may not store the updated persistent state to disk.

Also note that, if you make calls directly on servants (so the calls are not dispatched via the Freeze evictor), the evictor will have no idea when a servant's persistent state is modified; if any such direct call modifies the servant's data members, the update may be lost.

Iterating an Evictor

A Freeze evictor iterator provides the ability to iterate over the identities of the objects stored in an evictor. The operations are similar to Java iterator methods: `hasNext` returns true while there are more elements, and `next` returns the next identity:

Slice

```
local interface EvictorIterator {
    bool hasNext();
    Ice::Identity next();
};
```

You create an iterator by calling `getIterator` on your evictor:

Slice

```
EvictorIterator getIterator(string facet, int batchSize);
```

The new iterator is specific to a facet (specified by the `facet` parameter). Internally, this iterator will retrieve identities in batches of `batchSize` objects; we recommend using a fairly large batch size to get good performance.

Indexing an Evictor Database

A Freeze evictor supports the use of indexes to quickly find persistent servants using the value of a data member as the search criteria. The types allowed for these indexes are the same as those allowed for [Slice dictionary keys](#).

The `slice2freeze` and `slice2freezej` tools can generate an `Index` class when passed the `--index` option:

```
--index CLASS,TYPE,MEMBER[,case-sensitive|case-insensitive]
```

`CLASS` is the name of the class to be generated. `TYPE` denotes the type of class to be indexed (objects of different classes are not included in this index). `MEMBER` is the name of the data member in `TYPE` to index. When `MEMBER` has type `string`, it is possible to specify whether the index is case-sensitive or not. The default is case-sensitive.

The generated `Index` class supplies three methods whose definitions are mapped from the following Slice operations:

- `sequence<Ice::Identity> findFirst(member-type index, int firstN)`
Returns up to `firstN` objects of `TYPE` whose `MEMBER` is equal to `index`. This is useful to avoid running out of memory if the potential number of objects matching the criteria can be very large.
- `sequence<Ice::Identity> find(member-type index)`
Returns all the objects of `TYPE` whose `MEMBER` is equal to `index`.
- `int count(member-type index)`
Returns the number of objects of `TYPE` having `MEMBER` equal to `index`.

Indexes are associated with a Freeze evictor during evictor creation. See the definition of the `createBackgroundSaveEvictor` and `createTransactionalEvictor` functions for details.

Indexed searches are easy to use and very efficient. However, be aware that an index adds significant write overhead: with Berkeley DB, every update triggers a read from the database to get the old index entry and, if necessary, replace it.

If you add an index to an existing database, by default existing facets are not indexed. If you need to populate a new or empty index using the facets stored in your Freeze evictor, set the property `Freeze.Evictor.env-name.filename.PopulateEmptyIndices` to a non-zero value, which instructs Freeze to iterate over the corresponding facets and create the missing index entries during the call to `createBackgroundSaveEvictor` or `createTransactionalEvictor`. When you use this feature, you must register the object factories for all of the facet types before you create your evictor.

Using a Servant_INITIALIZER

In some applications, it may be necessary to initialize a servant after the servant is instantiated by the evictor but before an operation is dispatched to the servant. The Freeze evictor allows an application to specify a servant initializer for this purpose.

To illustrate the sequence of events, let us assume that a request has arrived for a servant that is not currently active:

1. The evictor restores a servant for the target Ice object (and facet) from the database. This involves two steps:
 - The Ice run time locates and invokes the factory for the Ice facet's type, thereby obtaining a new instance with uninitialized data members.
 - The data members are populated from the persistent state.
2. The evictor invokes the application's servant initializer (if any) for the servant.
3. If the evictor is a background-save evictor, it adds the servant to its cache.
4. The evictor dispatches the operation.

With a background-save evictor, the servant initializer is called before the object is inserted into the evictor's internal cache, and *without* holding any internal lock, but in such a way that when the servant initializer is called, the servant is guaranteed to be inserted in the evictor cache.

There is only one restriction on what a servant initializer can do: it must not make a remote invocation on the object (facet) being initialized. Failing to follow this rule will result in deadlocks.

The [file system example](#) demonstrates the use of a servant initializer.

Application Design Considerations for Evictors

The Freeze evictor creates a snapshot of a servant's state for persistent storage by marshaling the servant, just as if the servant were being

sent "over the wire" as a parameter to a remote invocation. Therefore, the Slice definitions for an object type must include the data members comprising the object's persistent state.

For example, we could define a Slice class as follows:

```

Slice

class Stateless {
    void calc();
};

```

However, without data members, there will not be any persistent state in the database for objects of this type, and hence there is little value in using the Freeze evictor for this type.

Obviously, Slice object types need to define data members, but there are other design considerations as well. For example, suppose we define a simple application as follows:

```

Slice

class Account {
    ["freeze:write"] void withdraw(int amount);
    ["freeze:write"] void deposit(int amount);

    int balance;
};

interface Bank {
    Account* createAccount();
};

```

In this application, we would use a Freeze evictor to manage `Account` objects that have a data member `balance` representing the persistent state of an account.

From an object-oriented design perspective, there is a glaring problem with these Slice definitions: implementation details (the persistent state) are exposed in the client-server contract. The client cannot directly manipulate the `balance` member because the `Bank` interface returns `Account` proxies, not `Account` instances. However, the presence of the data member may cause unnecessary confusion for client developers.

A better alternative is to clearly separate the persistent state as shown below:

Slice

```
interface Account {
    ["freeze:write"] void withdraw(int amount);
    ["freeze:write"] void deposit(int amount);
};

interface Bank {
    Account* createAccount();
};

class PersistentAccount implements Account {
    int balance;
};
```

Now the Freeze evictor can manage `PersistentAccount` objects, while clients interact with `Account` proxies. (Ideally, `PersistentAccount` would be defined in a different source file and inside a separate Slice module.)

Background Save Evictor

Freeze provides two types of evictors. This page describes the background save evictor.

Freeze also provides a [transactional evictor](#), with different persistence semantics. The on-disk format of these two types of evictors is the same: you can switch from one type of evictor to the other without any data transformation.

On this page:

- [Overview of the Background Save Evictor](#)
- [Creating a Background Save Evictor](#)
- [The Background Saving Thread](#)

- [Handling Fatal Evictor Errors](#)

Overview of the Background Save Evictor

A background save evictor keeps all its servants in a map and writes the state of newly-created, modified, and deleted servants to disk asynchronously, in a background thread. You can configure how often servants are saved; for example you could decide to save every three minutes, or whenever ten or more servants have been modified. For applications with frequent updates, this allows you to group many updates together to improve performance.

The downside of the background save evictor is recovery from a crash. Because saves are asynchronous, there is no way to force an immediate save to preserve a critical update. Moreover, you cannot group several related updates together: for example, if you transfer funds between two accounts (servants) and a crash occurs shortly after this update, it is possible that, once your application comes back up, you will see the update on one account but not on the other. Your application needs to handle such inconsistencies when restarting after a crash.

Similarly, a background save evictor provides no ordering guarantees for saves. If you update servant 1, servant 2, and then servant 1 again, it is possible that, after recovering from a crash, you will see the latest state for servant 1, but no updates at all for servant 2.

The background save evictor implements the local interface `Freeze::BackgroundSaveEvictor`, which derives from `Freeze::Evictor`.

Creating a Background Save Evictor

You create a background save evictor in C++ with the global function `Freeze::createBackgroundSaveEvictor`, and in Java with the static method `Freeze.Util.createBackgroundSaveEvictor`.

For C++, the signatures are as follows:

C++

```

BackgroundSaveEvictorPtr
createBackgroundSaveEvictor(
    const ObjectAdapterPtr& adapter,
    const string& envName,
    const string& filename,
    const ServantInitializerPtr& initializer = 0,
    const vector<IndexPtr>& indexes = vector<IndexPtr>(),
    bool createDb = true);

BackgroundSaveEvictorPtr
createBackgroundSaveEvictor(
    const ObjectAdapterPtr& adapter,
    const string& envName,
    DbEnv& dbEnv,
    const string& filename,
    const ServantInitializerPtr& initializer = 0,
    const vector<IndexPtr>& indexes = vector<IndexPtr>(),
    bool createDb = true);

```

For Java, the method signatures are:

Java

```

public static BackgroundSaveEvictor
createBackgroundSaveEvictor(
    Ice.ObjectAdapter adapter,
    String envName,
    String filename,
    ServantInitializer initializer,
    Index[] indexes,
    boolean createDb);

public static BackgroundSaveEvictor
createBackgroundSaveEvictor(
    Ice.ObjectAdapter adapter,
    String envName,
    com.sleepycat.db.Environment dbEnv,
    String filename,
    ServantInitializer initializer,
    Index[] indexes,
    boolean createDb);

```

Both C++ and Java provide two overloaded functions: in one case, Freeze opens and manages the underlying Berkeley DB environment; in the other case, you provide a `DbEnv` object that represents a Berkeley DB environment you opened yourself. (Usually, it is easiest to let Freeze take care of all interactions with Berkeley DB.)

The `envName` parameter represents the name of the underlying Berkeley DB environment, and is also used as the default Berkeley DB home directory. (See `Freeze.DbEnv.env-name.DbHome`.)

The `filename` parameter represents the name of the Berkeley DB database file associated with this evictor. The persistent state of all your servants is stored in this file.

The `initializer` parameter represents the [servant initializer](#). It is an optional parameter in C++; in Java, pass `null` if you do not need a servant initializer.

The `indexes` parameter is a vector or array of [evictor indexes](#). It is an optional parameter in C++; in Java, pass `null` if your evictor does not define an index.

Finally, the `createDb` parameter tells Freeze what to do when the corresponding Berkeley DB database does not exist. When true, Freeze creates a new database; when false, Freeze raises a `Freeze::DatabaseException`.

The Background Saving Thread

All persistence activity of a background save evictor is handled in a background thread created by the evictor. This thread wakes up periodically and saves the state of all newly-registered, modified, and destroyed servants in the evictor's queue.

For applications that experience bursts of activity that result in a large number of modified servants in a short period of time, you can also configure the evictor's thread to begin saving as soon as the number of modified servants reaches a certain threshold.

Synchronization Semantics for the Background Save Evictor

When the saving thread takes a snapshot of a servant it is about to save, it is necessary to prevent the application from modifying the servant's persistent data members at the same time.

The Freeze evictor and the application need to use a common synchronization to ensure correct behavior. In Java, this common synchronization is the servant itself: the Freeze evictor synchronizes the servant (a Java object) while taking the snapshot. In C++, the servant is required to inherit from the class `IceUtil::AbstractMutex`: the background save evictor locks the servant through this interface while taking a snapshot. On the application side, the servant's implementation is required to use the same mechanism to synchronize all operations that access the servant's Slice-defined data members.

Preventing Servant Eviction

Occasionally, automatically evicting and reloading all servants can be inefficient. You can remove a servant from the evictor's queue by locking this servant "in memory" using the `keep` or `keepFacet` operation on the evictor:

Slice

```

local interface BackgroundSaveEvictor extends Evictor {
    void keep(Ice::Identity id);
    void keepFacet(Ice::Identity id, string facet);
    void release(Ice::Identity id);
    void releaseFacet(Ice::Identity id, string facet);
};

```

`keep` and `keepFacet` are recursive: you need to call `release` or `releaseFacet` for this servant the same number of times to put it back in the evictor queue and make it eligible again for eviction.

Servants kept in memory (using `keep` or `keepFacet`) do not consume a slot in the evictor queue. As a result, the maximum number of servants in memory is approximately the number of kept servants plus the evictor size. (It can be larger while you have many evictable objects that are modified but not yet saved.)

Handling Fatal Evictor Errors

Freeze allows you to register a callback for handling fatal errors encountered by a background save evictor. If no callback is registered, the evictor aborts the application by default.

The application should assume that an evictor will not continue to work properly after encountering a fatal error.

Use `Freeze.Util.registerFatalErrorCallback (Java)` or `Freeze::registerFatalErrorCallback (C++)` to register the callback.

For C++, `registerFatalErrorCallback` accepts a function pointer of type `FatalErrorCallback`:

C++

```
typedef void (*FatalErrorCallback)(const BackgroundSaveEvictorPtr&,
const Ice::CommunicatorPtr&);
```

In Java, `registerFatalErrorCallback` accepts a reference to an object that implements `Freeze.FatalErrorCallback`:

Java

```
package Freeze;

public interface FatalErrorCallback
{
    void handleError(Evictor evictor, Ice.Communicator communicator,
RuntimeException ex);
}
```

Note that the `RuntimeException` argument may be null.

Transactional Evictor

Freeze provides two types of evictors. This page describes the transactional evictor.

Freeze also provides a [background save evictor](#), with different persistence semantics. The on-disk format of these two types of evictors is the same: you can switch from one type of evictor to the other without any data transformation.

On this page:

- [Overview of the Transactional Evictor](#)

- [Transaction Propagation](#)
- [Commit or Rollback on User Exception](#)
- [Database Deadlocks and Automatic Retries](#)
- [AMD and the Transactional Evictor](#)
- [Transactions and Freeze Maps](#)

Overview of the Transactional Evictor

A transactional evictor maintains a servant map, but only keeps read-only servants in this map. The state of these servants corresponds to the latest data on disk. Any servant creation, update, or deletion is performed within a database transaction. This transaction is committed (or rolled back) immediately, typically at the end of the dispatch of the current operation, and the associated servants are then discarded.

With such an evictor, you can ensure that several updates, often on different servants (possibly managed by different transactional evictors) are grouped together: either all or none of these updates occur. In addition, updates are written almost immediately, so crash recovery is a lot simpler: few (if any) updates will be lost, and you can maintain consistency between related persistent objects.

However, an application based on a transactional evictor is likely to write a lot more to disk than an application with a background save evictor, which may have an adverse impact on performance.

Creating a Transactional Evictor

You create a transactional evictor in C++ with the global function `Freeze::createTransactionalEvictor`, and in Java with the static method `Freeze.Util.createTransactionalEvictor`.

For C++, the signatures are as follows:

C++

```

typedef map<string, string> FacetTypeMap;

TransactionalEvictorPtr
createTransactionalEvictor(
    const ObjectAdapterPtr& adapter,
    const string& envName,
    const string& filename,
    const FacetTypeMap& facetTypes = FacetTypeMap(),
    const ServantInitializerPtr& initializer = 0,
    const vector<IndexPtr>& indexes = vector<IndexPtr>(),
    bool createDb = true);

TransactionalEvictorPtr
createTransactionalEvictor(
    const ObjectAdapterPtr& adapter,
    const string& envName,
    DbEnv& dbEnv,
    const string& filename,
    const FacetTypeMap& facetTypes = FacetTypeMap(),
    const ServantInitializerPtr& initializer = 0,
    const vector<IndexPtr>& indexes = vector<IndexPtr>(),
    bool createDb = true);

```

For Java, the method signatures are:

Java

```

public static TransactionalEvictor
createTransactionalEvictor(
    Ice.ObjectAdapter adapter,
    String envName,
    String filename,
    java.util.Map facetTypes,
    ServantInitializer initializer,
    Index[] indexes,
    boolean createDb);

public static TransactionalEvictor
createTransactionalEvictor(
    Ice.ObjectAdapter adapter,
    String envName,
    com.sleepycat.db.Environment dbEnv,
    String filename,
    java.util.Map facetTypes,
    ServantInitializer initializer,
    Index[] indexes,
    boolean createDb);

```

Both C++ and Java provide two overloaded functions: in one case, Freeze opens and manages the underlying Berkeley DB environment; in the other case, you provide a `DbEnv` object that represents a Berkeley DB environment you opened yourself. (Usually, it is easier to let Freeze take care of all interactions with Berkeley DB.)

The `envName` parameter represents the name of the underlying Berkeley DB environment, and is also used as the default Berkeley DB home directory. (See [Freeze.DbEnv.env-name.DbHome](#).)

The `filename` parameter represents the name of the Berkeley DB database file associated with this evictor. The persistent state of all your servants is stored in this file.

The `facetTypes` parameter allows you to specify a single class type (Slice [type ID](#) string) for each facet in your new evictor (see below). Most applications use only the default facet, represented by an empty string. This parameter is optional in C++; in Java, pass `null` if you do not want to specify such a facet-to-type mapping.

The `initializer` parameter represents the [servant initializer](#). It is an optional parameter in C++; in Java, pass `null` if you do not need a servant initializer.

The `indexes` parameter is a vector or array of [evictor indexes](#). It is an optional parameter in C++; in Java, pass `null` if your evictor does not define an index.

Finally, the `createDb` parameter tells Freeze what to do when the corresponding Berkeley DB database does not exist. When true, Freeze creates a new database; when false, Freeze raises a `Freeze::DatabaseException`.

Read and Write Operations

When a transactional evictor processes an incoming request without an associated transaction, it first needs to find out whether the corresponding operation is [read-only](#) or [read-write](#) (as specified by the `"freeze:read"` and `"freeze:write"` operation metadata). This is straightforward if the evictor knows the target's type; in this case, it simply instantiates and keeps a "dummy" servant to look up the attributes of each operation.

However, if the target type can vary, the evictor needs to look up and sometimes load a read-only servant to find this information. For read-write requests, it will then load the servant from disk a second time (within a new transaction). Once the transaction commits, the read-only servant — sometimes freshly loaded from disk — is discarded.

When you create a transactional evictor with `createTransactionalEvictor`, you can pass a facet name to type ID map to associate a single servant type with each facet and speed up the retrieval of these operation attributes.

Synchronization Semantics for the Transactional Evictor

With a transactional evictor, there is no need to perform any synchronization on the servants managed by the evictor:

- For read-only operations, the application must not modify any data member, and hence there is no need to synchronize. (Many threads can safely read the same data members concurrently.)
- For read-write operations, each operation dispatch gets its own private servant or servants (see transaction propagation below).

Not having to worry about synchronization can dramatically simplify your application code.

Transaction Propagation

Without a distributed transaction service, it is not possible to invoke several remote operations within the same transaction. Nevertheless, Freeze supports transaction propagation for collocated calls: when a request is dispatched within a transaction, the transaction is associated with the dispatch thread and will propagate to any other servant reached through a collocated call. If the target of a collocated call is managed by a transactional evictor associated with the same database environment, Freeze reuses the propagated transaction to load the servant and dispatch the request. This allows you to group updates to several servants within a single transaction.

You can also control how a transactional evictor handles an incoming transaction through optional metadata added after `"freeze:write"` and `"freeze:read"`. There are six valid directives:

- `freeze:read:never`
Verify that no transaction is propagated to this operation. If a transaction is present, the transactional evictor raises a `Freeze::DatabaseException`.
- `freeze:read:supports`
Accept requests with or without a transaction, and re-use the transaction if present. `"supports"` is the default for `"freeze:read"` operations.
- `freeze:read:mandatory` and `freeze:write:mandatory`
Verify that a transaction is propagated to this operation. If there is no transaction, the transactional evictor raises a `Freeze::DatabaseException`.
- `freeze:read:required` and `freeze:write:required`
Accept requests with or without a transaction, and re-use the transaction if present. If no transaction is propagated, the transactional evictor creates a new transaction before dispatching the request. `"required"` is the default for `"freeze:write"` operations.

Commit or Rollback on User Exception

When a transactional evictor processes an incoming read-write request, it starts a new database transaction, loads a servant within the transaction, dispatches the request, and then either commits or rolls back the transaction depending on the outcome of this dispatch. If the dispatch does not raise an exception, the transaction is committed just before the response is sent back to the client. If the dispatch raises a system exception, the transaction is rolled back. If the dispatch raises a user exception, by default, the transaction is committed. However, you can configure Freeze to rollback on user-exceptions by setting `Freeze.Evictor.env-name.fileName.RollbackOnUserException` to a non-zero value.

Database Deadlocks and Automatic Retries

When reading and writing in separate concurrent transactions, deadlocks are likely to occur. For example, one transaction may lock pages in a particular order while another transaction locks the same pages in a different order; the outcome is a deadlock. Berkeley DB automatically detects such deadlocks, and "kills" one of the transactions.

With a Freeze transactional evictor, the application does not need to catch any deadlock exceptions or retry when deadlock occurs because the transactional evictor automatically retries its transactions whenever it encounters a deadlock situation.

However, this can affect how you implement your operations: for any operation called within a transaction (mainly read-write operations), you must anticipate the possibility of several calls for the same request, all in the same dispatch thread.

AMD and the Transactional Evictor

When a transactional evictor dispatches a read-write operation implemented using AMD, it starts a transaction before dispatching the request, and commits or rolls back the transaction when the dispatch is done. Two threads are involved here: the *dispatch thread* and the *callback thread*. The dispatch thread is a thread from an Ice thread pool tasked with dispatching a request, and the callback thread is the thread that invokes the AMD callback to send the response to the client. These threads may be one and the same if the servant invokes the AMD callback from the dispatch thread.

It is important to understand the threading semantics of an AMD request with respect to the transaction:

- If a successful AMD response is sent from the dispatch thread, the transaction is committed *after* the response is sent. If a deadlock occurs during this commit, the request is not retried and the client receives no indication of the failure.
- If a successful AMD response is sent from another thread, the evictor commits its transaction when the dispatch thread completes, regardless of whether the servant has sent the AMD response. The callback thread waits until the transaction has been committed by the dispatch thread before sending the response.
- If a commit results in a deadlock and the AMD response has not yet been sent, the evictor cancels the original AMD callback and automatically retries the request again with a new AMD callback. Invocations on the original AMD callback are ignored (`ice_response` and `ice_exception` on this callback do nothing).
- Otherwise, if the servant sends an exception via the AMD callback, the response is sent directly to the client.

Transactions and Freeze Maps

A transactional evictor uses the same transaction objects as [Freeze maps](#), which allows you to update a Freeze map within a transaction managed by a transactional evictor.

You can get the current transaction created by a transactional evictor by calling `getCurrentTransaction`. Then, you would typically retrieve the associated Freeze connection (with `getConnection`) and construct a Freeze map using this connection:

Slice

```

local interface TransactionalEvictor extends Evictor {
    Transaction getCurrentTransaction();
    void setCurrentTransaction(Transaction tx);
};

```

A transactional evictor also gives you the ability to associate your own transaction with the current thread, using `setCurrentTransaction`. This is useful if you want to perform many updates within a single transaction, for example to add or remove many servants in the evictor. (A less convenient alternative is to implement all such updates within a read-write operation on some object.)

Using a Freeze Evictor in the File System Server

In this section, we present file system implementations that use a transactional evictor. The implementations are based on the ones discussed in [Object Life Cycle](#), and in this section we only discuss code that illustrates use of the Freeze evictor.

In general, incorporating a Freeze evictor into your application requires the following steps:

1. Evaluate your existing Slice definitions for a suitable persistent object type.
2. If no suitable type is found, you typically define a new derived class that captures your persistent state requirements. Consider placing these definitions in a separate file: they are only used by the server for persistence, and therefore do not need to appear in the "public" definitions required by clients. Also consider placing your persistent types in a separate module to avoid name clashes.
3. If you use [indexes with your evictor](#), generate code (using `slice2freeze` or `slice2freezej`) for your new definitions.
4. Create an evictor and register it as a servant locator with an object adapter.
5. Create instances of your persistent type and register them with the evictor.

Persistent Types for File System Evictor

Fortunately, it is unnecessary for us to change any of the existing file system Slice definitions to incorporate the Freeze evictor. However, we do need to add metadata definitions to inform the evictor which [operations modify object state](#):

Slice

```

module Filesystem {
    // ...

    interface Node {
        idempotent string name();

        ["freeze:write"]
        void destroy() throws PermissionDenied;
    };

    // ...

    interface File extends Node {
        idempotent Lines read();

        ["freeze:write"]
        idempotent void write(Lines text) throws GenericError;
    };

    // ...

    interface Directory extends Node {
        idempotent NodeDescSeq list();

        idempotent NodeDesc find(string name) throws NoSuchName;

        ["freeze:write"]
        File* createFile(string name) throws NameInUse;

        ["freeze:write"]
        Directory* createDirectory(string name) throws NameInUse;
    };
};

```

These definitions are identical to the original ones, with the exception of the added ["freeze:write"] directives.

The remaining definitions are in derived classes:

Slice

```
#include <Filesystem.ice>

module Filesystem {
    class PersistentDirectory;

    class PersistentNode implements Node {
        string nodeName;
        PersistentDirectory* parent;
    };

    class PersistentFile extends PersistentNode implements File {
        Lines text;
    };

    dictionary<string, NodeDesc> NodeDict;

    class PersistentDirectory extends PersistentNode implements
    Directory {
        ["freeze:write"]
        void removeNode(string name);

        NodeDict nodes;
    };
};
```

As you can see, we have sub-classed all of the file system interfaces. Let us examine each one in turn.

The `PersistentNode` class adds two data members: `nodeName` and `parent`.

We used `nodeName` instead of `name` because `name` is already used as an operation in the `Node` interface.

The file system implementation requires that a child node knows its parent node in order to properly implement the `destroy` operation. Previous implementations had a state member of type `DirectoryI`, but that is not workable here. It is no longer possible to pass the parent node to the child node's constructor because the evictor may be instantiating the child node (via a factory), and the parent node will not be known. Even if it were known, another factor to consider is that there is no guarantee that the parent node will be active when the child invokes on it, because the evictor may have evicted it. We solve these issues by storing a proxy to the parent node. If the child node invokes on the parent node via the proxy, the evictor automatically activates the parent node if necessary.

The `PersistentFile` class is very straightforward, simply adding a `text` member representing the contents of the file. Notice that the class extends `PersistentNode`, and therefore inherits the state members declared by the base class.

Finally, the `PersistentDirectory` class defines the `removeNode` operation, and adds the `nodes` state member representing the immediate children of the directory node. Since a child node contains only a proxy for its `PersistentDirectory` parent, and not a reference to an implementation class, there must be a Slice-defined operation that can be invoked when the child is destroyed.

If we had followed our earlier advice, we would have defined `Node`, `File`, and `Directory` classes in a separate `PersistentFilesystem` module, but in this example we use the existing `Filesystem` module for the sake of simplicity.

Adding an Evictor to the C++ File System Server

On this page:

- [The Server main Program in C++](#)
- [The Persistent Servant Class Definitions in C++](#)
- [Implementing a Persistent File in C++](#)
- [Implementing a Persistent Directory in C++](#)
- [Implementing NodeFactory in C++](#)

The Server main Program in C++

The server's `main` program is responsible for creating the evictor and initializing the root directory node. Many of the administrative duties, such as creating and destroying a communicator, are handled by the `Ice::Application` class. Our server `main` program has now become the following:

```

C++

#include <PersistentFilesystemI.h>

using namespace std;
using namespace Filesystem;

class FilesystemApp : virtual public Ice::Application
{
public:

    FilesystemApp(const string& envName) :
        _envName(envName)
    {
    }

    virtual int run(int, char*[])
    {
        Ice::ObjectFactoryPtr factory = new NodeFactory;
        communicator()->addObjectFactory(factory,
PersistentFile::ice_staticId());
        communicator()->addObjectFactory(factory,
PersistentDirectory::ice_staticId());

        Ice::ObjectAdapterPtr adapter =
communicator()->createObjectAdapter("EvictorFilesystem");

        Freeze::EvictorPtr evictor =
            Freeze::createTransactionalEvictor(adapter, _envName,
"evictorfs");
        FileI::_evictor = evictor;
        DirectoryI::_evictor = evictor;

        adapter->addServantLocator(evictor, "");

        Ice::Identity rootId;
        rootId.name = "RootDir";
    }
}

```

```
    if(!evictor->hasObject(rootId))
    {
        PersistentDirectoryPtr root = new DirectoryI;
        root->nodeName = "/";
        evictor->add(root, rootId);
    }

    adapter->activate();

    communicator()->waitForShutdown();
    if(interrupted())
    {
        cerr << appName() << ": received signal, shutting down" <<
endl;
    }

    return 0;
}

private:
    string _envName;
};

int
main(int argc, char* argv[])
{
    FilesystemApp app("db");
```

```

    return app.main(argc, argv, "config.server");
}

```

Let us examine the changes in detail. First, we are now including `PersistentFilesystemI.h`. This header file includes all of the other Freeze (and Ice) header files this source file requires.

Next, we define the class `FilesystemApp` as a subclass of `Ice::Application`, and provide a constructor taking a string argument:

```

C++

FilesystemApp(const string& envName) :
    _envName(envName) { }

```

The string argument represents the name of the database environment, and is saved for later use in `run`.

One of the first tasks `run` performs is installing the Ice [object factories](#) for `PersistentFile` and `PersistentDirectory`. Although these classes are not exchanged via Slice operations, they are marshalled and unmarshalled in exactly the same way when saved to and loaded from the database, therefore factories are required. A single instance of `NodeFactory` is installed for both types:

```

C++

Ice::ObjectFactoryPtr factory = new NodeFactory;
communicator()->addObjectFactory(factory,
PersistentFile::ice_staticId());
communicator()->addObjectFactory(factory,
PersistentDirectory::ice_staticId());

```

After creating the object adapter, the program initializes a [transactional evictor](#) by invoking `createTransactionalEvictor`. The third argument to `createTransactionalEvictor` is the name of the database file, which by default is created if it does not exist. The new evictor is then added to the object adapter as a servant locator for the default category:

```

C++

NodeI::_evictor = Freeze::createTransactionalEvictor(adapter,
_envName, "evictorfs");
adapter->addServantLocator(NodeI::_evictor, "");

```

Next, the program creates the root directory node if it is not already being managed by the evictor:

C++

```

Ice::Identity rootId;
rootId.name = "RootDir";
if(!evictor->hasObject(rootId))
{
    PersistentDirectoryPtr root = new DirectoryI;
    root->nodeName = "/";
    evictor->add(root, rootId);
}

```

Finally, the `main` function instantiates the `FilesystemApp`, passing `db` as the name of the database environment:

C++

```

int
main(int argc, char* argv[])
{
    FilesystemApp app("db");
    return app.main(argc, argv, "config.server");
}

```

The Persistent Servant Class Definitions in C++

The servant classes must also be changed to incorporate the Freeze evictor. We no longer derive the servants from a common base class. Instead, `FileI` and `DirectoryI` each have their own `_destroyed` and `_mutex` members, as well as a static `_evictor` smart pointer that points at the transactional evictor:

C++

```

#include <PersistentFilesystem.h>
#include <IceUtil/IceUtil.h>
#include <Freeze/Freeze.h>

namespace Filesystem {

class FileI : virtual public PersistentFile {
public:

    FileI();

    // Slice operations...

    static Freeze::EvictorPtr _evictor;

private:

    bool _destroyed;
    IceUtil::Mutex _mutex;
};

class DirectoryI : virtual public PersistentDirectory {
public:

    DirectoryI();

    // Slice operations...

    virtual void removeNode(const std::string&, const Ice::Current&);

    static Freeze::EvictorPtr _evictor;

public:
    bool _destroyed;
    IceUtil::Mutex _mutex;
};

```

In addition to the node implementation classes, we have also declared an object factory:

C++

```

namespace Filesystem {
    class NodeFactory : virtual public Ice::ObjectFactory {
    public:
        virtual Ice::ObjectPtr create(const std::string&);
        virtual void destroy();
    };

```

Implementing a Persistent FileI in C++

The FileI methods are mostly trivial, because the Freeze evictor handles persistence for us:

C++

```

Filesystem::FileI::FileI() : _destroyed(false)
{
}

string
Filesystem::FileI::name(const Ice::Current& c)
{
    IceUtil::Mutex::Lock lock(_mutex);

    if (_destroyed) {
        throw Ice::ObjectNotExistException(__FILE__, __LINE__, c.id, c.
facet, c.operation);
    }

    return nodeName;
}

void
Filesystem::FileI::destroy(const Ice::Current& c)
{
    {
        IceUtil::Mutex::Lock lock(_mutex);

        if (_destroyed) {
            throw Ice::ObjectNotExistException(__FILE__, __LINE__, c.id
, c.facet, c.operation);
        }
        _destroyed = true;
    }

    //
    // Because we use a transactional evictor,

```

```

    // these updates are guaranteed to be atomic.
    //
    parent?>removeNode(nodeName);
    _evictor?>remove(c.id);
}

Filesystem::Lines
Filesystem::FileI::read(const Ice::Current& c)
{
    IceUtil::Mutex::Lock lock(_mutex);

    if (_destroyed) {
        throw Ice::ObjectNotExistException(__FILE__, __LINE__, c.id, c.
facet, c.operation);
    }

    return text;
}

void
Filesystem::FileI::write(const Filesystem::Lines& text,
                        const Ice::Current& c)
{
    IceUtil::Mutex::Lock lock(_mutex);

    if (_destroyed) {
        throw Ice::ObjectNotExistException(__FILE__, __LINE__, c.id, c.
facet, c.operation);
    }
}

```

```

        this?>text = text;
    }

```

The code checks that the node has not been destroyed before acting on the invocation by updating or returning state. Note that `destroy` must update two separate nodes: as well as removing itself from the evictor, the node must also update the parent's node map. Because we are using a transactional evictor, the two updates are guaranteed to be atomic, so it is impossible to leave the file system in an inconsistent state.

Implementing a Persistent *DirectoryI* in C++

The `DirectoryI` implementation requires more substantial changes. We begin our discussion with the `createDirectory` operation:

```

C++

Filesystem::DirectoryPrx
Filesystem::DirectoryI::createDirectory(const string& name,
const Ice::Current& c)
{
    IceUtil::Mutex::Lock lock(_mutex);

    if (_destroyed) {
        throw Ice::ObjectNotExistException(__FILE__, __LINE__, c.id, c.
facet, c.operation);
    }

    if (name.empty() || nodes.find(name) != nodes.end()) {
        throw NameInUse(name);
    }

    Ice::Identity id;
    id.name = IceUtil::generateUUID();
    PersistentDirectoryPtr dir = new DirectoryI;
    dir?>nodeName = name;
    dir?>parent = PersistentDirectoryPrx::uncheckedCast(c.adapter?>crea
teProxy(c.id));
    DirectoryPrx proxy = DirectoryPrx::uncheckedCast(_evictor?>add(dir,
id));

    NodeDesc nd;
    nd.name = name;
    nd.type = DirType;
    nd.proxy = proxy;
    nodes[name] = nd;

    return proxy;
}

```

After validating the node name, the operation obtains a unique identity for the child directory, instantiates the servant, and registers it with the Freeze evictor. Finally, the operation creates a proxy for the child and adds the child to its node table.

The implementation of the `createFile` operation has the same structure as `createDirectory`:

C++

```

Filesystem::FilePrx
Filesystem::DirectoryI::createFile(const string& name,
                                   const Ice::Current& c)
{
    IceUtil::Mutex::Lock lock(_mutex);

    if (_destroyed) {
        throw Ice::ObjectNotExistException(__FILE__, __LINE__, c.id, c.
facet, c.operation);
    }

    if (name.empty() || nodes.find(name) != nodes.end()) {
        throw NameInUse(name);
    }

    Ice::Identity id;
    id.name = IceUtil::generateUUID();
    PersistentFilePtr file = new FileI;
    file->nodeName = name;
    file->parent = PersistentDirectoryPrx::uncheckedCast(c.adapter->cre
ateProxy(c.id));
    FilePrx proxy = FilePrx::uncheckedCast(_evictor->add(file, id));

    NodeDesc nd;
    nd.name = name;
    nd.type = FileType;
    nd.proxy = proxy;
    nodes[name] = nd;

    return proxy;
}

```

Implementing NodeFactory in C++

We use a single factory implementation for creating two types of Ice objects: `PersistentFile` and `PersistentDirectory`. These are the only two types that the Freeze evictor will be restoring from its database.

C++

```
Ice::ObjectPtr
Filesystem::NodeFactory::create(const string& type)
{
    if (type == PersistentFile::ice_staticId())
        return new FileI;
    else if (type == PersistentDirectory::ice_staticId())
        return new DirectoryI;
    else {
        assert(false);
        return 0;
    }
}

void
Filesystem::NodeFactory::destroy()
{
}
```

The remaining Slice operations have trivial implementations, so we do not show them here.

Adding an Evictor to the Java File System Server

The Server Main Program in Java

The server's `main` method is responsible for creating the evictor and initializing the root directory node. Many of the administrative duties, such as creating and destroying a communicator, are handled by the `Ice.Application` class. Our server `main` program has now become the following:

Java

```
import Filesystem.*;

public class Server extends Ice.Application
{
    public
    Server(String envName)
    {
        _envName = envName;
    }

    public int
    run(String[] args)
    {
        Ice.ObjectFactory factory = new NodeFactory();
        communicator().addObjectFactory(factory, PersistentFile.ice_sta
ticId());
        communicator().addObjectFactory(factory, PersistentDirectory.ic
e_staticId());

        Ice.ObjectAdapter adapter = communicator().createObjectAdapter(
"EvictorFilesystem");

        Freeze.Evictor evictor =
            Freeze.Util.createTransactionalEvictor(adapter, _envName, "
evictorfs",
null, null, null, true);
        DirectoryI._evictor = evictor;
        FileI._evictor = evictor;

        adapter.addServantLocator(evictor, "");

        Ice.Identity rootId = new Ice.Identity();
        rootId.name = "RootDir";
        if(!evictor.hasObject(rootId))
```

```
    {
        PersistentDirectory root = new DirectoryI();
        root.nodeName = "/";
        root.nodes =
new java.util.HashMap<java.lang.String, NodeDesc>();
        evictor.add(root, rootId);
    }

    adapter.activate();

    communicator().waitForShutdown();

    return 0;
}

public static void
main(String[] args)
{
    Server app = new Server("db");
    int status = app.main("Server", args, "config.server");
    System.exit(status);
}
```

```

    private String _envName;
}

```

Let us examine the changes in detail. First, we define the class `Server` as a subclass of `Ice.Application`, and provide a constructor taking a string argument:

Java

```

public
Server(String envName)
{
    _envName = envName;
}

```

The string argument represents the name of the database environment, and is saved for later use in `run`.

One of the first tasks `run` performs is installing the Ice [object factories](#) for `PersistentFile` and `PersistentDirectory`. Although these classes are not exchanged via Slice operations, they are marshalled and unmarshalled in exactly the same way when saved to and loaded from the database, therefore factories are required. A single instance of `NodeFactory` is installed for both types:

Java

```

Ice.ObjectFactory factory = new NodeFactory();
communicator().addObjectFactory(factory, PersistentFile.ice_staticId());
communicator().addObjectFactory(factory, PersistentDirectory.ice_staticId());

```

After creating the object adapter, the program initializes a [transactional evictor](#) by invoking `createTransactionalEvictor`. The third argument to `createTransactionalEvictor` is the name of the database, the fourth is null to indicate that we do not use facets, the fifth is null to indicate that we do not use a servant initializer, the sixth argument (null) indicates no indexes are in use, and the `true` argument requests that the database be created if it does not exist. The evictor is then added to the object adapter as a servant locator for the default category:

Java

```

Freeze.Evictor evictor =
    Freeze.Util.createTransactionalEvictor(adapter, _envName, "
evictorfs",
null, null, null, true);
DirectoryI._evictor = evictor;
FileI._evictor = evictor;

adapter.addServantLocator(evictor, "");

```

Next, the program creates the root directory node if it is not already being managed by the evictor:

Java

```
Ice.Identity rootId = new Ice.Identity();
rootId.name = "RootDir";
if(!evictor.hasObject(rootId))
{
    PersistentDirectory root = new DirectoryI();
    root.nodeName = "/";
    root.nodes = new java.util.HashMap<String, NodeDesc>();
    evictor.add(root, rootId);
}
```

Finally, the `main` function instantiates the `Server` class, passing `db` as the name of the database environment:

Java

```
public static void
main(String[] args)
{
    Server app = new Server("db");
    int status = app.main("Server", args, "config.server");
    System.exit(status);
}
```

The Persistent Servant Class Definitions in Java

The servant classes must also be changed to incorporate the Freeze evictor. The `FileI` class now has a static state member `_evictor`:

Java

```
import Filesystem.*;

public final class FileI extends PersistentFile
{
    public
    FileI()
    {
        _destroyed = false;
    }

    // Slice operations...

    public static Freeze.Evictor _evictor;
    private boolean _destroyed;
}
```

The `DirectoryI` class has undergone a similar transformation:

Java

```
import Filesystem.*;

public final class DirectoryI extends PersistentDirectory
{
    public
    DirectoryI()
    {
        _destroyed = false;
        nodes = new java.util.HashMap<String, NodeDesc>();
    }

    // Slice operations...

    public static Freeze.Evictor _evictor;
    private boolean _destroyed;
}
```

Implementing a Persistent `FileI` in Java

The `FileI` methods are mostly trivial, because the Freeze evictor handles persistence for us.

Java

```

public synchronized String
name(Ice.Current current)
{
    if (!_destroyed) {
        throw new Ice.ObjectNotExistException(current.id, current.f
acet, current.operation);
    }

    return nodeName;
}

public void
destroy(Ice.Current current)
    throws PermissionDenied
{
    synchronized(this) {
        if (!_destroyed) {
            throw new Ice.ObjectNotExistException(current.id, curre
nt.facet, current.operation);
        }
        _destroyed = true;
    }

    //
    // Because we use a transactional evictor,
    // these updates are guaranteed to be atomic.
    //
    parent.removeNode(nodeName);
    _evictor.remove(current.id);
}

public synchronized String[]
read(Ice.Current current)
{
    if (!_destroyed) {
        throw new Ice.ObjectNotExistException(current.id, current.f
acet, current.operation);
    }

    return (String[])text.clone();
}

public synchronized void
write(String[] text, Ice.Current current)
    throws GenericError
{
    if (!_destroyed) {
        throw new Ice.ObjectNotExistException(current.id, current.f
acet, current.operation);
    }
}

```

```

        this.text = text;
    }

```

The code checks that the node has not been destroyed before acting on the invocation by updating or returning state. Note that `destroy` must update two separate nodes: as well as removing itself from the evictor, the node must also update the parent's node map. Because we are using a transactional evictor, the two updates are guaranteed to be atomic, so it is impossible to leave the file system in an inconsistent state.

Implementing a Persistent DirectoryI in Java

The `DirectoryI` implementation requires more substantial changes. We begin our discussion with the `createDirectory` operation:

Java

```

public synchronized DirectoryPrx
createDirectory(String name, Ice.Current current)
    throws NameInUse
{
    if (_destroyed) {
        throw new Ice.ObjectNotExistException(current.id, current.facet, current.operation);
    }

    if (name.length() == 0 || nodes.containsKey(name)) {
        throw new NameInUse(name);
    }

    Ice.Identity id = current.adapter.getCommunicator().stringToIdentity(
        java.util.UUID.randomUUID().toString());
    PersistentDirectory dir = new DirectoryI();
    dir.nodeName = name;
    dir.parent = PersistentDirectoryPrxHelper.uncheckedCast(
        current.adapter.createProxy(current.id));
    DirectoryPrx proxy = DirectoryPrxHelper.uncheckedCast(_evictor.add(dir, id));

    NodeDesc nd = new NodeDesc();
    nd.name = name;
    nd.type = NodeType.DirType;
    nd.proxy = proxy;
    nodes.put(name, nd);

    return proxy;
}

```

After validating the node name, the operation obtains a unique identity for the child directory, instantiates the servant, and registers it with the Freeze evictor. Finally, the operation creates a proxy for the child and adds the child to its node table.

The implementation of the `createFile` operation has the same structure as `createDirectory`:

Java	
<pre> public synchronized FilePrx createFile(String name, Ice.Current current) throws NameInUse { if (!_destroyed) { throw new Ice.ObjectNotExistException(current.id, current.f acet, current.operation); } if (name.length() == 0 nodes.containsKey(name)) { throw new NameInUse(name); } Ice.Identity id = current.adapter.getCommunicator().stringToIde ntity(java.util.UUID.randomUUID().toString()); PersistentFile file = new FileI(); file.nodeName = name; file.parent = PersistentDirectoryPrxHelper.uncheckedCast(current.adapter.createProxy(current.id)); FilePrx proxy = FilePrxHelper.uncheckedCast(_evictor.add(file, id)); NodeDesc nd = new NodeDesc(); nd.name = name; nd.type = NodeType.FileType; nd.proxy = proxy; nodes.put(name, nd); return proxy; } </pre>	

The remaining Slice operations have trivial implementations, so we do not show them here.

Implementing NodeFactory in Java

We use a single factory implementation for creating two types of Ice objects: `PersistentFile` and `PersistentDirectory`. These are the only two types that the Freeze evictor will be restoring from its database.

Java

```
package Filesystem;

public class NodeFactory implements Ice.ObjectFactory
{
    public Ice.Object
    create(String type)
    {
        if (type.equals(PersistentFile.ice_staticId()))
            return new FileI();
        else if (type.equals(PersistentDirectory.ice_staticId()))
            return new DirectoryI();
        else {
            assert(false);
            return null;
        }
    }

    public void
    destroy()
    {
    }
}
```

Freeze Maps

A Freeze map is a persistent, associative container in which the key type must be a [legal dictionary key type](#) and the value type can be any primitive or user-defined Slice type. For each pair of key and value types, the developer uses a code-generation tool to produce a language-specific class that conforms to the standard conventions for maps in that language. For example, in C++, the generated class resembles a `std::map`, and in Java it implements the `java.util.SortedMap` interface. Most of the logic for storing and retrieving state to and from the database is implemented in a Freeze base class. The generated map classes derive from this base class, so they contain little code and therefore are efficient in terms of code size.

You can only store data types that are defined in Slice in a Freeze map. Types without a Slice definition (that is, arbitrary C++ or Java types) cannot be stored because a Freeze map reuses the Ice-generated marshaling code to create the persistent representation of the data in the database. This is especially important to remember when defining a [Slice class](#) whose instances will be stored in a Freeze map; only the "public" (Slice-defined) data members will be stored, not the private state members of any derived implementation class.

Freeze Connections

In order to create a Freeze map object, you first need to obtain a `Freeze Connection` object by connecting to a database environment.

As illustrated in the following figure, a Freeze map is associated with a single connection and a single database file. Connection and map objects are not thread-safe: if you want to use a connection or any of its associated maps from multiple threads, you must serialize access to them. If your application requires concurrent access to the same database file (persistent map), you must create several connections and associated maps.

Freeze connections and maps.

Freeze connections provide operations that allow you to begin a transaction, access the current transaction, get the communicator associated with a connection, close a connection, and remove a map index. See the [Slice API reference](#) for more information on these operations.

Using Transactions with Freeze Maps

You may optionally use transactions with Freeze maps. Freeze transactions provide the usual ACID (atomicity, concurrency, isolation, durability) properties. For example, a transaction allows you to group several database updates in one atomic unit: either all or none of the updates within the transaction occur.

You start a transaction by calling `beginTransaction` on the `Connection` object. Once a connection has an associated transaction, all operations on the map objects associated with this connection use this transaction. Eventually, you end the transaction by calling `commit` or `rollback`: `commit` saves all your updates while `rollback` undoes them. The `currentTransaction` operation returns the transaction associated with a connection, if any; otherwise, it returns `nil`.

Slice

```

module Freeze {

local interface Transaction {
    void commit();
    void rollback();
};

local interface Connection {
    Transaction beginTransaction();
    idempotent Transaction currentTransaction();
    // ...
};
};

```

If you do not use transactions, every non-iterator update is enclosed in its own internal transaction, and every read-write iterator has an associated internal transaction that is committed when the iterator is closed.

Using Transactions with C++

You must ensure that you either commit or roll back each transaction that you begin (otherwise, locks will be held by the database until they time out):

C++

```

ConnectionPtr connection = ...;

TransactionPtr tx = connection->beginTransaction();
try {

    // DB updates that might throw here...

    tx->commit();

    // More code that might throw here...

} catch (...) {
    try {
        tx->rollback();
    } catch (...) {
    }
    throw;
}

```

The outer try-catch blocks are necessary because, if the code encounters an exception, we must roll back any updates that were made. In turn, the attempt to roll back might throw itself, namely, if the code following the commit throws an exception (in which case the transaction cannot be rolled back because it is already committed).

Code such as this is difficult to maintain: for example, an early return statement can cause the transaction to be neither committed nor rolled back. The `TransactionHolder` class ensures that such errors cannot happen:

```
C++
```

```

namespace Freeze {
    class TransactionHolder {
    public:
        TransactionHolder(const ConnectionPtr&);
        ~TransactionHolder();

        void commit();
        void rollback();

    private:
        // Copy and assignment are forbidden.
        TransactionHolder(const TransactionHolder&);
        TransactionHolder& operator=(const TransactionHolder&);
    };
}

```

The constructor calls `beginTransaction` if the connection does not already have a transaction in progress, so instantiating the holder also starts a transaction. When the holder instance goes out of scope, its destructor calls `rollback` on the transaction and suppresses any exceptions that the rollback attempt might throw. This ensures that the transaction is rolled back if it was not previously committed or rolled back and ensures that an early return or an exception cannot cause the transaction to remain open:

```
C++
```

```

ConnectionPtr connection = ...;

{ // Open scope

    TransactionHolder tx(connection); // Begins transaction

    // DB updates that might throw here...

    tx.commit();

    // More code that might throw here...

} // Transaction rolled back here if not previously
  // committed or rolled back.

```

If you instantiate a `TransactionHolder` when a transaction is already in progress, it does nothing: the constructor notices that it could not begin a new transaction and turns `commit`, `rollback`, and the destructor into no-ops. For example, the nested `TransactionHolder` instance in the following code is benign and does nothing:

C++

```
ConnectionPtr connection = ...;

{ // Open scope

    TransactionHolder tx(connection); // Begins transaction

    // DB updates that might throw here...

    { // Open nested scope

        TransactionHolder tx2(connection); // Does nothing

        // DB updates that might throw here...

        tx2.commit(); // Does nothing

        // More code that might throw here...

    } // Destructor of tx2 does nothing

    tx.commit();

    // More code that might throw here...

} // Transaction rolled back here if not previously
  // committed or rolled back.
```

Using Transactions with Java

You must ensure that you either commit or roll back each transaction that you begin (otherwise, locks will be held by the database until they time out):

Java

```
Connection connection = ...;

Transaction tx = connection.beginTransaction();
try {

    // DB updates that might throw here...

    tx.commit();

    // More code that might throw here...

} catch (java.lang.RuntimeException ex) {
    try {
        tx.rollback();
    } catch (DatabaseException e) {
    }
    throw ex;
}
```

The catch handler ensures that the transaction is rolled back before re-throwing the exception. Note that the nested try-catch blocks are necessary: if the transaction committed successfully but the code following the commit throws an exception, the rollback attempt will fail therefore we need to suppress the corresponding `DatabaseException` that is raised in that case.

Also use caution with early return statements:

Java

```
Connection connection = ...;

Transaction tx = connection.beginTransaction();
try {

    // DB updates that might throw here...

    if (error) {
        // ...
        return; // Oops, bad news!
    }

    // ...

    tx.commit();

    // More code that might throw here...

} catch (java.lang.RuntimeException ex) {
    try {
        tx.rollback();
    } catch (DatabaseException e) {
    }
    throw ex;
}
```

The early `return` statement in the preceding code causes the transaction to be neither committed nor rolled back. To deal with this situation, avoid early return statements or ensure that you either commit or roll back the transaction before returning. Alternatively, you can use a `finally` block to ensure that the transaction is rolled back:

Java

```

Connection connection = ...;

try {

    Transaction tx = connection.beginTransaction();

    // DB updates that might throw here...

    if (error) {
        // ...
        return; // No problem, see finally block.
    }

    // ...

    tx.commit();

    // More code that might throw here...

} finally {
    if (connection.currentTransaction() != null)
        connection.currentTransaction().rollback();
}

```

Iterating over a Freeze Map

Iterators allow you to traverse the contents of a Freeze map. Iterators are implemented using Berkeley DB cursors and acquire locks on the underlying database page files. In C++, both read-only (`const_iterator`) and read-write iterators (`iterator`) are available. In Java, an iterator is read-write if it is obtained in the context of a transaction and read-only if it is obtained outside a transaction.

Locks held by an iterator are released when the iterator is closed (if you do not use transactions) or when the enclosing transaction ends. Releasing locks held by iterators is very important to let other threads access the database file through other connection and map objects. Occasionally, it is even necessary to release locks to avoid self-deadlock (waiting forever for a lock held by an iterator created by the same thread).

To improve ease of use and make self-deadlocks less likely, Freeze often closes iterators automatically. If you close a map or connection, associated iterators are closed. Similarly, when you start or end a transaction, Freeze closes all the iterators associated with the corresponding maps. If you do not use transactions, any write operation on a map (such as inserting a new element) automatically closes all iterators opened on the same map object, except for the current iterator when the write operation is performed through that iterator. In Java, Freeze also closes a read-only iterator when no more elements are available.

There is, however, one situation in C++ where an explicit iterator close is needed to avoid self-deadlock:

- you do not use transactions, and
- you have an open iterator that was used to update a map (it holds a write lock), and
- in the same thread, you read that map.

Read operations in C++ never close iterators automatically: you need to either use transactions or explicitly close the iterator that holds the write lock. This is not an issue in Java because you cannot use an iterator to update a map outside of a transaction.

Recovering from Freeze Map Deadlocks

If you use multiple threads to access a database file, Berkeley DB may acquire locks in conflicting orders (on behalf of different transactions or iterators). For example, an iterator could have a read-lock on page P1 and attempt to acquire a write-lock on page P2, while another iterator (on a different map object associated with the same database file) could have a read-lock on P2 and attempt to acquire a write-lock on P1.

When this occurs, Berkeley DB detects a deadlock and resolves it by returning a "deadlock" error to one or more threads. For all non-iterator operations performed outside any transaction, such as an insertion into a map, Freeze catches such errors and automatically retries the operation until it succeeds. (In that case, the most-recently acquired lock is released before retrying.) For other operations, Freeze reports this deadlock by raising `Freeze::DeadlockException`. In that case, the associated transaction or iterator is also automatically rolled back or closed. A properly written application must expect to catch deadlock exceptions and retry the transaction or iteration.

Key Sorting for Freeze Maps

Keys in Freeze maps and indexes are always sorted. By default, Freeze sorts keys according to their Ice-encoded binary representation; this is very efficient but the resulting order is rarely meaningful for the application. Starting with Ice 3.0, Freeze offers the ability to specify your own comparator objects so that you can customize the traversal order of your maps. Note however that the comparator of a Freeze map should remain the same throughout the life of the map. Berkeley DB stores records according to the key order provided by this comparator; switching to another comparator will cause undefined behavior.

Key Sorting for Freeze Maps in C++

In C++, you specify the name of your comparator objects during code generation. The generated map provides the standard features of `std::map`, so that iterators return entries according to the order you have defined for the main key with your comparator object. The `lower_bound`, `upper_bound`, and `equal_range` functions provide range-searches (see the definition of these functions on `std::map`).

Apart from these standard features, the [generated map](#) provides additional functions and methods to perform range searches using secondary keys. The additional functions are `lowerBoundForMember`, `upperBoundForMember`, and `equalRangeForMember`, where *Member* is the name of the secondary-key member. These functions return regular iterators on the Freeze map.

Key Sorting for Freeze Maps in Java

In Java, you supply comparator objects (instances of the standard Java interface `java.util.Comparator`) at run time when instantiating the generated map class. The [map constructor](#) accepts a comparator for the main key and optionally a collection of comparators for secondary keys. The map also provides a number of methods for performing range searches on the main key and on secondary keys.

Indexing a Freeze Map

Freeze maps support efficient reverse lookups: if you define an index when you generate your map (with `slice2freeze` or `slice2freezej`), the generated code provides additional methods for performing reverse lookups. If your value type is a structure or a class, you can also index on a member of the value, and several such indices can be associated with the same Freeze map.

Indexed searches are easy to use and very efficient. However, be aware that an index also adds significant write overhead: with Berkeley DB, every update triggers a read from the database to get the old index entry and, if necessary, replace it.

If you add an index to an existing map, Freeze automatically populates the index the next time you open the map. Freeze populates the index by instantiating each map entry, so it is important that you register the object factories for any class types in your map before you open the map.

Note that the index key comparator of a Freeze map index should remain the same throughout the life of the index. Berkeley DB stores records according to the key order provided by this comparator; switching to another comparator will cause undefined behavior.

Using a Freeze Map in C++

This page describes the C++ code generator and demonstrates how to use a Freeze map in a C++ program.

On this page:

- [Generating a Simple Map for C++](#)
- [The Freeze Map Class in C++](#)
- [Using Iterators with Freeze Maps in C++](#)
- [Sample Freeze Map Program in C++](#)

Generating a Simple Map for C++

We can use `slice2freeze` to generate a simple Freeze map:

```
$ slice2freeze --dict StringIntMap,string,int StringIntMap
```

This command directs the compiler to create a map named `StringIntMap`, with the Slice key type `string` and the Slice value type `int`. The final argument is the base name for the output files, to which the compiler appends the `.h` and `.cpp` suffixes. As a result, this command produces two C++ source files, `StringIntMap.h` and `StringIntMap.cpp`.

The Freeze Map Class in C++

If you examine the contents of the header file created by the example in the previous section, you will discover that a Freeze map is a subclass of the template class `Freeze::Map`:

```
C++
```

```
// StringIntMap.h

class StringIntMap : public Freeze::Map< std::string, Ice::Int, ... > {
public:
    StringIntMap(const Freeze::ConnectionPtr& connection,
                 const std::string& dbName,
                 bool createDb = true,
                 const Freeze::IceEncodingCompare& compare = ...);

    template <class _InputIterator>
    StringIntMap(const Freeze::ConnectionPtr& connection,
                 const std::string& dbName,
                 bool createDb,
                 _InputIterator first, _InputIterator last,
                 const Freeze::IceEncodingCompare& compare = ...);

    ...
};
```

The `Freeze::Map` template class closely resembles the STL container class `std::map`, as shown in the following class definition:

C++

```

namespace Freeze {
template<...> class Map {
public:
    typedef ... value_type;
    typedef ... iterator;
    typedef ... const_iterator;

    typedef size_t size_type;
    typedef ptrdiff_t difference_type;

    static void recreate(const Freeze::ConnectionPtr& connection,
                        const std::string& dbName,
                        const Freeze::IceEncodingCompare& compare = ..
.);

    bool operator==(const Map& rhs) const;
    bool operator!=(const Map& rhs) const;

    void swap(Map& rhs);

    iterator begin();
    const_iterator begin() const;

    iterator end();
    const_iterator end() const;

    bool empty() const;
    size_type size() const;
    size_type max_size() const;

    iterator insert(iterator /*position*/, const value_type& elem);

    std::pair<iterator, bool> insert(const value_type& elem);

    template <typename InputIterator>
    void insert(InputIterator first, InputIterator last);

    void put(const value_type& elem);

    template <typename InputIterator>
    void put(InputIterator first, InputIterator last);

    void erase(iterator position);
    size_type erase(const key_type& key);
    void erase(iterator first, iterator last);

    void clear();

```

```
void destroy(); // Non-standard.

iterator find(const key_type& key);
const_iterator find(const key_type& key) const;

size_type count(const key_type& key) const;

iterator lower_bound(const key_type& key);
const_iterator lower_bound(const key_type& key) const;
iterator upper_bound(const key_type& key);
const_iterator upper_bound(const key_type& key) const;

std::pair<iterator, iterator>
equal_range(const key_type& key);

std::pair<const_iterator, const_iterator>
equal_range(const key_type& key) const;

const Ice::CommunicatorPtr&
communicator() const;

...
```

```
};
}
```

The semantics of the `Freeze::Map` methods are identical to those of `std::map` unless otherwise noted. In particular, the overloaded `insert` method shown below ignores the `position` argument:

C++

```
iterator insert(iterator /*position*/, const value_type& elem);
```

A `Freeze` map class supports only those methods shown above; other features of `std::map`, such as allocators and overloaded array operators, are not available.

Non-standard methods that are specific to `Freeze` maps are discussed below:

- Constructors

The following overloaded constructors are provided:

C++

```
Map(const Freeze::ConnectionPtr& connection,
    const std::string& dbName,
    bool createDb = true,
    const Freeze::IceEncodingCompare& compare = ...);

template<class _InputIterator>
Map(const Freeze::ConnectionPtr& connection,
    const std::string& dbName,
    bool createDb,
    _InputIterator first, _InputIterator last,
    const Freeze::IceEncodingCompare& compare = ...);
```

The first constructor accepts a connection, the database name, a flag indicating whether to create the database if it does not exist, and an object used to compare keys. The second constructor accepts all of the parameters of the first, with the addition of iterators from which elements are copied into the map.

Note that a database can only contain the persistent state of one map type. Any attempt to instantiate maps of different types on the same database results in undefined behavior.

- Map copy

The `recreate` function copies an existing database:

C++

```
static void recreate(const Freeze::ConnectionPtr& connection,
                   const std::string& dbName,
                   const Freeze::IceEncodingCompare& compare = .
..)
```

The `dbName` parameter specifies an existing database name. The copy has the name `<dbName>.old-<uuid>`. For example, if the database name is `MyDB`, the copy might be named `MyDB.old-edefd55a-e66a-478d-a77b-f6d53292b873`. (Obviously, a different UUID is used each time you recreate a database).

- `destroy`
This method deletes the database from its environment and from the [Freeze catalog](#). If a transaction is not currently open, the method creates its own transaction in which to perform this task.
- `communicator`
This method returns the communicator with which the map's connection is associated.

Using Iterators with Freeze Maps in C++

A Freeze map's iterator works like its counterpart in `std::map`. The iterator class supports one convenient (but nonstandard) method:

```
C++
```

```
void set(const mapped_type& value)
```

Using this method, a program can replace the value at the iterator's current position.

Sample Freeze Map Program in C++

The program below demonstrates how to use a `StringIntMap` to store `<string, int>` pairs in a database. You will notice that there are no explicit `read` or `write` operations called by the program; instead, simply using the map has the side effect of accessing the database.

```
C++
```

```
#include <Freeze/Freeze.h>
#include <StringIntMap.h>

int
main(int argc, char* argv[])
{
    // Initialize the Communicator.
    //
    Ice::CommunicatorPtr communicator = Ice::initialize(argc, argv);

    // Create a Freeze database connection.
    //
    Freeze::ConnectionPtr connection =
    Freeze::createConnection(communicator, "db");

    // Instantiate the map.
    //
    StringIntMap map(connection, "simple");

    // Clear the map.
    //
    map.clear();
}
```

```
Ice::Int i;
StringIntMap::iterator p;

// Populate the map.
//
for (i = 0; i < 26; i++) {
    std::string key(1, 'a' + i);
    map.insert(make_pair(key, i));
}

// Iterate over the map and change the values.
//
for (p = map.begin(); p != map.end(); ++p)
    p.set(p->second + 1);

// Find and erase the last element.
//
p = map.find("z");
assert(p != map.end());
map.erase(p);

// Clean up.
//
connection->close();
communicator->destroy();
```

```

    return 0;
}

```

Prior to instantiating a Freeze map, the application must connect to a Berkeley DB database environment:

C++

```

Freeze::ConnectionPtr connection =
Freeze::createConnection(communicator, "db");

```

The second argument is the name of a Berkeley DB database environment; by default, this is also the file system directory in which Berkeley DB creates all database and administrative files. Note that [properties](#) with the prefix `Freeze.DbEnv` can modify a number of environment settings, including the file system directory. For the preceding example, you could change the directory to `FreezeDir` by setting the property `Freeze.DbEnv.db.DbHome` to `FreezeDir`.

Next, the code instantiates the `StringIntMap` on the connection. The constructor's second argument supplies the name of the database file, which by default is created if it does not exist:

C++

```

StringIntMap map(connection, "simple");

```

After instantiating the map, we clear it to make sure it is empty in case the program is run more than once:

C++

```

map.clear();

```

Next, we populate the map using a single-character string as the key:

C++

```

for (i = 0; i < 26; i++) {
    std::string key(1, 'a' + i);
    map.insert(make_pair(key, i));
}

```

Iterating over the map will look familiar to `std::map` users. However, to modify a value at the iterator's current position, we use the nonstandard `set` method:

C++

```
for (p = map.begin(); p != map.end(); ++p)
    p.set(p->second + 1);
```

Next, the program obtains an iterator positioned at the element with key `z`, and erases it:

C++

```
p = map.find("z");
assert(p != map.end());
map.erase(p);
```

Finally, the program closes the database connection:

C++

```
connection->close();
```

It is not necessary to explicitly close the database connection, but we demonstrate it here for the sake of completeness.

slice2freeze Command-Line Options

The Slice-to-Freeze compiler, `slice2freeze`, generates C++ classes for Freeze maps and Freeze Evictor indices.

`slice2freeze`'s first command-line parameter is the base name for the generated C++ files, and not a Slice file like with the other Slice compilers:

```
slice2freeze [options] BaseName [SliceFile1 SliceFile2 ...]
```

The compiler offers the following command-line options in addition to the [standard options](#):

`--header-ext EXT`

Changes the file extension for the generated header files from the default `h` to the extension specified by `EXT`.

`--source-ext EXT`

Changes the file extension for the generated source files from the default `cpp` to the extension specified by `EXT`.

`--add-header HDR[,GUARD]`

This option adds an include directive for the specified header at the beginning of the generated source file (preceding any other include directives). If `GUARD` is specified, the include directive is protected by the specified guard.

For example:

```
--add-header precompiled.h, __PRECOMPILED_H__
```

results in the following directives at the beginning of the generated source file:

```
C++
```

```
#ifndef __PRECOMPILED_H__
#define __PRECOMPILED_H__
#include <precompiled.h>
#endif
```

As this example demonstrates, the `--add-header` option is useful mainly for integrating the generated code with a compiler's precompiled header mechanism.

This option can be repeated to create include directives for several files.

`--include-dir DIR`

Modifies `#include` directives in source files to prepend the path name of each header file with the directory `DIR`. The discussion of `slice2cpp` provides more information.

`--dll-export SYMBOL`

Use `SYMBOL` to control DLL exports or imports. See the `slice2cpp` description for details.

`--dict NAME,KEY,VALUE[,sort[,COMPARE]]`

Generate a Freeze map class named *NAME* using *KEY* as key and *VALUE* as value. This option may be specified multiple times to generate several Freeze maps. *NAME* may be a scoped C++ name, such as `Demo::Struct1ObjectMap`. *KEY* and *VALUE* represent Slice types and therefore must use Slice syntax, such as `bool` or `Ice::Identity`. The type identified by *KEY* must be a [legal dictionary key type](#). By default, keys are sorted using their binary Ice-encoded representation. Include `sort` to sort with the *COMPARE* functor class. If *COMPARE* is not specified, the default value is `std::less<KEY>`.

```
--dict-index MAP[,MEMBER] [,case-sensitive|case-insensitive][,sort[,COMPARE]]
```

Add an index to the Freeze map named *MAP*. If *MEMBER* is specified, the map value type must be a structure or a class, and *MEMBER* must be a member of this structure or class. Otherwise, the entire value is indexed. When the indexed member (or entire value) is a string, the index can be case-sensitive (default) or case-insensitive. An index adds additional member functions to the generated C++ map:

- `iterator findByMEMBER(MEMBER_TYPE, bool = true);`
- `const_iterator findByMEMBER(MEMBER_TYPE, bool = true) const;`
- `iterator beginForMEMBER();`
- `const_iterator begin_ForMEMBER() const;`
- `iterator endForMEMBER();`
- `const_iterator endForMEMBER() const;`
- `iterator lowerBoundForMEMBER(MEMBER_TYPE);`
- `const_iterator lowerBoundForMEMBER(MEMBER_TYPE) const;`
- `iterator upperBoundForMEMBER(MEMBER_TYPE);`
- `const_iterator upperBoundForMEMBER(MEMBER_TYPE) const;`
- `std::pair<iterator, iterator> equalRangeForMEMBER(MEMBER_TYPE);`
- `std::pair<const_iterator, const_iterator> equalRangeForMEMBER(MEMBER_TYPE) const;`
- `int MEMBERCount(MEMBER_TYPE) const;`

When *MEMBER* is not specified, these functions are `findByValue` (const and non-const), `lowerBoundForValue` (const and non-const), `valueCount`, and so on. When *MEMBER* is specified, its first letter is capitalized in the `findBy` function name. *MEMBER_TYPE* corresponds to an in-parameter of the type of *MEMBER* (or the type of the value when *MEMBER* is not specified). For example, if *MEMBER* is a string, *MEMBER_TYPE* is a `const std::string&`.

By default, keys are sorted using their binary Ice-encoded representation. Include `sort` to sort with the *COMPARE* functor class. If *COMPARE* is not specified, the default value is `std::less<MEMBER_TYPE>`.

`findByMEMBER` returns an iterator to the first element in the Freeze map that matches the given index value. It returns `end()` if there is no match. When the second parameter is true (the default), the returned iterator provides only the elements with an exact match (and then skips to `end()`). Otherwise, the returned iterator sets a starting position and then provides all elements until the end of the map, sorted according to the index comparator.

`lowerBoundForMEMBER` returns an iterator to the first element in the Freeze map whose index value is not less than the given index value. It returns `end()` if there is no such element. The returned iterator provides all elements until the end of the map, sorted according to the index comparator.

`upperBoundForMEMBER` returns an iterator to the first element in the Freeze map whose index value is greater than the given index value. It returns `end()` if there is no such element. The returned iterator provides all elements until the end of the map, sorted according to the index comparator.

`beginForMEMBER` returns an iterator to the first element in the map.

`endForMEMBER` returns an iterator to the last element in the map.

`equalRangeForMEMBER` returns a range (pair of iterators) of all the elements whose index value matches the given index value. This function is similar to `findByMEMBER` (see above).

`MEMBERCount` returns the number of elements in the Freeze map whose index value matches the given index value.

Please note that index-derived iterators do not allow you to set new values in the underlying map.

```
--index CLASS,TYPE,MEMBER [,case-sensitive|case-insensitive]
```

Generate an [index class for a Freeze evictor](#). *CLASS* is the name of the class to be generated. *TYPE* denotes the type of class to be indexed (objects of different classes are not included in this index). *MEMBER* is the name of the data member in *TYPE* to index. When *MEMBER* has type `string`, it is possible to specify whether the index is case-sensitive or not. The default is case-sensitive.

Generating a Simple Map for Java

We can use `slice2freezej` to generate a simple Freeze map:

```
$ slice2freezej --dict StringIntMap,string,int
```

This command directs the compiler to create a map named `StringIntMap`, with the Slice key type `string` and the Slice value type `int`. The compiler produces one Java source file: `StringIntMap.java`.

The Freeze Map Class in Java

The class generated by `slice2freezej` implements the `Freeze.Map` interface, as shown below:

```

Java
package Freeze;

public interface Map<K, V> extends NavigableMap<K, V>
{
    void fastPut(K key, V value);
    void close();
    int closeAllIterators();
    void destroy();

    public interface EntryIterator<T> extends java.util.Iterator<T>
    {
        void close();
        void destroy(); // an alias for close
    }
}

```

The `Map` interface implements standard Java interfaces and provides nonstandard methods that improve efficiency and support database-oriented features. `Map` defines the following methods:

- `fastPut`
Inserts a new key-value pair. This method is more efficient than the standard `put` method because it avoids the overhead of reading and decoding the previous value associated with the key (if any).
- `close`
Closes the database associated with this map along with all open iterators. A map must be closed when it is no longer needed, either by closing the map directly or by closing the `Freeze.Connection` object with which this map is associated.

- `closeAllIterators`
Closes all open iterators and returns the number of iterators that were closed. We discuss iterators in more detail in the next section.
- `destroy`
Removes the database associated with this map along with any indices.

`Map` inherits much of its functionality from the `Freeze.NavigableMap` interface, which derives from the standard Java interface `java.util.SortedMap` and also supports a subset of the `java.util.NavigableMap` interface:

```

Java

package Freeze;

public interface NavigableMap<K, V> extends java.util.SortedMap<K, V>
{
    java.util.Map.Entry<K, V> firstEntry();
    java.util.Map.Entry<K, V> lastEntry();

    java.util.Map.Entry<K, V> ceilingEntry(K key);
    java.util.Map.Entry<K, V> floorEntry(K key);
    java.util.Map.Entry<K, V> higherEntry(K key);
    java.util.Map.Entry<K, V> lowerEntry(K key);

    K ceilingKey(K key);
    K floorKey(K key);
    K higherKey(K key);
    K lowerKey(K key);

    java.util.Set<K> descendingKeySet();
    NavigableMap<K, V> descendingMap();

    NavigableMap<K, V> headMap(K toKey, boolean inclusive);
    NavigableMap<K, V> tailMap(K fromKey, boolean inclusive);
    NavigableMap<K, V> subMap(K fromKey, boolean fromInclusive,
                             K toKey, boolean toInclusive);

    java.util.Map.Entry<K, V> pollFirstEntry();
    java.util.Map.Entry<K, V> pollLastEntry();

    boolean fastRemove(K key);
}

```

The `NavigableMap` interface provides a number of useful methods:

- `firstEntry`
`lastEntry`
Returns the first and last key-value pair, respectively.
- `ceilingEntry`
Returns the key-value pair associated with the least key greater than or equal to the given key, or null if there is no such key.
- `floorEntry`
Returns the key-value pair associated with the greatest key less than or equal to the given key, or null if there is no such key.
- `higherEntry`

Returns the key-value pair associated with the least key greater than the given key, or null if there is no such key.

- `lowerEntry`
Returns the key-value pair associated with the greatest key less than the given key, or null if there is no such key.
- `ceilingKey`
`floorKey`
`higherKey`
`lowerKey`
These methods have the same semantics as those described above, except they return only the key portion of the matching key-value pair or null if there is no such key.
- `descendingKeySet`
Returns a set representing a reverse-order view of the keys in this map.
- `descendingMap`
Returns a reverse-order view of the entries in this map.
- `headMap`
Returns a view of the portion of this map whose keys are less than (or equal to, if inclusive is true) the given key.
- `tailMap`
Returns a view of the portion of this map whose keys are greater than (or equal to, if inclusive is true) the given key.
- `subMap`
Returns a view of the portion of this map whose keys are within the given range.
- `pollFirstEntry`
`pollLastEntry`
Removes and returns the first and last key-value pair, respectively.
- `fastRemove`
Removes an existing key-value pair. As for `fastPut`, this method is a more efficient alternative to the standard `remove` method that returns true if a key-value pair was removed, or false if no match was found.

You must supply a [comparator](#) object when constructing the map in order to use many of these methods.

Note that `NavigableMap` also inherits overloaded methods named `headMap`, `tailMap`, and `subMap` from the `SortedMap` interface. These methods have the same semantics as the ones defined in `NavigableMap` but they omit the boolean arguments (refer to the JDK documentation for complete details). Although these methods are declared as returning a `SortedMap`, the actual type of the returned object is a `NavigableMap` that you can downcast if necessary.

There are some limitations in the sub maps returned by the `headMap`, `tailMap` and `subMap` methods:

- A new entry in the Freeze map cannot be added via a sub map, therefore calling `put` raises `UnsupportedOperationException`.
- An existing entry in the Freeze map cannot be removed via a sub map or iterator for a [secondary key](#).

Now let us examine the contents of the source file created by the example in the previous section:

Java

```
public class StringIntMap extends ...
    // implements Freeze.Map<String, Integer>
{
    public StringIntMap(
        Freeze.Connection connection,
        String dbName,
        boolean createDb,
        java.util.Comparator<String> comparator);

    public StringIntMap(
        Freeze.Connection connection,
        String dbName,
        boolean createDb);

    public StringIntMap(
        Freeze.Connection connection,
        String dbName);
}
```

`StringIntMap` derives from an internal Freeze base class that implements the interface `Freeze.Map<String, Integer>`. The generated class defines several overloaded constructors whose arguments are described below:

- `connection`
The Freeze connection object.
- `dbName`
The name of the database in which to store this map's persistent state. Note that a database can only contain the persistent state of one map type. Any attempt to instantiate maps of different types on the same database results in undefined behavior.
- `createDb`
A flag indicating whether the map should create the database if it does not already exist. If this argument is not specified, the default value is `true`.
- `comparator`
An object used to [compare the map's keys](#). If this argument is not specified, the default behavior compares the encoded form of the keys.

Why Comparators are Important

The constructor of a Freeze map optionally accepts a comparator object for the primary key and, if any [indices](#) are generated, a second object that supplies comparators for each of the index keys. If you do not supply a comparator, Freeze simply compares the encoded form of the keys. This default behavior is acceptable when comparing keys for equality, but using the encoded form cannot work reliably when comparing keys for ordering purposes.

For example, many of the methods in `NavigableMap` perform greater-than or less-than comparisons on keys, including `ceilingEntry`, `headMap`, and `tailMapForMEMBER`. All of these methods raise `UnsupportedOperationException` if you failed to supply a corresponding comparator when constructing the map. (The same applies to `NavigableMap` objects created for secondary keys.) In fact, the only `NavigableMap` methods that do *not* require a comparator are `firstEntry`, `lastEntry`, `pollFirstEntry`, `pollLastEntry`, and `fastRemove`.

As you can see, the functionality of a Freeze map is quite limited if no comparators are configured, therefore we recommend using comparators at all times.

Using Iterators with Freeze Maps in Java

You can iterate over a Freeze map just as you can with any container that implements the `java.util.Map` interface. For example, the code below displays the key and value of each element:

```

Java

StringIntMap m = new StringIntMap(...);
java.util.Iterator<java.util.Map.Entry<String, Integer>> i =
m.entrySet().iterator();
while (i.hasNext()) {
    java.util.Map.Entry<String, Integer> e = i.next();
    System.out.println("Key: " + e.getKey());
    System.out.println("Value: " + e.getValue());
}

```

Generally speaking, a program should [close an iterator when it is no longer necessary](#). (An iterator that is garbage collected without being closed emits a warning message.) However, an explicit close was not necessary in the preceding example because Freeze automatically closes a read-only iterator when it reaches the last element (a read-only iterator is one that is opened outside of any transaction). If instead our program had stopped using the iterator prior to reaching the last element, an explicit close would have been necessary:

```

Java

StringIntMap m = new StringIntMap(...);
java.util.Iterator<java.util.Map.Entry<String, Integer>> i =
m.entrySet().iterator();
while (i.hasNext()) {
    java.util.Map.Entry<String, Integer> e = i.next();
    System.out.println("Key: " + e.getKey());
    System.out.println("Value: " + e.getValue());
    if (e.getValue().intValue() == 5)
        break;
}
((Freeze.Map.EntryIterator)i).close();

```

Closing the iterator requires downcasting it to a Freeze-specific interface named `Freeze.Map.EntryIterator`. The definition of this interface was shown in the previous section.

Freeze maps also support the enhanced `for` loop functionality. Here is a simpler way to write our original program:

```

Java

StringIntMap m = new StringIntMap(...);
for (java.util.Map.Entry<String, Integer> e : m.entrySet()) {
    System.out.println("Key: " + e.getKey());
    System.out.println("Value: " + e.getValue());
}

```

As in the first example, Freeze automatically closes the iterator when no more elements are available. Although the enhanced `for` loop is convenient, it is not appropriate for all situations because the loop hides its iterator and therefore prevents the program from accessing the iterator in order to close it. In this case, you can use the traditional `while` loop instead of the `for` loop, or you can invoke `closeAllIterat`

ors on the map as shown below:

```

Java

StringIntMap m = new StringIntMap(...);
for (java.util.Map.Entry<String, Integer> e : m.entrySet()) {
    System.out.println("Key: " + e.getKey());
    System.out.println("Value: " + e.getValue());
    if (e.getValue().intValue() == 5)
        break;
}
int num = m.closeAllIterators();
assert(num <= 1); // The iterator may already be closed.
```

The `closeAllIterators` method returns an integer representing the number of iterators that were actually closed. This value can be useful for diagnostic purposes, such as to assert that a program is correctly closing its iterators.

Generating Indices for Freeze Maps in Java

Using the `--dict-index` option to define an index for a secondary key causes `slice2freezej` to generate the following additional code in a Freeze map:

- A static nested class named `IndexComparators`, which allows you to supply a custom comparator object for each index in the map.
- An overloading of the map constructor that accepts an instance of `IndexComparators`.
- An overloading of the `recreate` method that accepts an instance of `IndexComparators`.
- Searching, counting, and range-searching methods for finding key-value pairs using the secondary key.

We discuss each of these additions in more detail below. In this discussion, *MEMBER* refers to the optional argument of the `--dict-index` option, and *MEMBER_TYPE* refers to the type of that member. As explained earlier, if *MEMBER* is not specified, `slice2freezej` creates an index for the value type of the map. The sample code presented in this section assumes we have generated a Freeze map using the following command:

```

Java

$ slice2freezej --dict StringIntMap,string,int --dict-index StringIntMap
```

By default, index keys are sorted using their binary Ice-encoded representation. This is an efficient sorting scheme but does not necessarily provide a meaningful traversal order for applications. You can choose a different order by providing an instance of the `IndexComparators` class to the map constructor. This class has a public data member holding a comparator (an instance of `java.util.Comparator<MEMBER_TYPE>`) for each index in the map. The class also provides an empty constructor as well as a convenience constructor that allows you to instantiate and initialize the object all at once. The name of each data member is *MEMBER*`Comparator`. If *MEMBER* is not specified, the `IndexComparators` class has a single data member named `valueComparator`.

Much of the functionality offered by a map index requires that you provide a [custom comparator](#).

Here is the definition of `IndexComparators` for `StringIntMap`:

Java

```
public class StringIntMap ... {
    public static class IndexComparators {
        public IndexComparators() {}

        public IndexComparators(java.util.Comparator<Integer> valueComp
arator);

        public java.util.Comparator<Integer> valueComparator;
    }
    ...
}
```

To instantiate a Freeze map using your custom comparators, you must use the overloaded constructor that accepts the `IndexComparators` object. For our `StringIntMap`, this constructor has the following definition:

Java

```
public class StringIntMap ... {
    public StringIntMap(
        Freeze.Connection connection,
        String dbName,
        boolean createDb,
        java.util.Comparator<String> comparator,
        IndexComparators indexComparators);
    ...
}
```

Now we can instantiate our `StringIntMap` as follows:

Java

```
java.util.Comparator<String> myMainKeyComparator = ...;
StringIntMap.IndexComparators indexComparators =
new StringIntMap.IndexComparators();
indexComparators.valueComparator = ...;
StringIntMap m = new StringIntMap(connection, "stringIntMap", true,
myMainKeyComparator, indexComparators);
```

If you later need to change the index configuration of a Freeze map, you can use one of the `recreate` methods to update the database. Here are the definitions from `StringIntMap`:

Java

```

public class StringIntMap ... {
    public static void recreate(
        Freeze.Connection connection,
        String dbName,
        java.util.Comparator<String> comparator);

    public static void recreate(
        Freeze.Connection connection,
        String dbName,
        java.util.Comparator<String> comparator,
        IndexComparators indexComparators);

    ...
}

```

The first overloading is generated for every map, whereas the second overloading is only generated when the map has at least one index. As its name implies, the `recreate` method creates a new copy of the database. More specifically, the method removes any existing indices, copies every key-value pair to a temporary database, and finally replaces the old database with the new one. As a side-effect, this process also populates any remaining indices. The first overloading of `recreate` is useful when you have regenerated the map to remove the last index and wish to clean up the map's database state.

`slice2freezej` also generates a number of index-specific methods. The names of these methods incorporate the member name (*MEMBER*), or use value if *MEMBER* is not specified. In each method name, the value of *MEMBER* is used unchanged if it appears at the beginning of the method's name. Otherwise, if *MEMBER* is used elsewhere in the method name, its first letter is capitalized. The index methods are described below:

- `public Freeze.Map.EntryIterator<Map.Entry<K, V>> findByMEMBER(MEMBER_TYPE index)`
- `public Freeze.Map.EntryIterator<Map.Entry<K, V>> findByMEMBER(MEMBER_TYPE index, boolean onlyDups)`
Returns an iterator over elements of the Freeze map starting with an element with whose index value matches the given index value. If there is no such element, the returned iterator is empty (`hasNext` always returns false). When the second parameter is true (or is not provided), the returned iterator provides only "duplicate" elements, that is, elements with the very same index value. Otherwise, the iterator sets a starting position in the map, and then provides elements until the end of the map, sorted according to the index comparator. Any attempt to modify the map via this iterator results in an `UnsupportedOperationException`.
- `public int MEMBERCount(MEMBER_TYPE index)`
Returns the number of elements in the Freeze map whose index value matches the given index value.
- `public NavigableMap<MEMBER_TYPE, Set<Map.Entry<K, V>>> headMapForMEMBER(MEMBER_TYPE to, boolean inclusive)`
`public NavigableMap<MEMBER_TYPE, Set<Map.Entry<K, V>>> headMapForMEMBER(MEMBER_TYPE to)`
Returns a view of the portion of the Freeze map whose keys are less than (or equal to, if `inclusive` is true) the given key. If `inclusive` is not specified, the method behaves as if `inclusive` is false.
- `public NavigableMap<MEMBER_TYPE, Set<Map.Entry<K, V>>> tailMapForMEMBER(MEMBER_TYPE from, boolean inclusive)`
- `public NavigableMap<MEMBER_TYPE, Set<Map.Entry<K, V>>> tailMapForMEMBER(MEMBER_TYPE from)`
Returns a view of the portion of the Freeze map whose keys are greater than (or equal to, if `inclusive` is true) the given key. If `inclusive` is not specified, the method behaves as if `inclusive` is true.
- `public NavigableMap<MEMBER_TYPE, Set<Map.Entry<K, V>>> subMapForMEMBER(MEMBER_TYPE from, boolean fromInclusive,`

```
MEMBER_TYPE to, boolean toInclusive)
```

```
public NavigableMap<MEMBER_TYPE, Set<Map.Entry<K, V>>>
subMapForMEMBER(MEMBER_TYPE from, MEMBER_TYPE to)
```

Returns a view of the portion of the Freeze map whose keys are within the given range. If `fromInclusive` and `toInclusive` are not specified, the method behaves as if `fromInclusive` is true and `toInclusive` is false.

- ```
public NavigableMap<MEMBER_TYPE, Set<Map.Entry<K, V>>>
mapForMEMBER()
```

Returns a view of the entire Freeze map ordered by the index key.

For the methods returning a `NavigableMap`, the key type is the secondary key type and the value is the set of matching key-value pairs from the Freeze map. (For the sake of readability, we have omitted the `java.util` prefix from `Set` and `Map.Entry`.) In other words, the returned map is a mapping of the secondary key to all of the entries whose value contains the same key. Any attempt to add, remove, or modify an element via a sub map view or an iterator of a sub map view results in an `UnsupportedOperationException`.

Note that iterators returned by the `findByMEMBER` methods, as well as those created for sub map views, may need to be closed explicitly, just like iterators obtained for the main Freeze map.

Here are the definitions of the index methods for `StringIntMap`:

### Java

```
public Freeze.Map.EntryIterator<Map.Entry<String, Integer>>
findByValue(Integer index);

public Freeze.Map.EntryIterator<Map.Entry<String, Integer>>
findByValue(Integer index, boolean onlyDups);

public int valueCount(Integer index);

public NavigableMap<Integer, Set<Map.Entry<String, Integer>>>
headMapForValue(Integer to, boolean inclusive);
public NavigableMap<Integer, Set<Map.Entry<String, Integer>>>
headMapForValue(Integer to);

public NavigableMap<Integer, Set<Map.Entry<String, Integer>>>
tailMapForValue(Integer from, boolean inclusive);
public NavigableMap<Integer, Set<Map.Entry<String, Integer>>>
tailMapForValue(Integer from);

public NavigableMap<Integer, Set<Map.Entry<String, Integer>>>
subMapForValue(Integer from, boolean fromInclusive,
 Integer to, boolean toInclusive);
public NavigableMap<Integer, Set<Map.Entry<String, Integer>>>
subMapForValue(Integer from, Integer to);

public NavigableMap<Integer, Set<Map.Entry<String, Integer>>>
mapForValue();
```

### Sample Freeze Map Program in Java

The program below demonstrates how to use a `StringIntMap` to store `<string, int>` pairs in a database. You will notice that there are no explicit read or write operations called by the program; instead, simply using the map has the side effect of accessing the database.

## Java

```
public class Client
{
 public static void
 main(String[] args)
 {
 // Initialize the Communicator.
 //
 Ice.Communicator communicator = Ice.Util.initialize(args);

 // Create a Freeze database connection.
 //
 Freeze.Connection connection =
Freeze.Util.createConnection(communicator, "db");

 // Instantiate the map.
 //
 StringIntMap map = new StringIntMap(connection, "simple", true);

 // Clear the map.
 //
 map.clear();

 int i;

 // Populate the map.
 //
 for (i = 0; i < 26; i++) {
 final char[] ch = { (char)('a' + i) };
 map.put(new String(ch), i);
 }

 // Iterate over the map and change the values.
 //
 for (java.util.Map.Entry<String, Integer> e : map.entrySet()) {
 Integer in = e.getValue();
 e.setValue(in.intValue() + 1);
 }

 // Find and erase the last element.
 //
 boolean b;
 b = map.containsKey("z");
 assert(b);
 b = map.fastRemove("z");
 assert(b);

 // Clean up.
 //
 }
}
```

```
map.close();
connection.close();
communicator.destroy();

System.exit(0);
```

```

 }
}

```

Prior to instantiating a Freeze map, the application must connect to a Berkeley DB database environment:

#### Java

```

Freeze.Connection connection =
Freeze.Util.createConnection(communicator, "db");

```

The second argument is the name of a Berkeley DB database environment; by default, this is also the file system directory in which Berkeley DB creates all database and administrative files.

Next, the code instantiates the `StringIntMap` on the connection. The constructor's second argument supplies the name of the database file, and the third argument indicates that the database should be created if it does not exist:

#### Java

```

StringIntMap map = new StringIntMap(connection, "simple", true);

```

After instantiating the map, we clear it to make sure it is empty in case the program is run more than once:

#### Java

```

map.clear();

```

We populate the map, using a single-character string as the key. As with `java.util.Map`, the key and value types must be Java objects but the compiler takes care of autoboxing the integer argument:

#### Java

```

for (i = 0; i < 26; i++) {
 final char[] ch = { (char)('a' + i) };
 map.put(new String(ch), i);
}

```

Iterating over the map is no different from iterating over any other map that implements the `java.util.Map` interface:

#### Java

```

for (java.util.Map.Entry<String, Integer> e : map.entrySet()) {
 Integer in = e.getValue();
 e.setValue(in.intValue() + 1);
}

```

Next, the program verifies that an element exists with key `z`, and then removes it using `fastRemove`:

**Java**

```
b = map.containsKey("z");
assert(b);
b = map.fastRemove("z");
assert(b);
```

Finally, the program closes the map and its connection.

**Java**

```
map.close();
connection.close();
```

## slice2freezej Command-Line Options

The Slice-to-Freeze compiler, `slice2freezej`, creates Java classes for Freeze maps. The compiler offers the following command-line options in addition to the [standard options](#):

`--dict NAME,KEY,VALUE`

Generate a Freeze map class named *NAME* using *KEY* as key and *VALUE* as value. This option may be specified multiple times to generate several Freeze maps. *NAME* may be a scoped Java name, such as `Demo.Struct1ObjectMap`. *KEY* and *VALUE* represent Slice types and therefore must use Slice syntax, such as `bool` or `Ice::Identity`. The type identified by *KEY* must be a [legal dictionary key type](#).

`--dict-index MAP[,MEMBER][,case-sensitive|case-insensitive]`

Add an [index](#) to the Freeze map named *MAP*. If *MEMBER* is specified, the map value type must be a structure or a class, and *MEMBER* must be the name of a member of that type. If *MEMBER* is not specified, the entire value is indexed. When the indexed member (or entire value) is a string, the index can be case-sensitive (default) or case-insensitive.

`--index CLASS,TYPE,MEMBER[,case-sensitive|case-insensitive]`

Generate an [index class](#) for a Freeze evictor. *CLASS* is the name of the index class to be generated. *TYPE* denotes the type of class to be indexed (objects of different classes are not included in this index). *MEMBER* is the name of the data member in *TYPE* to index. When *MEMBER* has type `string`, it is possible to specify whether the index is case-sensitive or not. The default is case-sensitive.

`--meta META`

Define the global metadata directive *META*. Using this option is equivalent to defining the global metadata *META* in each named Slice file, as well as in any file included by a named Slice file.

## Using a Freeze Map in the File System Server

We can use a Freeze map to add persistence to the file system server, and we'll present implementations in both C++ and Java. However, a [Freeze evictor](#) is often a better choice for applications (such as the file system server) in which the persistent value is an Ice object.

In general, incorporating a Freeze map into your application requires the following steps:

1. Evaluate your existing Slice definitions for suitable key and value types.
2. If no suitable key or value types are found, define new (possibly derived) types that capture your persistent state requirements. Consider placing these definitions in a separate file: these types are only used by the server for persistence, and therefore do not need to appear in the "public" definitions required by clients. Also consider placing your persistent types in a separate module to avoid name clashes.
3. Generate a Freeze map for your persistent types using the Freeze compiler.
4. Use the Freeze map in your operation implementations.

### Choosing Key and Value Types for the File System

Our goal is to implement the file system using Freeze maps for all persistent storage, including files and their contents. There are various options for how to implement the server. For this example, the server is stateless; whenever a client invokes an operation, the server accesses the database to satisfy the request. Implementing the server in this way has the advantage that it scales very well: we do not need a separate servant for each node; instead two [default servants](#), one for directories and one for files, are sufficient. This keeps the memory requirements of the server to a minimum and also allows us to rely on the database for transactions and locking. (This is a very common implementation technique for servers that act as a front end to a database: the server is a simple facade that implements each operation by accessing the database.)

Our first step is to select the Slice types we will use for the key and value types for our maps. For each file, we need to store the name of the file, its parent directory, and the contents of the file. For directories, we also store the name and parent directory, as well as a dictionary that keeps track of the subdirectories and files in that directory. This leads to Slice definitions (in file `FilesystemDB.ice`) as follows:

```

 Slice

#include <Filesystem.ice>
#include <Ice/Identity.ice>

module FilesystemDB {
 struct FileEntry {
 string name;
 Ice::Identity parent;
 Filesystem::Lines text;
 };

 dictionary<string, Filesystem::NodeDesc> StringNodeDescDict;

 struct DirectoryEntry {
 string name;
 Ice::Identity parent;
 StringNodeDescDict nodes;
 };
};

```

Note that the definitions are placed into a separate module, so they do not affect the existing definitions of the non-persistent version of the application. For reference, here is the definition of `NodeDesc` once more:

## Slice

```
module Filesystem {
 // ...

 enum NodeType { DirType, FileType };

 struct NodeDesc {
 string name;
 NodeType type;
 Node* proxy;
 };

 // ...
};
```

To store the persistent state for the file system, we use two Freeze maps: one map for files and one map for directories. For files, we map the identity of the file to its corresponding `FileEntry` structure and, similarly, for directories, we map the identity of the directory to its corresponding `DirectoryEntry` structure.

When a request arrives from a client, the object identity is available in the server. The server uses the identity to retrieve the state of the target node for the request from the database and act on that state accordingly.

## Adding a Freeze Map to the C++ File System Server

Here we present a C++ implementation of the [file system server](#).

On this page:

- [Generating the File System Maps in C++](#)
- [The Server Main Program in C++](#)
- [The Servant Class Definitions in C++](#)
- [Implementing Filel with a Freeze Map in C++](#)
- [Implementing Directoryl with a Freeze Map in C++](#)

### Generating the File System Maps in C++

Now that we have selected our key and value types, we can generate the maps as follows:

```
$ slice2freeze -I$(ICE_HOME)/slice -I. --ice --dict \
 FilesystemDB::IdentityFileEntryMap,Ice::Identity,\
 FilesystemDB::FileEntry \
 IdentityFileEntryMap FilesystemDB.ice \
 $(ICE_HOME)/slice/Ice/Identity.ice
$ slice2freeze -I$(ICE_HOME)/slice -I. --ice --dict \
 FilesystemDB::IdentityDirectoryEntryMap,Ice::Identity,\
 FilesystemDB::DirectoryEntry \
 IdentityDirectoryEntryMap FilesystemDB.ice \
 $(ICE_HOME)/slice/Ice/Identity.ice
```

The resulting map classes are named `IdentityFileEntryMap` and `IdentityDirectoryEntryMap`.

### The Server Main Program in C++

The server's main program is very simple:

```
C++
```

```
#include <FilesystemI.h>
#include <IdentityFileEntryMap.h>
#include <IdentityDirectoryEntryMap.h>
#include <Ice/Application.h>
#include <Freeze/Freeze.h>

using namespace std;
using namespace Filesystem;
using namespace FilesystemDB;

class FilesystemApp : public virtual Ice::Application
{
public:

 FilesystemApp(const string& envName)
 : _envName(envName)
 {
```

```

 }

 virtual int run(int, char*[])
 {
 shutdownOnInterrupt();

 Ice::ObjectAdapterPtr adapter =
 communicator()->createObjectAdapter("MapFilesystem");

 const Freeze::ConnectionPtr connection(
 Freeze::createConnection(communicator(), _envName));

 const IdentityFileEntryMap fileDB(connection, FileI::filesDB());
 const IdentityDirectoryEntryMap dirDB(
 connection,
 DirectoryI::directoriesDB());

 adapter->addDefaultServant(new FileI(communicator(), _envName),
 "file");
 adapter->addDefaultServant(new DirectoryI(communicator(), _envName),
 "");

 adapter->activate();

 communicator()->waitForShutdown();

 if(interrupted())
 cerr << appName()
 << ": received signal, shutting down" << endl;

 return 0;
 }

private:

 string _envName;
};

int
main(int argc, char* argv[])
{
 FilesystemApp app("db");

```

```

 return app.main(argc, argv, "config.server");
}

```

Let us examine the code in detail. First, we are now including `IdentityFileEntry.h` and `IdentityDirectoryEntry.h`. These header files includes all of the other Freeze (and Ice) header files we need.

Next, we define the class `FilesystemApp` as a subclass of `Ice::Application`, and provide a constructor taking a string argument:

```

C++

FilesystemApp(const string& envName)
 : _envName(envName) {}

```

The string argument represents the name of the database environment, and is saved for later use in `run`.

The interesting part of `run` are the few lines of code that create the database connection and the two maps that store files and directories, plus the code to add the two default servants:

```

C++

const Freeze::ConnectionPtr connection(
 Freeze::createConnection(communicator(), _envName));

const IdentityFileEntryMap fileDB(connection, FileI::filesDB());
const IdentityDirectoryEntryMap dirDB(
 connection,
 DirectoryI::directoriesDB());

adapter->addDefaultServant(new FileI(communicator(), _envName),
 "file");
adapter->addDefaultServant(new DirectoryI(communicator(), _envName), "");

```

`run` keeps the database connection open for the duration of the program for performance reasons. As we will see shortly, individual operation implementations will use their own connections; however, it is substantially cheaper to create second (and subsequent connections) than it is to create the first connection.

For the default servants, we use `file` as the category for files. For directories, we use the empty default category.

### ***The Servant Class Definitions in C++***

The class definition for `FileI` is very simple:

**C++**

```

namespace Filesystem {
 class FileI : public File {
 public:
 FileI(const Ice::CommunicatorPtr& communicator,
 const std::string& envName);

 // Slice operations...

 static std::string filesDB();

 private:
 void halt(const Freeze::DatabaseException& ex) const;

 const Ice::CommunicatorPtr _communicator;
 const std::string _envName;
 };
}

```

The `FileI` class stores the communicator and the environment name. These members are initialized by the constructor. The `filesDB` static member function returns the name of the file map, and the `halt` member function is used to stop the server if it encounters a catastrophic error.

The `DirectoryI` class looks very much the same, also storing the communicator and environment name. The `directoriesDB` static member function returns the name of the directory map.

**C++**

```

namespace Filesystem {
 class DirectoryI : public Directory {
 public:
 DirectoryI(const Ice::CommunicatorPtr& communicator,
 const std::string& envName);

 // Slice operations...

 static std::string directoriesDB();

 private:
 void halt(const Freeze::DatabaseException& ex) const;

 const Ice::CommunicatorPtr _communicator;
 const std::string _envName;
 };
}

```

**Implementing `FileI` with a Freeze Map in C++**

The `FileI` constructor and the `filesDB` and `halt` member functions have trivial implementations:

```

C++

FileI::FileI(const Ice::CommunicatorPtr& communicator,
 const string& envName)
 : _communicator(communicator), _envName(envName)
{
}

string
FileI::filesDB()
{
 return "files";
}

void
FileI::halt(const Freeze::DatabaseException& ex) const
{
 Ice::Error error(_communicator->getLogger());
 error << "fatal exception: " << ex
 << "\n*** Aborting application ***";

 abort();
}

```

The Slice operations all follow the same implementation strategy: we create a database connection and the file map and place the body of the operation into an infinite loop:

**C++**

```

string
FileI::someOperation(/* ... */ const Ice::Current& c)
{
 const Freeze::ConnectionPtr connection(
 Freeze::createConnection(_communicator, _envName));
 IdentityFileEntryMap fileDB(connection, filesDB());

 for (;;) {
 try {

 // Operation implementation here...

 } catch (const Freeze::DeadlockException&) {
 continue;
 } catch (const Freeze::DatabaseException& ex) {
 halt(ex);
 }
 }
}

```

Each operation creates its own database connection and map for concurrency reasons: the database takes care of all the necessary locking, so there is no need for any other synchronization in the server. If the database detects a deadlock, the code handles the corresponding `DeadlockException` and simply tries again until the operation eventually succeeds; any other database exception indicates that something has gone seriously wrong and terminates the server.

Here is the implementation of the `name` method:

## C++

```

string
FileI::name(const Ice::Current& c)
{
 const Freeze::ConnectionPtr connection(
 Freeze::createConnection(_communicator, _envName));
 IdentityFileEntryMap fileDB(connection, filesDB());

 for (;;) {
 try {
 IdentityFileEntryMap::iterator p = fileDB.find(c.id);
 if (p == fileDB.end()) {
 throw Ice::ObjectNotExistException(__FILE__, __LINE__);
 }
 return p->second.name;
 } catch (const Freeze::DeadlockException&) {
 continue;
 } catch (const Freeze::DatabaseException& ex) {
 halt(ex);
 }
 }
}

```

The implementation could hardly be simpler: the default servant uses the identity in the `Current` object to index into the file map. If a record with this identity exists, it returns the name of the file as stored in the `FileEntry` structure in the map. Otherwise, if no such entry exists, it throws `ObjectNotExistException`. This happens if the file existed at some time in the past but has since been destroyed.

The `read` implementation is almost identical. It returns the text that is stored by the `FileEntry`:

**C++**

```

Lines
FileI::read(const Ice::Current& c)
{
 const Freeze::ConnectionPtr connection(
 Freeze::createConnection(_communicator, _envName));
 IdentityFileEntryMap fileDB(connection, filesDB());

 for (;;) {
 try {
 IdentityFileEntryMap::iterator p = fileDB.find(c.id);
 if (p == fileDB.end()) {
 throw Ice::ObjectNotExistException(__FILE__, __LINE__);
 }
 return p->second.text;
 } catch (const Freeze::DeadlockException&) {
 continue;
 } catch (const Freeze::DatabaseException& ex) {
 halt(ex);
 }
 }
}

```

The `write` implementation updates the file contents and calls `set` on the iterator to update the map with the new contents:

## C++

```

void
FileI::write(const Filesystem::Lines& text, const Ice::Current& c)
{
 const Freeze::ConnectionPtr connection(
 Freeze::createConnection(_communicator, _envName));
 IdentityFileEntryMap fileDB(connection, filesDB());

 for (;;) {
 try {
 IdentityFileEntryMap::iterator p = fileDB.find(c.id);
 if (p == fileDB.end()) {
 throw Ice::ObjectNotExistException(__FILE__, __LINE__);
 }
 FileEntry entry = p->second;
 entry.text = text;
 p.set(entry);
 break;
 } catch (const Freeze::DeadlockException&) {
 continue;
 } catch (const Freeze::DatabaseException& ex) {
 halt(ex);
 }
 }
}

```

Finally, the `destroy` implementation for files must update two maps: it needs to remove its own entry in the file map as well as update the `nodes` map in the parent to remove itself from the parent's map of children. This raises a potential problem: if one update succeeds but the other one fails, we end up with an inconsistent file system: either the parent still has an entry to a non-existent file, or the parent lacks an entry to a file that still exists.

To make sure that the two updates happen atomically, `destroy` performs them in a transaction:

## C++

```

void
FileI::destroy(const Ice::Current& c)
{
 const Freeze::ConnectionPtr connection(
 Freeze::createConnection(_communicator, _envName));
 IdentityFileEntryMap fileDB(connection, filesDB());
 IdentityDirectoryEntryMap dirDB(connection,
DirectoryI::directoriesDB());

 for (;;) {
 try {
 Freeze::TransactionHolder txn(connection);

 IdentityFileEntryMap::iterator p = fileDB.find(c.id);
 if (p == fileDB.end()) {
 throw Ice::ObjectNotExistException(__FILE__, __LINE__);
 }
 FileEntry entry = p->second;

 IdentityDirectoryEntryMap::iterator pp =
dirDB.find(entry.parent);
 if (pp == dirDB.end()) {
 halt(Freeze::DatabaseException(
 __FILE__, __LINE__,
 "consistency error: file without parent"));
 }

 DirectoryEntry dirEntry = pp->second;
 dirEntry.nodes.erase(entry.name);
 pp.set(dirEntry);

 fileDB.erase(p);
 txn.commit();
 break;
 } catch (const Freeze::DeadlockException&) {
 continue;
 } catch (const Freeze::DatabaseException& ex) {
 halt(ex);
 }
 }
}

```

As you can see, the code first establishes a transaction and then locates the file in the parent directory's map of nodes. After removing the file from the parent, the code updates the parent's persistent state by calling `set` on the parent iterator and then removes the file from the file map before committing the transaction.

**Implementing *DirectoryI* with a Freeze Map in C++**

The `DirectoryI::directoriesDB` implementation returns the string `directories`, and the `halt` implementation is the same as for `FileI`, so we do not show them here.

Turning to the constructor, we must cater for two different scenarios:

- The server is started with a database that already contains a number of nodes.
- The server is started for the very first time with an empty database.

This means that the root directory (which must always exist) may or may not be present in the database. Accordingly, the constructor looks for the root directory (with the fixed identity `RootDir`); if the root directory does not exist in the database, it creates it:

```

C++

DirectoryI::DirectoryI(const Ice::CommunicatorPtr& communicator,
const string& envName)
 : _communicator(communicator), _envName(envName)
{
 const Freeze::ConnectionPtr connection =
 Freeze::createConnection(_communicator, _envName);
 IdentityDirectoryEntryMap dirDB(connection, directoriesDB());

 for (;;) {
 try {
 Ice::Identity rootId;
 rootId.name = "RootDir";
 IdentityDirectoryEntryMap::const_iterator p =
dirDB.find(rootId);
 if (p == dirDB.end()) {
 DirectoryEntry d;
 d.name = "/";
 dirDB.put(make_pair(rootId, d));
 }
 break;
 } catch (const Freeze::DeadlockException&) {
 continue;
 } catch (const Freeze::DatabaseException& ex) {
 halt(ex);
 }
 }
}

```

Next, let us examine the implementation of `createDirectory`. Similar to the `FileI::destroy` operation, `createDirectory` must update both the parent's nodes map and create a new entry in the directory map. These updates must happen atomically, so we perform them in a separate transaction:

```

C++

DirectoryPrx
DirectoryI::createDirectory(const string& name, const Ice::Current& c)
{

```

```

const Freeze::ConnectionPtr connection(
 Freeze::createConnection(_communicator, _envName));
IdentityDirectoryEntryMap directoryDB(connection, directoriesDB());

for (;;) {
 try {
 Freeze::TransactionHolder txn(connection);

 IdentityDirectoryEntryMap::iterator p =
 directoryDB.find(c.id);
 if (p == directoryDB.end()) {
 throw Ice::ObjectNotExistException(__FILE__, __LINE__);
 }

 DirectoryEntry entry = p->second;
 if (name.empty()
|| entry.nodes.find(name) != entry.nodes.end()) {
 throw NameInUse(name);
 }

 DirectoryEntry d;
 d.name = name;
 d.parent = c.id;

 Ice::Identity id;
 id.name = IceUtil::generateUUID();
 DirectoryPrx proxy = DirectoryPrx::uncheckedCast(c.adapter-
>createProxy(id));

 NodeDesc nd;
 nd.name = name;
 nd.type = DirType;
 nd.proxy = proxy;
 entry.nodes.insert(make_pair(name, nd));

 p.set(entry);
 directoryDB.put(make_pair(id, d));

 txn.commit();

 return proxy;
 } catch (const Freeze::DeadlockException&) {
 continue;
 } catch (const Freeze::DatabaseException& ex) {
 halt(ex);
 }
}

```

```

 }
}

```

After establishing the transaction, the code ensures that the directory does not already contain an entry with the same name and then initializes a new `DirectoryEntry`, setting the name to the name of the new directory, and the parent to its own identity. The identity of the new directory is a UUID, which ensures that all directories have unique identities. In addition, the UUID prevents the [accidental rebirth](#) of a file or directory in the future.

The code then initializes a new `NodeDesc` structure with the details of the new directory and, finally, updates its own map of children as well as adding the new directory to the map of directories before committing the transaction.

The `createFile` implementation is almost identical, so we do not show it here. Similarly, the `name` and `destroy` implementations are almost identical to the ones for `FileI`, so let us move to `list`:

### C++

```

NodeDescSeq
DirectoryI::list(const Ice::Current& c)
{
 const Freeze::ConnectionPtr connection(
 Freeze::createConnection(_communicator, _envName));
 IdentityDirectoryEntryMap directoryDB(connection, directoriesDB());

 for (;;) {
 try {
 IdentityDirectoryEntryMap::iterator p =
directoryDB.find(c.id);
 if (p == directoryDB.end()) {
 throw Ice::ObjectNotExistException(__FILE__, __LINE__);
 }
 NodeDescSeq result;
 for (StringNodeDescDict::const_iterator q =
p->second.nodes.begin();
 q != p->second.nodes.end(); ++q) {
 result.push_back(q->second);
 }
 return result;
 } catch (const Freeze::DeadlockException&) {
 continue;
 } catch (const Freeze::DatabaseException& ex) {
 halt(ex);
 }
 }
}

```

Again, the code is very simple: it iterates over the `nodes` map, adding each `NodeDesc` structure to the returned sequence.

The `find` implementation is even simpler, so we do not show it here.

## Adding a Freeze Map to the Java File System Server

Here we present a Java implementation of the file system server.

On this page:

- [Generating the File System Maps in Java](#)
- [The Server Main Program in Java](#)
- [Implementing Filel with a Freeze Map in Java](#)
- [Implementing Directoryl with a Freeze Map in Java](#)

### Generating the File System Maps in Java

Now that we have selected our key and value types, we can generate the maps as follows:

```
$ slice2freezej -I$(ICE_HOME)/slice -I. --ice --dict \
 FilesystemDB.IdentityFileEntryMap,Ice::Identity,\
 FilesystemDB::FileEntry \
 IdentityFileEntryMap FilesystemDB.ice \
 $(ICE_HOME)/slice/Ice/Identity.ice
$ slice2freezej -I$(ICE_HOME)/slice -I. --ice --dict \
 FilesystemDB.IdentityDirectoryEntryMap,Ice::Identity,\
 FilesystemDB::DirectoryEntry \
 IdentityDirectoryEntryMap FilesystemDB.ice \
 $(ICE_HOME)/slice/Ice/Identity.ice
```

The resulting map classes are named `IdentityFileEntryMap` and `IdentityDirectoryEntryMap`.

### The Server Main Program in Java

The server's main program is very simple:

```
Java
```

```
import Filesystem.*;
import FilesystemDB.*;

public class Server extends Ice.Application
{
 public
 Server(String envName)
 {
 _envName = envName;
 }

 public int
 run(String[] args)
 {
 Ice.ObjectAdapter adapter =
communicator().createObjectAdapter("MapFilesystem");

 Freeze.Connection connection = null;
```

```

 try {
 connection = Freeze.Util.createConnection(communicator(),
 _envName);
 IdentityFileEntryMap fileDB =
new IdentityFileEntryMap(connection, FileI.filesDB(), true);
 IdentityDirectoryEntryMap dirDB =
 new IdentityDirectoryEntryMap(connection, DirectoryI.di
rectoriesDB(), true);

 adapter.addDefaultServant(new FileI(communicator(), _envNam
e), "file");
 adapter.addDefaultServant(new DirectoryI(communicator(), _e
nvName), "");

 adapter.activate();

 communicator().waitForShutdown();
 } finally {
 connection.close();
 }

 return 0;
 }

 public static void
 main(String[] args)
 {
 Server app = new Server("db");
 app.main("MapServer", args, "config.server");
 System.exit(0);
 }

```

```

 private String _envName;
}

```

First, we import the `Filesystem` and `FilesystemDB` packages.

Next, we define the class `FilesystemApp` as a subclass of `Ice.Application`, and provide a constructor taking a string argument:

#### Java

```

FilesystemApp(const string& envName)
 : _envName(envName) {}

```

The string argument represents the name of the database environment, and is saved for later use in `run`.

The interesting part of `run` are the few lines of code that create the database connection and the two maps that store files and directories, plus the code to add the two default servants:

#### Java

```

 connection = Freeze.Util.createConnection(communicator(),
 _envName);
 IdentityFileEntryMap fileDB =
 new IdentityFileEntryMap(connection, FileI.filesDB(), t
 rue);
 IdentityDirectoryEntryMap dirDB =
 new IdentityDirectoryEntryMap(connection, DirectoryI.di
 rectoriesDB(), true);

 adapter.addDefaultServant(new FileI(communicator(), _envNam
 e), "file");
 adapter.addDefaultServant(new DirectoryI(communicator(), _e
 nvName), "");

```

`run` keeps the database connection open for the duration of the program for performance reasons. As we will see shortly, individual operation implementations will use their own connections; however, it is substantially cheaper to create second (and subsequent connections) than it is to create the first connection.

For the default servants, we use `file` as the category for files. For directories, we use the empty default category.

#### ***Implementing `FileI` with a Freeze Map in Java***

The class definition for `FileI` is very simple:

## Java

```

public class FileI extends _FileDisp
{
 public
 FileI(Ice.Communicator communicator, String envName)
 {
 _communicator = communicator;
 _envName = envName;
 }

 // Slice operations...

 public static String
 filesDB()
 {
 return "files";
 }

 private void
 halt(Freeze.DatabaseException e)
 {
 java.io.StringWriter sw = new java.io.StringWriter();
 java.io.PrintWriter pw = new java.io.PrintWriter(sw);
 e.printStackTrace(pw);
 pw.flush();
 _communicator.getLogger().error(
 "fatal database error\n" + sw.toString() +
 "\n*** Halting JVM ***");
 Runtime.getRuntime().halt(1);
 }

 private Ice.Communicator _communicator;
 private String _envName;
}

```

The `FileI` class stores the communicator and the environment name. These members are initialized by the constructor. The `filesDB` static method returns the name of the file map, and the `halt` member function is used to stop the server if it encounters a catastrophic error.

The Slice operations all follow the same implementation strategy: we create a database connection and the file map and place the body of the operation into an infinite loop:

### Java

```

public String
someOperation(/* ... */ Ice.Current c)
{
 Freeze.Connection connection =
Freeze.Util.createConnection(_communicator, _envName);
 try {
 IdentityFileEntryMap fileDB =
new IdentityFileEntryMap(connection, filesDB());

 for (;;) {
 try {

 // Operation implementation here...

 } catch (Freeze.DeadlockException ex) {
 continue;
 } catch (Freeze.DatabaseException ex) {
 halt(ex);
 }
 }
 } finally {
 connection.close();
 }
}

```

Each operation creates its own database connection and map for concurrency reasons: the database takes care of all the necessary locking, so there is no need for any other synchronization in the server. If the database detects a deadlock, the code handles the corresponding `DeadlockException` and simply tries again until the operation eventually succeeds; any other database exception indicates that something has gone seriously wrong and terminates the server.

Here is the implementation of the `name` method:

## Java

```

public String
name(Ice.Current c)
{
 Freeze.Connection connection =
Freeze.Util.createConnection(_communicator, _envName);
 try
 {
 IdentityFileEntryMap fileDB =
new IdentityFileEntryMap(connection, filesDB());

 for (;;) {
 try {
 FileEntry entry = fileDB.get(c.id);
 if (entry == null) {
 throw new Ice.ObjectNotExistException();
 }
 return entry.name;
 } catch (Freeze.DeadlockException ex) {
 continue;
 } catch (Freeze.DatabaseException ex) {
 halt(ex);
 }
 }
 } finally {
 connection.close();
 }
}

```

The implementation could hardly be simpler: the default servant uses the identity in the `Current` object to index into the file map. If a record with this identity exists, it returns the name of the file as stored in the `FileEntry` structure in the map. Otherwise, if no such entry exists, it throws `ObjectNotExistException`. This happens if the file existed at some time in the past but has since been destroyed.

The `read` implementation is almost identical. It returns the text that is stored by the `FileEntry`:

## Java

```

public String[]
read(Ice.Current c)
{
 Freeze.Connection connection =
 Freeze.Util.createConnection(_communicator, _envName);
 try {
 IdentityFileEntryMap fileDB = new
IdentityFileEntryMap(connection, filesDB());

 for (;;) {
 try {
 FileEntry entry = fileDB.get(c.id);
 if (entry == null) {
 throw new Ice.ObjectNotExistException();
 }
 return entry.text;
 } catch (Freeze.DeadlockException ex) {
 continue;
 } catch (Freeze.DatabaseException ex) {
 halt(ex);
 }
 }
 } finally {
 connection.close();
 }
}

```

The `write` implementation updates the file contents and calls `put` on the iterator to update the map with the new contents:

## Java

```

public void
write(String[] text, Ice.Current c)
 throws GenericError
{
 Freeze.Connection connection =
Freeze.Util.createConnection(_communicator, _envName);
 try {
 IdentityFileEntryMap fileDB =
new IdentityFileEntryMap(connection, filesDB());

 for (;;) {
 try {
 FileEntry entry = fileDB.get(c.id);
 if (entry == null) {
 throw new Ice.ObjectNotExistException();
 }
 entry.text = text;
 fileDB.put(c.id, entry);
 break;
 } catch (Freeze.DeadlockException ex) {
 continue;
 } catch (Freeze.DatabaseException ex) {
 halt(ex);
 }
 }
 } finally {
 connection.close();
 }
}

```

Finally, the `destroy` implementation for files must update two maps: it needs to remove its own entry in the file map as well as update the `nodes` map in the parent to remove itself from the parent's map of children. This raises a potential problem: if one update succeeds but the other one fails, we end up with an inconsistent file system: either the parent still has an entry to a non-existent file, or the parent lacks an entry to a file that still exists.

To make sure that the two updates happen atomically, `destroy` performs them in a transaction:

## Java

```

public void
destroy(Ice.Current c)
 throws PermissionDenied
{
 Freeze.Connection connection =
Freeze.Util.createConnection(_communicator, _envName);
 try {

```

```

 IdentityFileEntryMap fileDB =
new IdentityFileEntryMap(connection, filesDB());
 IdentityDirectoryEntryMap dirDB =
 new IdentityDirectoryEntryMap(connection, DirectoryI.directoriesDB());

 for (;;) {
 Freeze.Transaction txn = null;
 try {
 txn = connection.beginTransaction();

 FileEntry entry = fileDB.get(c.id);
 if (entry == null) {
 throw new Ice.ObjectNotExistException();
 }

 DirectoryEntry dirEntry = (DirectoryEntry)dirDB.get
(entry.parent);

 if (dirEntry == null) {
 halt(new Freeze.DatabaseException(
"consistency error: file without parent"));
 }

 dirEntry.nodes.remove(entry.name);
 dirDB.put(entry.parent, dirEntry);

 fileDB.remove(c.id);

 txn.commit();
 txn = null;
 break;
 } catch (Freeze.DeadlockException ex) {
 continue;
 } catch (Freeze.DatabaseException ex) {
 halt(ex);
 } finally {
 if (txn != null) {
 txn.rollback();
 }
 }
 }
 }
 finally
 {
 connection.close();
 }
}

```

```
}
}
```

As you can see, the code first establishes a transaction and then locates the file in the parent directory's map of nodes. After removing the file from the parent, the code updates the parent's persistent state by calling `put` on the parent iterator and then removes the file from the file map before committing the transaction.

### ***Implementing `DirectoryI` with a Freeze Map in Java***

The `DirectoryI.directoriesDB` implementation returns the string `directories`, and the `halt` implementation is the same as for `FileI`, so we do not show them here.

Turning to the constructor, we must cater for two different scenarios:

- The server is started with a database that already contains a number of nodes.
- The server is started for the very first time with an empty database.

This means that the root directory (which must always exist) may or may not be present in the database. Accordingly, the constructor looks for the root directory (with the fixed identity `RootDir`); if the root directory does not exist in the database, it creates it:

## Java

```

public
DirectoryI(Ice.Communicator communicator, String envName)
{
 _communicator = communicator;
 _envName = envName;

 Freeze.Connection connection =
Freeze.Util.createConnection(_communicator, _envName);
 try {
 IdentityDirectoryEntryMap dirDB =
 new IdentityDirectoryEntryMap(connection,
directoriesDB());

 for (;;) {
 try {
 Ice.Identity rootId =
new Ice.Identity("RootDir", "");
 DirectoryEntry entry = dirDB.get(rootId);
 if (entry == null) {
 dirDB.put(rootId, new DirectoryEntry("/",
new Ice.Identity("", ""), null));
 }
 break;
 } catch (Freeze.DeadlockException ex) {
 continue;
 } catch (Freeze.DatabaseException ex) {
 halt(ex);
 }
 }
 } finally {
 connection.close();
 }
}

```

Next, let us examine the implementation of `createDirectory`. Similar to the `FileI::destroy` operation, `createDirectory` must update both the parent's nodes map and create a new entry in the directory map. These updates must happen atomically, so we perform them in a separate transaction:

## Java

```

public DirectoryPrx
createDirectory(String name, Ice.Current c)
 throws NameInUse
{
 Freeze.Connection connection =

```

```

Freeze.Util.createConnection(_communicator, _envName);
 try {
 IdentityDirectoryEntryMap dirDB =
 new IdentityDirectoryEntryMap(connection,
directoriesDB());

 for (;;) {
 Freeze.Transaction txn = null;
 try {
 txn = connection.beginTransaction();

 DirectoryEntry entry = dirDB.get(c.id);
 if (entry == null) {
 throw new Ice.ObjectNotExistException();
 }
 if(name.length() == 0
|| entry.nodes.get(name) != null) {
 throw new NameInUse(name);
 }

 DirectoryEntry newEntry =
new DirectoryEntry(name, c.id, null);
 Ice.Identity id = new Ice.Identity(java.util.UUID.r
andomUUID().toString(), "");
 DirectoryPrx proxy =
DirectoryPrxHelper.uncheckedCast(c.adapter.createProxy(id));

 entry.nodes.put(name, new NodeDesc(name,
NodeType.DirType, proxy));
 dirDB.put(c.id, entry);
 dirDB.put(id, newEntry);

 txn.commit();
 txn = null;

 return proxy;
 } catch (Freeze.DeadlockException ex) {
 continue;
 } catch (Freeze.DatabaseException ex) {
 halt(ex);
 } finally {
 if(txn != null) {
 txn.rollback();
 }
 }
 }
 } finally {
 connection.close();
 }

```

```
}
}
```

After establishing the transaction, the code ensures that the directory does not already contain an entry with the same name and then initializes a new `DirectoryEntry`, setting the name to the name of the new directory, and the parent to its own identity. The identity of the new directory is a UUID, which ensures that all directories have unique identities. In addition, the UUID prevents the [accidental rebirth](#) of a file or directory in the future.

The code then initializes a new `NodeDesc` structure with the details of the new directory and, finally, updates its own map of children as well as adding the new directory to the map of directories before committing the transaction.

The `createFile` implementation is almost identical, so we do not show it here. Similarly, the `name` and `destroy` implementations are almost identical to the ones for `FileI`, so let us move to `list`:

## Java

```

public NodeDesc[]
list(Ice.Current c)
{
 Freeze.Connection connection =
 Freeze.Util.createConnection(_communicator, _envName);
 try {
 IdentityDirectoryEntryMap dirDB =
 new IdentityDirectoryEntryMap(connection,
directoriesDB());

 for (;;) {
 try {
 DirectoryEntry entry = dirDB.get(c.id);
 if (entry == null) {
 throw new Ice.ObjectNotExistException();
 }
 NodeDesc[] result =
new NodeDesc[entry.nodes.size()];
 java.util.Iterator<NodeDesc> p =
entry.nodes.values().iterator();
 for (int i = 0; i < entry.nodes.size(); ++i) {
 result[i] = p.next();
 }
 return result;
 } catch (Freeze.DeadlockException ex) {
 continue;
 } catch (Freeze.DatabaseException ex) {
 halt(ex);
 }
 }
 } finally {
 connection.close();
 }
}

```

Again, the code is very simple: it iterates over the `nodes` map, adding each `NodeDesc` structure to the returned sequence.

The `find` implementation is even simpler, so we do not show it here.

## Freeze Catalogs

In each database environment, Freeze maintains an internal table that contains type information describing all the databases in the environment. This table is an instance of a [Freeze map](#) in which the key is a string representing the database name and the value is an instance of `Freeze::CatalogData`:

| Slice                                                                                                                           |
|---------------------------------------------------------------------------------------------------------------------------------|
| <pre> module Freeze {     struct CatalogData {         bool evictor;         string key;         string value;     }; }; </pre> |

An entry describes an [evictor](#) database if the `evictor` member is true, in which case the `key` and `value` members are empty strings. An entry that describes a Freeze map sets `evictor` to false; the `key` and `value` members contain the Slice types used when the map was defined.

[FreezeScript](#) tools such as `transformdb` and `dumpdb` access the catalog to obtain type information when none is supplied by the user. You can also use `dumpdb` to display the catalog of a database environment.

Freeze applications may access the catalog in the same manner as any other Freeze map. For example, the following C++ code displays the contents of a catalog:

| C++                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <pre> #include &lt;Freeze/Catalog.h&gt; ... string envName = ...; Freeze::ConnectionPtr conn = Freeze::createConnection(communicator, envName); Freeze::Catalog catalog(conn, Freeze::catalogName()); for (Freeze::Catalog::const_iterator p = catalog.begin();     p != catalog.end(); ++p) {     if (p-&gt;second.evictor)         cout &lt;&lt; p-&gt;first &lt;&lt; ": evictor" &lt;&lt; endl;     else         cout &lt;&lt; p-&gt;first &lt;&lt; ": map&lt;" &lt;&lt; p-&gt;second.key             &lt;&lt; ", " &lt;&lt; p-&gt;second.value &lt;&lt; "&gt;" &lt;&lt; endl; } conn-&gt;close(); </pre> |

The equivalent Java code is shown below:

**Java**

```
String envName = ...;
Freeze.Connection conn =
Freeze.Util.createConnection(communicator, envName);
Freeze.Catalog catalog =
new Freeze.Catalog(conn, Freeze.Util.catalogName(), true);
for (java.util.Map.Entry<String, Freeze.CatalogData> e :
 catalog.entrySet()) {
 String name = e.getKey();
 Freeze.CatalogData data = e.getValue();
 if (data.evictor)
 System.out.println(name + ": evictor");
 else
 System.out.println(name + ": map<" + data.key + ", " +
data.value + ">");
}
conn.close();
```

## Backing Up Freeze Databases

When you store important information in a Freeze database environment, you should consider regularly backing up the database environment.

There are two forms of backups: cold backups, where you just copy your database environment directory while no application is using these files (very straightforward), and hot backups, where you backup a database environment while an application is actively reading and writing data.

In order to perform a hot backup on a Freeze environment, you need to configure this Freeze environment with two non-default settings:

- `Freeze.DbEnv.envName.OldLogsAutoDelete=0`  
This instructs Freeze to keep old log files instead of periodically deleting them. This setting is necessary for proper hot backups; it implies that you will need to take care of deleting old files yourself (typically as part of your periodic backup procedure).
- `Freeze.DbEnv.envName.DbPrivate=0`  
By default, Freeze is configured with `DbPrivate` set to 1, which means only one process at a time can safely access the database environment. When performing hot backups, you need to access this database environment concurrently from various Berkeley DB utilities (such as `db_archive` or `db_hotbackup`), so you need to set this property to 0.

The `Freeze/backup` C++ demo in your Ice distribution shows one way to perform such backups and recovery. Please consult the Berkeley DB documentation for further details.

## FreezeScript

Freeze supplies a valuable set of services for simplifying the use of persistence in Ice applications. However, while Freeze makes it easy for an application to manage its persistent state, there are additional administrative responsibilities that must also be addressed:

- **Migration**  
As an application evolves, it is not unusual for the types describing its persistent state to evolve as well. When these changes occur, a great deal of time can be saved if existing databases can be migrated to the new format while preserving as much information as possible.
- **Inspection**  
The ability to examine a database can be helpful during every stage of the application's lifecycle, from development to deployment.

FreezeScript provides tools for performing both of these activities on Freeze [map](#) and [evictor](#) databases. These databases have a well-defined structure because the key and value of each record consist of the marshaled bytes of their respective Slice types. This design allows the FreezeScript tools to operate on any Freeze database using only the Slice definitions for the database types.

## Migrating a Freeze Database

The FreezeScript tool `transformdb` migrates a database created by a Freeze [map](#) or [evictor](#). It accomplishes this by comparing the "old" Slice definitions (i.e., the ones that describe the current contents of the database) with the "new" Slice definitions, and making whatever modifications are necessary to ensure that the transformed database is compatible with the new definitions.

This would be difficult to achieve by writing a custom transformation program because that program would require static knowledge of the old and new types, which frequently define many of the same symbols and would therefore prevent the program from being loaded. The `transformdb` tool avoids this issue using an interpretive approach: the Slice definitions are parsed and used to drive the migration of the database records.

The tool supports two modes of operation:

1. [Automatic migration](#) – the database is migrated in a single step using only the default set of transformations.
2. [Custom migration](#) – you supply a script to augment or override the default transformations.

## Automatic Database Migration

On this page:

- [Type Compatibility Rules for Automatic Migration](#)
- [Default Values for Automatic Migration](#)
- [Running an Automatic Migration](#)

The default transformations performed by `transformdb` preserve as much information as possible. However, there are practical limits to the tool's capabilities, since the only information it has is obtained by performing a comparison of the Slice definitions.

For example, suppose our old definition for a structure is the following:

**Slice**

```
struct AStruct {
 int i;
};
```

We want to migrate instances of this struct to the following revised definition:

**Slice**

```
struct AStruct {
 int j;
};
```

As the developers, we know that the `int` member has been renamed from `i` to `j`, but to `transformdb` it appears that member `i` was removed and member `j` was added. The default transformation results in exactly that behavior: the value of `i` is lost, and `j` is initialized to a default value. If we need to preserve the value of `i` and transfer it to `j`, then we need to use [custom migration](#).

The changes that occur as a type system evolves can be grouped into three categories:

- **Data members**  
The data members of class and structure types are added, removed, or renamed. As discussed above, the default transformations initialize new and renamed data members to [default values](#).
- **Type names**  
Types are added, removed, or renamed. New types do not pose a problem for database migration when used to define a new data member; the member is initialized with [default values](#) as usual. On the other hand, if the new type replaces the type of an existing data member, then type compatibility becomes a factor (see the following item).  
  
Removed types generally do not cause problems either, because any uses of that type must have been removed from the new Slice definitions (e.g., by removing data members of that type). There is one case, however, where removed types become an issue, and that is for [polymorphic classes](#).  
  
Renamed types are a concern, just like renamed data members, because of the potential for losing information during migration. This is another situation for which [custom migration](#) is recommended.
- **Type content**  
Examples of changes of type content include the key type of a dictionary, the element type of a sequence, or the type of a data member. If the old and new types are not [compatible](#), then the default transformation emits a warning, discards the current value, and reinitializes it with a [default value](#).

### Type Compatibility Rules for Automatic Migration

Changes in the type of a value are restricted to certain sets of compatible changes. This section describes the type changes supported by the default transformations. All incompatible type changes result in a warning indicating that the current value is being discarded and a

default value for the new type assigned in its place. Additional flexibility is provided by [custom migration](#).

### Boolean

A value of type `bool` can be transformed to and from `string`. The legal string values for a `bool` value are `"true"` and `"false"`.

### Integer

The integer types `byte`, `short`, `int`, and `long` can be transformed into each other, but only if the current value is within range of the new type. These integer types can also be transformed into `string`.

### Floating Point

The floating-point types `float` and `double` can be transformed into each other, as well as to `string`. No attempt is made to detect a loss of precision during transformation.

### String

A `string` value can be transformed into any of the primitive types, as well as into enumeration and proxy types, but only if the value is a legal string representation of the new type. For example, the string value `"Pear"` can be transformed into the enumeration `Fruit`, but only if `Pear` is an enumerator of `Fruit`.

### Enum

An enumeration can be transformed into an enumeration with the same [type ID](#), or into a string. Transformation between enumerations is performed symbolically. For example, consider our old type below:

```

Slice

enum Fruit { Apple, Orange, Pear };

```

Suppose the enumerator `Pear` is being transformed into the following new type:

```

Slice

enum Fruit { Apple, Pear };

```

The transformed value in the new enumeration is also `Pear`, despite the fact that `Pear` has changed positions in the new type. However, if the old value had been `Orange`, then the default transformation emits a warning because that enumerator no longer exists, and initializes the new value to `Apple` (the default value).

If an enumerator has been renamed, then [custom migration](#) is required to convert enumerators from the old name to the new one.

### Sequence

A sequence can be transformed into another sequence type, even if the new sequence type does not have the same type id as the old type, but only if the element types are compatible. For example, `sequence<short>` can be transformed into `sequence<int>`, regardless of the names given to the sequence types.

### Dictionary

A dictionary can be transformed into another dictionary type, even if the new dictionary type does not have the same [type ID](#) as the old type, but only if the key and value types are compatible. For example, `dictionary<int, string>` can be transformed into `dictionary<long, string>`, regardless of the names given to the dictionary types.

Caution is required when changing the key type of a dictionary, because the default transformation of keys could result in duplication. For example, if the key type changes from `int` to `short`, any `int` value outside the range of `short` results in the key being initialized to a default value (namely zero). If zero is already used as a key in the dictionary, or another out-of-range key is encountered, then a duplication

occurs. The transformation handles key duplication by removing the duplicate element from the transformed dictionary. (Custom migration can be useful in these situations if the default behavior is not acceptable.)

### Structure

A `struct` type can only be transformed into another `struct` type with the same [type ID](#). Data members are transformed as appropriate for their types.

### Proxy

A proxy value can be transformed into another proxy type, or into `string`. Transformation into another proxy type is done with the same semantics as in a language mapping: if the new type does not match the old type, then the new type must be a base type of the old type (that is, the proxy is widened).

### Class

A `class` type can only be transformed into another `class` type with the same [type ID](#). A data member of a `class` type is allowed to be widened to a base type. Data members are transformed as appropriate for their types. See [Transforming Objects](#) for more information on transforming classes.

## Default Values for Automatic Migration

Data types are initialized with default values, as shown.

| Type        | Default Value                            |
|-------------|------------------------------------------|
| Boolean     | <code>false</code>                       |
| Numeric     | Zero (0)                                 |
| String      | Empty string                             |
| Enumeration | The first enumerator                     |
| Sequence    | Empty sequence                           |
| Dictionary  | Empty dictionary                         |
| Struct      | Data members are initialized recursively |
| Proxy       | Nil                                      |
| Class       | Nil                                      |

## Running an Automatic Migration

In order to use automatic transformation, we need to supply the following information to `transformdb`:

- The old and new Slice definitions
- The old and new types for the database key and value
- The database environment directory, the database file name, and the name of a new database environment directory to hold the transformed database

Here is an example of a `transformdb` command:

```
$ transformdb --old old/MyApp.ice --new new/MyApp.ice \
--key int,string --value ::Employee db emp.db newdb
```

Briefly, the `--old` and `--new` options specify the old and new Slice definitions, respectively. These options can be specified as many times as necessary in order to load all of the relevant definitions. The `--key` option indicates that the database key is evolving from `int` to `string`. The `--value` option specifies that `::Employee` is used as the database value type in both old and new type definitions, and therefore only needs to be specified once. Finally, we provide the pathname of the database environment directory (`db`), the file name of the database (`emp.db`), and the pathname of the database environment directory for the transformed database (`newdb`).

## Custom Database Migration

Custom migration is useful when your types have changed in ways that make [automatic migration](#) difficult or impossible. It is also convenient to use custom migration when you have complex initialization requirements for new types or new data members, because custom migration enables you to perform many of the same tasks that would otherwise require you to write a throwaway program.

Custom migration operates in conjunction with automatic migration, allowing you to inject your own transformation rules at well-defined intercept points in the automatic migration process. These rules are called *transformation descriptors*, and are written in XML.

On this page:

- [Simple Example of Custom Migration](#)
- [Overview of Transformation Descriptors](#)
- [Transformation Flow of Execution](#)
- [Transformation Descriptor Scopes](#)
- [Guidelines for Transformation Descriptors](#)

### Simple Example of Custom Migration

We can use a simple example to demonstrate the utility of custom migration. Suppose our application uses a [Freeze map](#) whose key type is `string` and whose value type is an enumeration, defined as follows:

```
Slice
```

```
enum BigThree { Ford, DaimlerChrysler, GeneralMotors };
```

We now wish to rename the enumerator `DaimlerChrysler`, as shown in our new definition:

```
Slice
```

```
enum BigThree { Ford, Daimler, GeneralMotors };
```

According to the [rules for default transformations](#), all occurrences of the `DaimlerChrysler` enumerator would be transformed into `Ford`, because `Chrysler` no longer exists in the new definition and therefore the default value `Ford` is used instead.

To remedy this situation, we use the following transformation descriptors:

```
XML
```

```
<transformdb>
 <database key="string" value="::BigThree">
 <record>
 <if test="oldvalue == ::Old::DaimlerChrysler">
 <set target="newvalue" value="::New::Daimler"/>
 </if>
 </record>
 </database>
</transformdb>
```

When executed, these descriptors convert occurrences of `DaimlerChrysler` in the old type system into `Daimler` in the transformed database's new type system.

## Overview of Transformation Descriptors

As we saw in the previous example, FreezeScript [transformation descriptors](#) are written in XML.

A transformation descriptor file has a well-defined structure. The top-level descriptor in the file is `<transformdb>`. A `<database>` descriptor must be present within `<transformdb>` to define the key and value types used by the database. Inside `<database>`, the `<record>` descriptor triggers the transformation process.

During transformation, type-specific actions are supported by the `<transform>` and `<init>` descriptors, both of which are children of `<transformdb>`. One `<transform>` descriptor and one `<init>` descriptor may be defined for each type in the new Slice definitions. Each time `transformdb` creates a new instance of a type, it executes the `<init>` descriptor for that type, if one is defined. Similarly, each time `transformdb` transforms an instance of an old type into a new type, the `<transform>` descriptor for the new type is executed.

The `<database>`, `<record>`, `<transform>`, and `<init>` descriptors may contain general-purpose action descriptors such as `<if>`, `<set>`, and `<echo>`. These actions resemble statements in programming languages like C++ and Java, in that they are executed in the order of definition and their effects are cumulative. Actions can make use of the [expression language](#) that should look familiar to C++ and Java programmers.

## Transformation Flow of Execution

The transformation descriptors are executed as follows:

- `<database>` is executed first. Each child descriptor of `<database>` is executed in the order of definition. If a `<record>` descriptor is present, database transformation occurs at that point. Any child descriptors of `<database>` that follow `<record>` are not executed until transformation completes.
- During transformation of each record, `transformdb` creates instances of the new key and value types, which includes the execution of the `<init>` descriptors for those types. Next, the old key and value are transformed into the new key and value, in the following manner:
  1. Locate the `<transform>` descriptor for the type.
  2. If no descriptor is found, or the descriptor exists and it does not preclude default transformation, then transform the data as in [automatic database migration](#).
  3. If the `<transform>` descriptor exists, execute it.
  4. Finally, execute the child descriptors of `<record>`.

## Transformation Descriptor Scopes

The `<database>` descriptor creates a global scope, allowing child descriptors of `<database>` to define symbols that are accessible in any descriptor.

In order for a global symbol to be available to a `<transform>` or `<init>` descriptor, the symbol must be defined before the `<record>` descriptor is executed.

Furthermore, certain other descriptors create local scopes that exist only for the duration of the descriptor's execution. For example, the `<transform>` descriptor creates a local scope and defines the symbols `old` and `new` to represent a value in its old and new forms. Child descriptors of `<transform>` can also define new symbols in the local scope, as long as those symbols do not clash with an existing symbol in that scope. It is legal to add a new symbol with the same name as a symbol in an outer scope, but the outer symbol will not be accessible during the descriptor's execution.

The global scope is useful in many situations. For example, suppose you want to track the number of times a certain value was encountered during transformation. This can be accomplished as shown below:

## XML

```

<transformdb>
 <database key="string" value="::Ice::Identity">
 <define name="categoryCount" type="int" value="0"/>
 <record/>
 <echo message="categoryCount = " value="categoryCount"/>
 </database>
 <transform type="::Ice::Identity">
 <if test="new.category == 'Accounting'">
 <set target="categoryCount" value="categoryCount + 1"/>
 </if>
 </transform>
</transformdb>

```

In this example, the `<define>` descriptor introduces the symbol `categoryCount` into the global scope, defining it as type `int` with an initial value of zero. Next, the `<record>` descriptor causes transformation to proceed. Each occurrence of the type `Ice::Identity` causes its `<transform>` descriptor to be executed, which examines the `category` member and increases `categoryCount` if necessary. Finally, after transformation completes, the `<echo>` descriptor displays the final value of `categoryCount`.

To reinforce the relationships between descriptors and scopes, consider the following diagram. Several descriptors are shown, including the symbols they define in their local scopes. In this example, the `<iterate>` descriptor has a dictionary target and therefore the default symbol for the element value, `value`, hides the symbol of the same name in the parent `<init>` descriptor's scope.

This situation can be avoided by assigning a different symbol name to the element value.

In addition to symbols in the `<iterate>` scope, child descriptors of `<iterate>` can also refer to symbols from the `<init>` and `<database>` scopes.

*Relationship between descriptors and scopes.*

### Guidelines for Transformation Descriptors

There are three points at which you can intercept the transformation process: when transforming a record (`<record>`), when transforming an instance of a type (`<transform>`), and when creating an instance of a type (`<init>`).

In general, `<record>` is used when your modifications require access to both the key and value of the record. For example, if the database key is needed as a factor in an equation, or to identify an element in a dictionary, then `<record>` is the only descriptor in which this type of modification is possible. The `<record>` descriptor is also convenient to use when the number of changes to be made is small, and does not warrant the effort of writing separate `<transform>` or `<init>` descriptors.

The `<transform>` descriptor has a more limited scope than `<record>`. It is used when changes must potentially be made to all instances of a type (regardless of the context in which that type is used) and access to the old value is necessary. The `<transform>` descriptor does not have access to the database key and value, therefore decisions can only be made based on the old and new instances of the type in question.

Finally, the `<init>` descriptor is useful when access to the old instance is not required in order to properly initialize a type. In most cases, this activity could also be performed by a `<transform>` descriptor that simply ignored the old instance, so `<init>` may seem redundant. However, there is one situation where `<init>` is required: when it is necessary to initialize an instance of a type that is introduced by the new Slice definitions. Since there are no instances of this type in the current database, a `<transform>` descriptor for that type would never be executed.

## FreezeScript Transformation XML Reference

This page describes the XML elements comprising the FreezeScript transformation descriptors.

On this page:

- [<transformdb> Descriptor Element](#)
- [<database> Descriptor Element](#)
- [<record> Descriptor Element](#)
- [<transform> Descriptor Element](#)
- [<init> Descriptor Element](#)
- [<iterate> Descriptor Element](#)
- [<if> Descriptor Element](#)
- [<set> Descriptor Element](#)
- [<add> Descriptor Element](#)
- [<define> Descriptor Element](#)
- [<remove> Descriptor Element](#)
- [<fail> Descriptor Element](#)
- [<delete> Descriptor Element](#)
- [<echo> Descriptor Element](#)

### <transformdb> Descriptor Element

The top-level descriptor in a descriptor file. It requires at least one `<database>` descriptor, and supports any number of `<transform>` and `<init>` child descriptors. This descriptor has no attributes.

### <database> Descriptor Element

The attributes of this descriptor define the old and new key and value types for the database to be transformed, and optionally the name of the database to which these types apply. It supports any number of child descriptors, but at most one `<record>` descriptor. The `<database>` descriptor also creates a [global scope](#) for user-defined symbols.

The attributes supported by the `<database>` descriptor are described in the following table:

Name	Description
name	Specifies the name of the database defined by this descriptor. (Optional)
key	Specifies the Slice types of the old and new keys. If the types are the same, only one needs to be specified. Otherwise, the types are separated by a comma.
value	Specifies the Slice types of the old and new values. If the types are the same, only one needs to be specified. Otherwise, the types are separated by a comma.

As an example, consider the following `<database>` descriptor. In this case, the [Freeze map](#) to be transformed currently has key type `int` and value type `::Employee`, and is migrating to a key type of `string`:

**XML**

```
<database key="int,string" value="::Employee">
```

### <record> Descriptor Element

Commences the transformation. Child descriptors are executed for each record in the database, providing the user with an opportunity to examine the record's old key and value, and optionally modify the new key and value. Default transformations, as well as `<transform>` and `<init>` descriptors, are executed before the child descriptors. The `<record>` descriptor introduces the following symbols into a local scope: `oldkey`, `newkey`, `oldvalue`, `newvalue`, `facet`. These symbols are accessible to child descriptors, but not to `<transform>` or `<init>` descriptors. The `oldkey` and `oldvalue` symbols are read-only. The `facet` symbol is a string indicating the facet name of the object in the current record, and is only relevant for [Freeze evictor](#) databases.

Use caution when modifying database keys to ensure that duplicate keys do not occur. If a duplicate database key is encountered,

transformation fails immediately.

Note that database transformation only occurs if a `<record>` descriptor is present.

### `<transform>` Descriptor Element

Customizes the transformation for all instances of a type in the *new* Slice definitions. The children of this descriptor are executed after the optional [default transformation](#) has been performed. Only one `<transform>` descriptor can be specified for a type, but a `<transform>` descriptor is not required for every type. The symbols `old` and `new` are introduced into a local scope and represent the old and new values, respectively. The `old` symbol is read-only. The attributes supported by this descriptor are described in the following table:

Name	Description
<code>type</code>	Specifies the Slice <a href="#">type ID</a> for the type's new definition.
<code>default</code>	If <code>false</code> , no default transformation is performed on values of this type. If not specified, the default value is <code>true</code> .
<code>base</code>	This attribute determines whether <code>&lt;transform&gt;</code> descriptors of base class types are executed. If <code>true</code> , the <code>&lt;transform&gt;</code> descriptor of the immediate base class is invoked. If no descriptor is found for the immediate base class, the class hierarchy is searched until a descriptor is found. The execution of any base class descriptors occurs after execution of this descriptor's children. If not specified, the default value is <code>true</code> .
<code>rename</code>	Indicates that a type in the old Slice definitions has been renamed to the new type identified by the <code>type</code> attribute. The value of this attribute is the type ID of the old Slice definition. Specifying this attribute relaxes the <a href="#">strict compatibility rules</a> for <code>enum</code> , <code>struct</code> and <code>class</code> types.

Below is an example of a `<transform>` descriptor that initializes a new data member:

```

XML

<transform type="::Product">
 <set target="new.salePrice" value="old.listPrice * old.discount"/>
</transform>
```

For class types, `transformdb` first attempts to locate a `<transform>` descriptor for the object's most-derived type. If no descriptor is found, `transformdb` proceeds up the class hierarchy in an attempt to find a descriptor. The base object type, `Object`, is the root of every class hierarchy and is included in the search for descriptors. It is therefore possible to define a `<transform>` descriptor for type `Object`, which will be invoked for every class instance.

Note that `<transform>` descriptors are executed recursively. For example, consider the following Slice definitions:

```

Slice

struct Inner {
 int sum;
};
struct Outer {
 Inner i;
};
```

When `transformdb` is performing the default transformation on a value of type `Outer`, it recursively performs the default transformation on the `Inner` member, then executes the `<transform>` descriptor for `Inner`, and finally executes the `<transform>` descriptor for `Outer`. However, if default transformation is disabled for `Outer`, then no transformation is performed on the `Inner` member and therefore the `<transform>` descriptor for `Inner` is not executed.

### `<init>` Descriptor Element

Defines custom initialization rules for all instances of a type in the new Slice definitions. Child descriptors are executed each time the type is instantiated. The typical use case for this descriptor is for types that have been introduced in the new Slice definitions and whose instances require default values different than what `transformdb` supplies. The symbol `value` is introduced into a local scope to represent the instance. The attributes supported by this descriptor are described in the following table:

Name	Description
<code>type</code>	Specifies the Slice <code>type</code> ID of the type's new definition.

Here is a simple example of an `<init>` descriptor:

**XML**

```
<init type="::Player">
 <set target="value.currency" value="100"/>
</init>
```

Note that, like `<transform>`, `<init>` descriptors are executed recursively. For example, if an `<init>` descriptor is defined for a `struct` type, the `<init>` descriptors of the `struct`'s members are executed before the `struct`'s descriptor.

### `<iterate>` Descriptor Element

Iterates over a dictionary or sequence, executing child descriptors for each element. The symbol names selected to represent the element information may conflict with existing symbols in the enclosing scope, in which case those outer symbols are not accessible to child descriptors. The attributes supported by this descriptor are described in the following table:

Name	Description
<code>target</code>	The sequence or dictionary.
<code>index</code>	The symbol name used for the sequence index. If not specified, the default symbol is <code>i</code> .
<code>element</code>	The symbol name used for the sequence element. If not specified, the default symbol is <code>elem</code> .
<code>key</code>	The symbol name used for the dictionary key. If not specified, the default symbol is <code>key</code> .
<code>value</code>	The symbol name used for the dictionary value. If not specified, the default symbol is <code>value</code> .

Shown below is an example of an `<iterate>` descriptor that sets the new data member `reviewSalary` to `true` if the employee's salary is greater than \$3000:

**XML**

```
<iterate target="new.employeeMap" key="id" value="emp">
 <if test="emp.salary > 3000">
 <set target="emp.reviewSalary" value="true"/>
 </if>
</iterate>
```

### `<if>` Descriptor Element

Conditionally executes child descriptors. The attributes supported by this descriptor are described in the following table:

Name	Description
------	-------------

test	A boolean expression.
------	-----------------------

Child descriptors are executed if the expression in `test` evaluates to true.

### <set> Descriptor Element

Modifies a value. The `value` and `type` attributes are mutually exclusive. If `target` denotes a dictionary element, that element must already exist (i.e., `<set>` cannot be used to add an element to a dictionary). The attributes supported by this descriptor are described in the following table:

Name	Description
<code>target</code>	An <a href="#">expression</a> that must select a modifiable value.
<code>value</code>	An <a href="#">expression</a> that must evaluate to a value compatible with the target's type.
<code>type</code>	If specified, set the target to be an instance of the given Slice class. The value is a <a href="#">type ID</a> from the new Slice definitions. The class must be compatible with the target's type.
<code>length</code>	An integer expression representing the desired new length of a sequence. If the new length is less than the current size of the sequence, elements are removed from the end of the sequence. If the new length is greater than the current size, new elements are added to the end of the sequence. If <code>value</code> or <code>type</code> is also specified, it is used to initialize each new element.
<code>convert</code>	If <code>true</code> , additional type conversions are supported: between integer and floating point, and between integer and enumeration. Transformation fails immediately if a range error occurs. If not specified, the default value is <code>false</code> .

The `<set>` descriptor below modifies a member of a dictionary element:

XML
<pre>&lt;set target="new.parts['P105J3'].cost" value="new.parts['P105J3'].cost * 1.05"/&gt;</pre>

This `<set>` descriptor adds an element to a sequence and initializes its value:

XML
<pre>&lt;set target="new.partsList" length="new.partsList.length + 1" value="'P105J3'"/&gt;</pre>

As another example, the following `<set>` descriptor changes the value of an enumeration:

XML
<pre>&lt;set target="new.ingredient" value="::New::Apple"/&gt;</pre>

Notice in this example that the value refers to a [symbol](#) in the new Slice definitions.

### <add> Descriptor Element

Adds a new element to a sequence or dictionary. It is legal to add an element while traversing the sequence or dictionary using `<iterate>`, however the traversal order after the addition is undefined. The `key` and `index` attributes are mutually exclusive, as are the `value` and `type` attributes. If neither `value` nor `type` is specified, the new element is initialized with a default value. The attributes supported by this

descriptor are described in the following table:

Name	Description
target	An <a href="#">expression</a> that must select a modifiable sequence or dictionary.
key	An <a href="#">expression</a> that must evaluate to a value compatible with the target dictionary's key type.
index	An <a href="#">expression</a> that must evaluate to an integer value representing the insertion position. The new element is inserted before <code>index</code> . The value must not exceed the length of the target sequence.
value	An <a href="#">expression</a> that must evaluate to a value compatible with the target dictionary's value type, or the target sequence's element type.
type	If specified, set the target value or element to be an instance of the given Slice class. The value is a <a href="#">type ID</a> from the new Slice definitions. The class must be compatible with the target dictionary's value type, or the target sequence's element type.
convert	If <code>true</code> , additional type conversions are supported: between integer and floating point, and between integer and enumeration. Transformation fails immediately if a range error occurs. If not specified, the default value is <code>false</code> .

Below is an example of an `<add>` descriptor that adds a new dictionary element and then initializes its member:

**XML**

```

<add target="new.parts" key="'P105J4'"/>
<set target="new.parts['P105J4'].cost" value="3.15"/>

```

### `<define>` Descriptor Element

Defines a new symbol in the current scope. The attributes supported by this descriptor are described in the following table:

Name	Description
name	The name of the new symbol. An error occurs if the name matches an existing symbol in the current scope.
type	The name of the symbol's formal Slice type. For user-defined types, the name should be prefixed with <code>::Old</code> or <code>::New</code> to indicate the source of the type. The prefix can be omitted for primitive types.
value	An <a href="#">expression</a> that must evaluate to a value compatible with the symbol's type.
convert	If <code>true</code> , additional type conversions are supported: between integer and floating point, and between integer and enumeration. Execution fails immediately if a range error occurs. If not specified, the default value is <code>false</code> .

Below are two examples of the `<define>` descriptor. The first example defines the symbol `identity` to have type `Ice::Identity`, and proceeds to initialize its members using `<set>`:

**XML**

```

<define name="identity" type="::New::Ice::Identity"/>
<set target="identity.name" value="steve"/>
<set target="identity.category" value="Admin"/>

```

The second example uses the enumeration we first saw in our discussion of [custom database migration](#) to define the symbol `manufacturer` and assign it a default value:

## XML

```
<define name="manufacturer" type="::New::BigThree"
value="::New::Daimler"/>
```

**<remove> Descriptor Element**

Removes an element from a sequence or dictionary. It is legal to remove an element while traversing a sequence or dictionary using `<iterate>`, however the traversal order after removal is undefined. The attributes supported by this descriptor are described in the following table:

Name	Description
target	An <a href="#">expression</a> that must select a modifiable sequence or dictionary.
key	An <a href="#">expression</a> that must evaluate to a value compatible with the key type of the target dictionary.
index	An <a href="#">expression</a> that must evaluate to an integer value representing the index of the sequence element to be removed.

**<fail> Descriptor Element**

Causes transformation to fail immediately. If `test` is specified, transformation fails only if the [expression](#) evaluates to `true`. The attributes supported by this descriptor are described in the following table:

Name	Description
message	A message to display upon transformation failure.
test	A boolean <a href="#">expression</a> .

The following `<fail>` descriptor terminates the transformation if a range error is detected:

## XML

```
<fail message="range error occurred in ticket count!"
test="old.ticketCount > 32767"/>
```

**<delete> Descriptor Element**

Causes transformation of the current database record to cease, and removes the record from the transformed database. This descriptor has no attributes.

**<echo> Descriptor Element**

Displays values and informational messages. If no attributes are specified, only a newline is printed. The attributes supported by this descriptor are described in the following table:

Name	Description
message	A message to display.
value	An <a href="#">expression</a> . The value of the expression is displayed in a structured format.

Shown below is an `<echo>` descriptor that uses both `message` and `value` attributes:

**XML**

```
<if test="old.ticketCount > 32767">
 <echo message="deleting record with invalid ticket count: "
value="old.ticketCount" />
 <delete/>
</if>
```

- [Using transformdb on an Open Environment](#)

### Execution Modes for transformdb

The tool operates in one of three modes:

- Automatic migration
- Custom migration
- Analysis

The only difference between `automatic` and `custom` migration modes is the source of the transformation descriptors: for automatic migration, `transformdb` internally generates and executes a default set of descriptors, whereas for custom migration the user specifies an external file containing the transformation descriptors to be executed.

In analysis mode, `transformdb` creates a file containing the default transformation descriptors it would have used during automatic migration. You would normally review this file and possibly customize it prior to executing the tool again in its custom migration mode.

### Using Database Catalogs during Transformation

Freeze maintains schema information in a `catalog` for each database environment. If necessary, `transformdb` will use the catalog to determine the names of the databases in the environment, and to determine the key and value types of a particular database. There are two advantages to the tool's use of the catalog:

- Allows `transformdb` to operate on all of the databases in a single invocation
- Eliminates the need for you to specify type information for a database.

For example, you can use automatic migration to transform all of the databases at one time, as shown below:

```
$ transformdb [options] old-env new-env
```

Since we omitted the name of a database to be migrated, `transformdb` uses the catalog in the environment `old-env` to discover all of the databases and their types, generates default transformations for each database, and performs the migration. However, we must still ensure that `transformdb` has loaded the old and new Slice types used by *all* of the databases in the environment.

### Slice Options for transformdb

The tool supports the [standard command-line options](#) common to all Slice processors, with the exception of the include directory (`-I`) option. The options specific to `transformdb` are described below:

- `--old SLICE`  
`--new SLICE`  
Loads the old or new Slice definitions contained in the file `SLICE`. These options may be specified multiple times if several files must

be loaded. However, it is the user's responsibility to ensure that duplicate definitions do not occur (which is possible when two files are loaded that share a common include file). One strategy for avoiding duplicate definitions is to load a single Slice file that contains only `#include` statements for each of the Slice files to be loaded. No duplication is possible in this case if the included files use include guards correctly.

- `--include-old DIR`  
`--include-new DIR`  
Adds the directory `DIR` to the set of include paths for the old or new Slice definitions.

### Type Options for `transformdb`

In invocation modes for which `transformdb` requires that you define the types used by a database, you must specify one of the following options:

- `--key TYPE[ ,TYPE]`  
`--value TYPE[ ,TYPE]`  
Specifies the Slice type(s) of the database key and value. If the type does not change, then the type only needs to be specified once. Otherwise, the old type is specified first, followed by a comma and the new type. For example, the option `--key int, string` indicates that the database key is migrating from `int` to `string`. On the other hand, the option `--key int, int` indicates that the key type does not change, and could be given simply as `--key int`. Type changes are restricted to those allowed by the [compatibility rules](#), but custom migration provides additional flexibility.
- `-e`  
Indicates that a [Freeze evictor](#) database is being migrated. As a convenience, this option automatically sets the database key and value types to those appropriate for the Freeze evictor, and therefore the `--key` and `--value` options are not necessary. Specifically, the key type of a Freeze evictor database is `Ice::Identity`, and the value type is `Freeze::ObjectRecord`. The latter is defined in the Slice file `Freeze/EvictorStorage.ice`; however, this file does not need to be loaded into your old and new Slice definitions.

### General Options for `transformdb`

These options may be specified during analysis or migration, as indicated below:

- `-i`  
Requests that `transformdb` ignore type changes that violate the [compatibility rules](#). If this option is not specified, `transformdb` fails immediately if such a violation occurs. With this option, a warning is displayed but `transformdb` continues the requested action. The `-i` option can be specified in analysis or automatic migration modes.
- `-p`  
During migration, this option requests that `transformdb` [purge object instances](#) whose type is no longer found in the new Slice definitions.
- `-c`  
Use catastrophic recovery on the old Berkeley DB database environment prior to migration.
- `-w`  
Suppress duplicate warnings during migration. This option is especially useful to minimize diagnostic messages when `transformdb` would otherwise emit the same warning many times, such as when it detects the same issue in every record of a database.

### Database Arguments for `transformdb`

In addition to the options described above, `transformdb` accepts as many as three arguments that specify the names of databases and database environments:

- `dbenv`  
The pathname of the old database environment directory.
- `db`  
The name of an existing database file in `dbenv`. `transformdb` never modifies this database.
- `newdbenv`  
The pathname of the database environment directory to contain the transformed database(s). This directory must exist and must not contain an existing database whose name matches a database being migrated.

## Performing an Automatic Migration

You can use `transformdb` to automatically migrate one database or all databases in an environment.

### Migrating a Single Database

Use the following command line to migrate one database:

```
$ transformdb [slice-opts] [type-opts] [gen-opts] dbenv db newdbenv
```

If you omit `type-opts`, the tool obtains type information for database `db` from the `catalog`. For example, consider the following command, which uses automatic migration to transform a database with a key type of `int` and value type of `string` into a database with the same key type and a value type of `long`:

```
$ transformdb --key int --value string,long dbhome data.db newdbhome
```

Note that we did not need to specify the Slice options `--old` or `--new` because our key and value types are primitives. Upon successful completion, the file `newdbhome/data.db` contains our transformed database.

### Migrating All Databases

To migrate all databases in the environment, use a command like the one shown below:

```
$ transformdb [slice-opts] [gen-opts] dbenv newdbenv
```

In this invocation mode, you must ensure that `transformdb` has loaded the old and new Slice definitions for all of the types it will encounter among the databases in the environment.

## Performing a Migration Analysis

Custom migration is a two-step process: you first write the transformation descriptors, and then execute them to transform a database. To assist you in the process of creating a descriptor file, `transformdb` can generate a default set of transformation descriptors by comparing your old and new Slice definitions. This feature is enabled by specifying the following option:

- `-o FILE`  
Specifies the descriptor file `FILE` to be created during analysis. No migration occurs in this invocation mode.

### Generated File

The generated file contains a `<transform>` descriptor for each type that appears in both old and new Slice definitions, and an `<init>` descriptor for types that appear only in the new Slice definitions. In most cases, these descriptors are empty. However, they can contain XML comments describing changes detected by `transformdb` that may require action on your part.

For example, let us revisit the enumeration we defined in our discussion of [custom database migration](#):

```
Slice
```

```
enum BigThree { Ford, DaimlerChrysler, GeneralMotors };
```

This enumeration has evolved into the one shown below. In particular, the `DaimlerChrysler` enumerator has been renamed to reflect a corporate name change:

```
Slice
```

```
enum BigThree { Ford, Daimler, GeneralMotors };
```

Next we run `transformdb` in analysis mode:

```
$ transformdb --old old/BigThree.ice --new new/BigThree.ice --key string \
--value ::BigThree -o transform.xml
```

The generated file `transform.xml` contains the following descriptor for the enumeration `BigThree`:

```
XML
```

```
<transform type="::BigThree">
 <!-- NOTICE: enumerator `DaimlerChrysler' has been removed -->
</transform>
```

The comment indicates that enumerator `DaimlerChrysler` is no longer present in the new definition, reminding us that we need to add logic in this `<transform>` descriptor to change all occurrences of `DaimlerChrysler` to `Daimler`.

The descriptor file generated by `transformdb` is well-formed and does not require any manual intervention prior to being executed. However, executing an unmodified descriptor file is simply the equivalent of using automatic migration.

### Invocation Modes

The sample command line shown in the previous section specified the key and value types of the database explicitly. This invocation mode has the following general form:

```
$ transformdb [slice-opts] [type-opts] [gen-opts] -o FILE
```

Upon successful completion, the generated file contains a `<database>` descriptor that records the type information supplied by `type-opts`, in addition to the `<transform>` and `<init>` descriptors described earlier.

For your convenience, you can omit `type-opts` and allow `transformdb` to obtain type information from the catalog instead:

```
$ transformdb [slice-opts] [gen-opts] -o FILE dbenv
```

In this case, the generated file contains a `<database>` descriptor for each database in the catalog. Note that in this invocation mode, `transformdb` must assume that the names of the database key and value types have not changed, since the only type information available is the catalog in the old database environment. If the tool is unable to locate a new `Slice` definition for a database's key or value type, it emits a warning message and generates a placeholder value in the output file that you must modify prior to migration.

## Performing a Custom Migration

After preparing a descriptor file, either by writing one completely yourself, or modifying one generated by the analysis mode described in the previous section, you are ready to migrate a database. One additional option is provided for migration:

- `-f FILE`  
Execute the transformation descriptors in the file `FILE`.

To transform one database, use the following command:

```
$ transformdb [slice-opts] [gen-opts] -f FILE dbenv db newdbenv
```

The tool searches the descriptor file for a `<database>` descriptor whose `name` attribute matches `db`. If no match is found, it searches for a `<database>` descriptor that does not have a `name` attribute.

If you want to transform all databases in the environment, you can omit the database name:

```
$ transformdb [slice-opts] [gen-opts] -f FILE dbenv newdbenv
```

In this case, the descriptor file must contain a `<database>` element for each database in the environment.

Continuing our enumeration example from the analysis discussion above, assume we have modified `transform.xml` to convert the `Chrysler` enumerator, and are now ready to execute the transformation:

```
$ transformdb --old old/BigThree.ice --new new/BigThree.ice -f
transform.xml \
dbhome bigthree.db newdbhome
```

### `transformdb` Usage Strategies

If it becomes necessary for you to transform a Freeze database, we generally recommend that you attempt to use automatic migration first, unless you already know that custom migration is necessary. Since transformation is a non-destructive process, there is no harm in attempting an automatic migration, and it is a good way to perform a sanity check on your `transformdb` arguments (for example, to ensure that all the necessary Slice files are being loaded), as well as on the database itself. If `transformdb` detects any incompatible type changes, it displays an error message for each incompatible change and terminates without doing any transformation. In this case, you may want to run `transformdb` again with the `-i` option, which ignores incompatible changes and causes transformation to proceed.

Pay careful attention to any warnings that `transformdb` emits, as these may indicate the need for using custom migration. For example, if we had attempted to transform the database containing the `BigThree` enumeration from previous sections using automatic migration, any occurrences of the `Chrysler` enumerator would display the following warning:

```
warning: unable to convert 'Chrysler' to ::BigThree
```

If custom migration appears to be necessary, use analysis to generate a default descriptor file, then review it for `NOTICE` comments and edit as necessary. Liberal use of the `<echo>` descriptor can be beneficial when testing your descriptor file, especially from within the `<record>` descriptor where you can display old and new keys and values.

## Transforming Objects

The polymorphic nature of Slice classes can cause problems for database migration. As an example, the Slice parser can ensure that a set of Slice definitions loaded into `transformdb` is complete for all types but classes (and exceptions, but we ignore those because they are not persistent). `transformdb` cannot know that a database may contain instances of a subclass that is derived from one of the loaded classes but whose definition is not loaded. Alternatively, the type of a class instance may have been renamed and cannot be found in the new Slice definitions.

By default, these situations result in immediate transformation failure. However, the `-p` option is a (potentially drastic) way to handle these situations: if a class instance has no equivalent in the new Slice definitions and this option is specified, `transformdb` removes the instance any way it can. If the instance appears in a sequence or dictionary element, that element is removed. Otherwise, the database record containing the instance is deleted.

Now, the case of a class type being renamed is handled easily enough using custom migration and the `rename` attribute of the `<transform>` descriptor. However, there are legitimate cases where the destructive nature of the `-p` option can be useful. For example, if a class type has been removed and it is simply easier to start with a database that is guaranteed not to contain any instances of that type, then the `-p` option may simplify the broader migration effort.

This is another situation in which running an automatic migration first can help point out the trouble spots in a potential migration. Using the `-p` option, `transformdb` emits a warning about the missing class type and continues, rather than halting at the first occurrence, enabling you to discover whether you have forgotten to load some Slice definitions, or need to rename a type.

## Using `transformdb` on an Open Environment

It is possible to use `transformdb` to migrate databases in an environment that is currently open by another process, but if you are not careful you can easily corrupt the environment and cause the other process to fail. To avoid such problems, you must configure both `transformdb` and the other process to set `Freeze.DbEnv.env-name.DbPrivate=0`. This property has a default value of one, therefore you must explicitly set it to zero. Note that `transformdb` makes no changes to the existing database environment, but it requires exclusive access to the new database environment until transformation is complete.

If you run `transformdb` on an open environment but neglect to set `Freeze.DbEnv.env-name.DbPrivate=0`, you can expect `transformdb` to terminate immediately with an error message stating that the database environment is locked. Before running `transformdb` on an open environment, we strongly recommend that you first verify that the other process was also configured with `Freeze.DbEnv.env-name.DbPrivate=0`.

## Inspecting a Freeze Database

The FreezeScript tool `dumpdb` is used to examine a Freeze database. Its simplest invocation displays every record of the database, but the tool also supports more selective activities. In fact, `dumpdb` supports a scripted mode that shares many of the same XML descriptors as `transformdb`, enabling sophisticated filtering and reporting.

### Topics

- [Using dumpdb](#)

## Using dumpdb

This page describes `dumpdb` and provides advice on how to best use it.

On this page:

- [Overview of Inspection Descriptors](#)
- [Inspection Flow of Execution](#)
- [Inspection Descriptor Scopes](#)

  - [Dump Selected Records](#)
  - [Creating a Sample Descriptor File](#)
  - [Executing a Descriptor File](#)
  - [Examine the Catalog](#)
- [Using dumpdb on an Open Environment](#)

### Overview of Inspection Descriptors

`dumpdb` can read [descriptors](#) from an XML file. A `dumpdb` descriptor file has a well-defined structure. The top-level descriptor in the file is `<dumpdb>`. A `<database>` descriptor must be present within `<dumpdb>` to define the key and value types used by the database. Inside `<database>`, the `<record>` descriptor triggers database traversal. Shown below is an example that demonstrates the structure of a minimal descriptor file:

**XML**

```

<dumpdb>
 <database key="string" value="::Employee">
 <record>
 <echo message="Key: " value="key"/>
 <echo message="Value: " value="value"/>
 </record>
 </database>
</dumpdb>

```

During traversal, type-specific actions are supported by the `<dump>` descriptor, which is a child of `<dumpdb>`. One `<dump>` descriptor may be defined for each type in the Slice definitions. Each time `dumpdb` encounters an instance of a type, the `<dump>` descriptor for that type is executed.

The `<database>`, `<record>`, and `<dump>` descriptors may contain general-purpose action descriptors such as `<if>` and `<echo>`. These actions resemble statements in programming languages like C++ and Java, in that they are executed in the order of definition and their effects are cumulative. Actions can make use of the FreezeScript [expression language](#).

Although `dumpdb` descriptors are not allowed to modify the database, they can still define local symbols for scripting purposes. Once a symbol is defined by the `<define>` descriptor, other descriptors such as `<set>`, `<add>`, and `<remove>` can be used to manipulate the symbol's value.

### Inspection Flow of Execution

The descriptors are executed as follows:

- `<database>` is executed first. Each child descriptor of `<database>` is executed in the order of definition. If a `<record>` descriptor is present, database traversal occurs at that point. Any child descriptors of `<database>` that follow `<record>` are not executed until traversal completes.
- For each record, `dumpdb` interprets the key and value, invoking `<dump>` descriptors for each type it encounters. For example, if the value type of the database is a `struct`, then `dumpdb` first attempts to invoke a `<dump>` descriptor for the structure type, and then recursively interprets the structure's members in the same fashion.

## Inspection Descriptor Scopes

The `<database>` descriptor creates a global scope, allowing child descriptors of `<database>` to define symbols that are accessible in any descriptor.

In order for a global symbol to be available to a `<dump>` descriptor, the symbol must be defined before the `<record>` descriptor is executed.

Furthermore, certain other descriptors create local scopes that exist only for the duration of the descriptor's execution. For example, the `<dump>` descriptor creates a local scope and defines the symbol `value` to represent a value of the specified type. Child descriptors of `<dump>` can also define new symbols in the local scope, as long as those symbols do not clash with an existing symbol in that scope. It is legal to add a new symbol with the same name as a symbol in an outer scope, but the outer symbol will not be accessible during the descriptor's execution.

The global scope is useful in many situations. For example, suppose you want to track the number of times a certain value was encountered during database traversal. This can be accomplished as shown below:

**XML**

```
<dumpdb>
 <database key="string" value="::Ice::Identity">
 <define name="categoryCount" type="int" value="0"/>
 <record/>
 <echo message="categoryCount = " value="categoryCount"/>
 </database>
 <dump type="::Ice::Identity">
 <if test="value.category == `Accounting'">
 <set target="categoryCount" value="categoryCount + 1"/>
 </if>
 </dump>
</dumpdb>
```

In this example, the `<define>` descriptor introduces the symbol `categoryCount` into the global scope, defining it as type `int` with an initial value of zero. Next, the `<record>` descriptor causes traversal to proceed. Each occurrence of the type `Ice::Identity` causes its `<dump>` descriptor to be executed, which examines the `category` member and increases `categoryCount` if necessary. Finally, after traversal completes, the `<echo>` descriptor displays the final value of `categoryCount`.

To reinforce the relationships between descriptors and scopes, consider the diagram in the figure below. Several descriptors are shown, including the symbols they define in their local scopes. In this example, the `<iterate>` descriptor has a dictionary target and therefore the default symbol for the element value, `value`, hides the symbol of the same name in the parent `<dump>` descriptor's scope.

This situation can be avoided by assigning a different symbol name to the element value.

In addition to symbols in the `<iterate>` scope, child descriptors of `<iterate>` can also refer to symbols from the `<dump>` and `<databases>` scopes.

Relationship between descriptors and scopes.

### Command Line Options for `dumpdb`

The tool supports the [standard command-line options](#) common to all Slice processors listed. The options specific to `dumpdb` are described below:

- `--load SLICE`  
Loads the Slice definitions contained in the file `SLICE`. This option may be specified multiple times if several files must be loaded. However, it is the user's responsibility to ensure that duplicate definitions do not occur (which is possible when two files are loaded that share a common include file). One strategy for avoiding duplicate definitions is to load a single Slice file that contains only `#include` statements for each of the Slice files to be loaded. No duplication is possible in this case if the included files use include guards correctly.
- `--key TYPE`  
`--value TYPE`  
Specifies the Slice type of the database key and value. If these options are not specified, and the `-e` option is not used, `dumpdb` obtains type information from the [Freeze catalog](#).
- `-e`  
Indicates that a [Freeze evictor](#) database is being examined. As a convenience, this option automatically sets the database key and value types to those appropriate for the Freeze evictor, and therefore the `--key` and `--value` options are not necessary. Specifically, the key type of a Freeze evictor database is `Ice::Identity`, and the value type is `Freeze::ObjectRecord`. The latter is defined in the Slice file `Freeze/EvictorStorage.ice`, however this file does not need to be explicitly loaded. If this option is not specified, and the `--key` and `--value` options are not used, `dumpdb` obtains type information from the [Freeze catalog](#).
- `-o FILE`  
Create a file named `FILE` containing sample descriptors for the loaded Slice definitions. If type information is not specified, `dumpdb` obtains it from the [Freeze catalog](#). If the `--select` option is used, its expression is included in the sample descriptors. Database traversal does not occur when the `-o` option is used.
- `-f FILE`  
Execute the descriptors in the file named `FILE`. The file's `<database>` descriptor specifies the key and value types; therefore it is not necessary to supply type information.
- `--select EXPR`  
Only display those records for which the [expression](#) `EXPR` is true. The expression can refer to the symbols `key` and `value`.

- `-c, --catalog`  
Display information about the databases in an environment, or about a particular database. This option presents the type information contained in the [Freeze catalog](#).

### Database Arguments for `dumpdb`

If `dumpdb` is invoked to examine a database, it requires two arguments:

- `dbenv`  
The pathname of the database environment directory.
- `db`  
The name of the database file. `dumpdb` opens this database as read-only, and traversal occurs within a transaction.

To display [catalog](#) information using the `-c` option, the database environment directory `dbenv` is required. If the database file argument `db` is omitted, `dumpdb` displays information about every database in the catalog.

### `dumpdb` Use Cases

The [command line options](#) support several modes of operation:

- Dump an entire database.
- Dump selected records of a database.
- Emit a sample descriptor file.
- Execute a descriptor file.
- Examine the catalog.

These use cases are described in the following sections.

#### ***Dump an Entire Database***

The simplest way to examine a database with `dumpdb` is to dump its entire contents. You must specify the database key and value types, load the necessary Slice definitions, and supply the names of the database environment directory and database file. For example, this command dumps a Freeze map database whose key type is `string` and value type is `Employee`:

```
$ dumpdb --key string --value ::Employee --load Employee.ice db emp.db
```

As a convenience, you may omit the key and value types, in which case `dumpdb` obtains them from the [catalog](#):

```
$ dumpdb --load Employee.ice db emp.db
```

#### ***Dump Selected Records***

If only certain records are of interest to you, the `--select` option provides a convenient way to filter the output of `dumpdb` using an [expression](#). In the following example, we select employees from the accounting department:

```
$ dumpdb --load Employee.ice --select "value.dept == 'Accounting'" db
emp.db
```

In cases where the database records contain polymorphic class instances, you must be careful to specify an expression that can be successfully evaluated against all records. For example, `dumpdb` fails immediately if the expression refers to a data member that does not exist in the class instance. The safest way to write an expression in this case is to check the type of the class instance before referring to any

of its data members.

In the example below, we assume that a Freeze evictor database contains instances of various classes in a class hierarchy, and we are only interested in instances of `Manager` whose employee count is greater than 10:

```
$ dumpdb -e --load Employee.ice \
--select "value.servant.ice_id == '::Manager' and
value.servant.group.length > 10" \
db emp.db
```

Alternatively, if `Manager` has derived classes, then the expression can be written in a different way so that instances of `Manager` and any of its derived classes are considered:

```
$ dumpdb -e --load Employee.ice \
--select "value.servant.ice_isA('::Manager') and
value.servant.group.length > 10" \
db emp.db
```

### Creating a Sample Descriptor File

If you require more sophisticated filtering or scripting capabilities, then you must use a descriptor file. The easiest way to get started with a descriptor file is to generate a template using `dumpdb`:

```
$ dumpdb --key string --value ::Employee --load Employee.ice -o dump.xml
```

The output file `dump.xml` is complete and can be executed immediately if desired, but typically the file is used as a starting point for further customization. Again, you may omit the key and value types by specifying the database instead:

```
$ dumpdb --load Employee.ice -o dump.xml db emp.db
```

If the `--select` option is specified, its expression is included in the generated `<record>` descriptor as the value of the `test` attribute in an `<if>` descriptor.

`dumpdb` terminates immediately after generating the output file.

### Executing a Descriptor File

Use the `-f` option when you are ready to execute a descriptor file. For example, we can execute the descriptor we generated in the previous section using this command:

```
$ dumpdb -f dump.xml --load Employee.ice db emp.db
```

### Examine the Catalog

The `-c` option displays the contents of the database environment's `catalog`:

```
$ dumpdb -c db
```

The output indicates whether each database in the environment is associated with an evictor or a map. For maps, the output includes the key and value types.

If you specify the name of a database, `dumpdb` only displays the type information for that database:

```
$ dumpdb -c db emp.db
```

### Using `dumpdb` on an Open Environment

It is possible to use `dumpdb` to migrate databases in an environment that is currently open by another process, but if you are not careful you can easily corrupt the environment and cause the other process to fail. To avoid such problems, you must configure both `dumpdb` and the other process to set `Freeze.DbEnv.env-name.DbPrivate=0`. This property has a default value of one, therefore you must explicitly set it to zero.

If you run `dumpdb` on an open environment but neglect to set `Freeze.DbEnv.env-name.DbPrivate=0`, you can expect `dumpdb` to terminate immediately with an error message stating that the database environment is locked. Before running `dumpdb` on an open environment, we strongly recommend that you first verify that the other process was also configured with `Freeze.DbEnv.env-name.DbPrivate=0`.

## FreezeScript Inspection XML Reference

This page describes the XML elements comprising the FreezeScript inspection descriptors.

On this page:

- [<dumpdb> Descriptor Element](#)
- [<database> Descriptor Element](#)
- [<record> Descriptor Element](#)
- [<dump> Descriptor Element](#)
- [<iterate> Descriptor Element](#)
- [<if> Descriptor Element](#)
- [<set> Descriptor Element](#)
- [<add> Descriptor Element](#)
- [<define> Descriptor Element](#)
- [<remove> Descriptor Element](#)
- [<fail> Descriptor Element](#)
- [<echo> Descriptor Element](#)

### <dumpdb> Descriptor Element

The top-level descriptor in a descriptor file. It requires one child descriptor, `<database>`, and supports any number of `<dump>` descriptors. This descriptor has no attributes.

### <database> Descriptor Element

The attributes of this descriptor define the key and value types of the database. It supports any number of child descriptors, but at most one `<record>` descriptor. The `<database>` descriptor also creates a [global scope](#) for user-defined symbols.

The attributes supported by the `<database>` descriptor are described in the following table:

Name	Description
key	Specifies the Slice type of the database key.
value	Specifies the Slice type of the database value.

As an example, consider the following `<database>` descriptor. In this case, the [Freeze map](#) to be examined has key type `int` and value type `::Employee`:

**XML**

```
<database key="int" value="::Employee">
```

### <record> Descriptor Element

Commences the database traversal. Child descriptors are executed for each record in the database, but after any `<dump>` descriptors are executed. The `<record>` descriptor introduces the read-only symbols `key`, `value` and `facet` into a local scope. These symbols are accessible to child descriptors, but not to `<dump>` descriptors. The `facet` symbol is a string indicating the [facet name](#) of the object in the current record, and is only relevant for [Freeze evictor](#) databases.

Note that database traversal only occurs if a `<record>` descriptor is present.

### <dump> Descriptor Element

Executed for all instances of a Slice type. Only one `<dump>` descriptor can be specified for a type, but a `<dump>` descriptor is not required for every type. The read-only symbol `value` is introduced into a local scope. The attributes supported by this descriptor are described in the following table:

Name	Description
type	Specifies the Slice type ID.
base	If type denotes a Slice class, this attribute determines whether the <dump> descriptor of the base class is invoked. If true, the base class descriptor is invoked after executing the child descriptors. If not specified, the default value is true.
contents	For class and struct types, this attribute determines whether descriptors are executed for members of the value. For sequence and dictionary types, this attribute determines whether descriptors are executed for elements. If not specified, the default value is true.

Below is an example of a <dump> descriptor that searches for certain products:

**XML**

```

<dump type="::Product">
 <if test="value.description.find('scanner') != -1">
 <echo message="Scanner SKU: " value="value.SKU"/>
 </if>
</dump>

```

For class types, `dumpdb` first attempts to locate a <dump> descriptor for the object's most-derived type. If no descriptor is found, `dumpdb` proceeds up the class hierarchy in an attempt to find a descriptor. The base object type, `Object`, is the root of every class hierarchy and is included in the search for descriptors. It is therefore possible to define a <dump> descriptor for type `Object`, which will be invoked for every class instance.

Note that <dump> descriptors are executed recursively. For example, consider the following Slice definitions:

**Slice**

```

struct Inner {
 int sum;
};
struct Outer {
 Inner i;
};

```

When `dumpdb` is interpreting a value of type `Outer`, it executes the <dump> descriptor for `Outer`, then recursively executes the <dump> descriptor for the `Inner` member, but only if the `contents` attribute of the `Outer` descriptor has the value `true`.

### <iterate> Descriptor Element

Iterates over a dictionary or sequence, executing child descriptors for each element. The symbol names selected to represent the element information may conflict with existing symbols in the enclosing scope, in which case those outer symbols are not accessible to child descriptors. The attributes supported by this descriptor are described in the following table:

Name	Description
target	The sequence or dictionary.
index	The symbol name used for the sequence index. If not specified, the default symbol is <code>i</code> .
element	The symbol name used for the sequence element. If not specified, the default symbol is <code>elem</code> .
key	The symbol name used for the dictionary key. If not specified, the default symbol is <code>key</code> .
value	The symbol name used for the dictionary value. If not specified, the default symbol is <code>value</code> .

Shown below is an example of an `<iterate>` descriptor that displays the name of an employee if the employee's salary is greater than \$3000.

XML
<pre>&lt;iterate target="value.employeeMap" key="id" value="emp"&gt;   &lt;if test="emp.salary &gt; 3000"&gt;     &lt;echo message="Employee: " value="emp.name"/&gt;   &lt;/if&gt; &lt;/iterate&gt;</pre>

### `<if>` Descriptor Element

Conditionally executes child descriptors. The attributes supported by this descriptor are described in the following table:

Name	Description
test	A boolean <a href="#">expression</a> .

Child descriptors are executed if the expression in `test` evaluates to true.

### `<set>` Descriptor Element

Modifies a value. The `value` and `type` attributes are mutually exclusive. If `target` denotes a dictionary element, that element must already exist (i.e., `<set>` cannot be used to add an element to a dictionary). The attributes supported by this descriptor are described in the following table:

Name	Description
target	An <a href="#">expression</a> that must select a modifiable value.
value	An <a href="#">expression</a> that must evaluate to a value compatible with the target's type.
type	The Slice <a href="#">type ID</a> of a class to be instantiated. The class must be compatible with the target's type.
length	An integer <a href="#">expression</a> representing the desired new length of a sequence. If the new length is less than the current size of the sequence, elements are removed from the end of the sequence. If the new length is greater than the current size, new elements are added to the end of the sequence. If <code>value</code> or <code>type</code> is also specified, it is used to initialize each new element.
convert	If <code>true</code> , additional type conversions are supported: between integer and floating point, and between integer and enumeration. Transformation fails immediately if a range error occurs. If not specified, the default value is <code>false</code> .

The `<set>` descriptor below modifies a member of a dictionary element:

XML
<pre>&lt;set target="new.parts['P105J3'].cost" value="new.parts['P105J3'].cost * 1.05"/&gt;</pre>

This `<set>` descriptor adds an element to a sequence and initializes its value:

## XML

```
<set target="new.partsList" length="new.partsList.length + 1"
value=" 'P105J3' " />
```

**<add> Descriptor Element**

Adds a new element to a sequence or dictionary. It is legal to add an element while traversing the sequence or dictionary using `<iterate>`, however the traversal order after the addition is undefined. The `key` and `index` attributes are mutually exclusive, as are the `value` and `type` attributes. If neither `value` nor `type` is specified, the new element is initialized with a default value. The attributes supported by this descriptor are described in the following table:

Name	Description
<code>target</code>	An <a href="#">expression</a> that must select a modifiable sequence or dictionary.
<code>key</code>	An <a href="#">expression</a> that must evaluate to a value compatible with the target dictionary's key type.
<code>index</code>	An <a href="#">expression</a> that must evaluate to an integer value representing the insertion position. The new element is inserted before <code>index</code> . The value must not exceed the length of the target sequence.
<code>value</code>	An <a href="#">expression</a> that must evaluate to a value compatible with the target dictionary's value type, or the target sequence's element type.
<code>type</code>	The Slice <a href="#">type ID</a> of a class to be instantiated. The class must be compatible with the target dictionary's value type, or the target sequence's element type.
<code>convert</code>	If <code>true</code> , additional type conversions are supported: between integer and floating point, and between integer and enumeration. Transformation fails immediately if a range error occurs. If not specified, the default value is <code>false</code> .

Below is an example of an `<add>` descriptor that adds a new dictionary element and then initializes its member:

## XML

```
<add target="new.parts" key=" 'P105J4' " />
<set target="new.parts['P105J4'].cost" value="3.15" />
```

**<define> Descriptor Element**

Defines a new symbol in the current scope. The attributes supported by this descriptor are described in the following table:

Name	Description
<code>name</code>	The name of the new symbol. An error occurs if the name matches an existing symbol in the current scope.
<code>type</code>	The name of the symbol's formal Slice type.
<code>value</code>	An <a href="#">expression</a> that must evaluate to a value compatible with the symbol's type.
<code>convert</code>	If <code>true</code> , additional type conversions are supported: between integer and floating point, and between integer and enumeration. Execution fails immediately if a range error occurs. If not specified, the default value is <code>false</code> .

Below are two examples of the `<define>` descriptor. The first example defines the symbol `identity` to have type `Ice::Identity`, and proceeds to initialize its members using `<set>`:

**XML**

```
<define name="identity" type="::Ice::Identity"/>
<set target="identity.name" value="steve"/>
<set target="identity.category" value="Admin"/>
```

The second example uses the enumeration we first saw in our discussion of [custom database migration](#) to define the symbol `manufacturer` and assign it a default value:

**XML**

```
<define name="manufacturer" type="::BigThree"
value="::DaimlerChrysler"/>
```

**<remove> Descriptor Element**

Removes an element from a sequence or dictionary. It is legal to remove an element while traversing a sequence or dictionary using `<iterate>`, however the traversal order after removal is undefined. The attributes supported by this descriptor are described in the following table:

Name	Description
<code>target</code>	An <a href="#">expression</a> that must select a modifiable sequence or dictionary.
<code>key</code>	An <a href="#">expression</a> that must evaluate to a value compatible with the key type of the target dictionary.
<code>index</code>	An <a href="#">expression</a> that must evaluate to an integer value representing the index of the sequence element to be removed.

**<fail> Descriptor Element**

Causes transformation to fail immediately. If `test` is specified, transformation fails only if the expression evaluates to `true`. The attributes supported by this descriptor are described in the following table:

Name	Description
<code>message</code>	A message to display upon transformation failure.
<code>test</code>	A boolean <a href="#">expression</a> .

The following `<fail>` descriptor terminates the transformation if a range error is detected:

**XML**

```
<fail message="range error occurred in ticket count!"
test="value.ticketCount > 32767"/>
```

**<echo> Descriptor Element**

Displays values and informational messages. If no attributes are specified, only a newline is printed. The attributes supported by this descriptor are described in the following table:

Name	Description
message	A message to display.
value	An <a href="#">expression</a> . The value of the expression is displayed in a structured format.

Shown below is an `<echo>` descriptor that uses both `message` and `value` attributes:

**XML**

```
<if test="value.ticketCount > 32767">
 <echo message="range error occurred in ticket count: "
value="value.ticketCount" />
</if>
```

## FreezeScript Descriptor Expression Language

An expression language is provided for use in FreezeScript descriptors.

On this page:

- [Operators in FreezeScript](#)
- [Literals in FreezeScript](#)
- [Symbols in FreezeScript](#)
- [The nil Keyword in FreezeScript](#)
- [Accessing Elements in FreezeScript](#)
- [Reserved Keywords in FreezeScript](#)
- [Implicit Data Members in FreezeScript](#)
- [Calling Functions in FreezeScript](#)
  - [String Member Functions](#)
  - [Dictionary Member Functions](#)
  - [Object Member Functions](#)
  - [Global Functions](#)

### Operators in FreezeScript

The language supports the usual complement of operators: `and`, `or`, `not`, `{+}`, `-`, `/`, `*`, `%`, `<`, `>`, `==`, `!=`, `<=`, `>=`, `(`, `)`. Note that the `<` character must be escaped as `&lt;` in order to comply with XML syntax restrictions.

### Literals in FreezeScript

Literal values can be specified for integer, floating point, boolean, and string. The expression language supports the same [syntax for literal values](#) as that of Slice, with one exception: string literals must be enclosed in single quotes.

### Symbols in FreezeScript

Certain descriptors introduce symbols that can be used in expressions. These symbols must comply with the naming rules for Slice identifiers (i.e., a leading letter followed by zero or more alphanumeric characters). Data members are accessed using dotted notation, such as `value.memberA.memberB`.

Expressions can refer to Slice constants and enumerators using scoped names. In a `transformdb` descriptor, there are two sets of Slice definitions, therefore the expression must indicate which set of definitions it is accessing by prefixing the scoped name with `::Old` or `::New`. For example, the expression `old.fruitMember == ::Old::Pear` evaluates to `true` if the data member `fruitMember` has the enumerated value `Pear`. In `dumpdb`, only one set of Slice definitions is present and therefore the constant or enumerator can be identified without any special prefix.

### The nil Keyword in FreezeScript

The keyword `nil` represents a nil value of type `Object`. This keyword can be used in expressions to test for a nil object value, and can also be used to set an object value to nil.

### Accessing Elements in FreezeScript

Dictionary and sequence elements are accessed using array notation, such as `userMap['joe']` or `stringSeq[5]`. An error occurs if an expression attempts to access a dictionary or sequence element that does not exist. For dictionaries, the recommended practice is to check for the presence of a key before accessing it:

#### XML

```
<if test="userMap.containsKey('joe') and userMap['joe'].active">
```

(This example shows that you can also [call functions](#) in FreezeScript.)

Similarly, expressions involving sequences should check the length of the sequence:

```
XML
```

```
<if test="stringSeq.length > 5 and stringSeq[5] == 'fruit'">
```

The `length` member is an [implicit data member](#).

## Reserved Keywords in FreezeScript

The following keywords are reserved: `and`, `or`, `not`, `true`, `false`, `nil`.

## Implicit Data Members in FreezeScript

Certain `Slice` types support implicit data members:

- Dictionary and sequence instances have a member `length` representing the number of elements.
- Object instances have a member `ice_id` denoting the actual type of the object.

## Calling Functions in FreezeScript

The expression language supports two forms of function invocation: member functions and global functions. A member function is invoked on a particular data value, whereas global functions are not bound to a data value. For instance, here is an expression that invokes the `find` member function of a `string` value:

```
old.stringValue.find('theSubstring') != -1
```

And here is an example that invokes the global function `stringToIdentity`:

```
stringToIdentity(old.stringValue)
```

If a function takes multiple arguments, the arguments must be separated with commas.

## String Member Functions

The `string` data type supports the following member functions:

- `int find(string match[, int start])`  
Returns the index of the substring, or `-1` if not found. A starting position can optionally be supplied.
- `string replace(int start, int len, string str)`  
Replaces a given portion of the string with a new substring, and returns the modified string.
- `string substr(int start[, int len])`  
Returns a substring beginning at the given start position. If the optional length argument is supplied, the substring contains at most `len` characters, otherwise the substring contains the remainder of the string.

## Dictionary Member Functions

The dictionary data type supports the following member function:

- `bool containsKey(key)`  
Returns `true` if the dictionary contains an element with the given key, or `false` otherwise. The `key` argument must have a value that is compatible with the dictionary's key type.

## Object Member Functions

Object instances support the following member function:

- `bool ice_isA(string id)`  
Returns `true` if the object implements the given interface type, or `false` otherwise. This function cannot be invoked on a nil object.

## Global Functions

The following global functions are provided:

- `string generateUUID()`  
Returns a new UUID.
- `string identityToString(Ice::Identity id)`  
Converts an identity into its string representation.
- `string lowercase(string str)`  
Returns a new string converted to lowercase.
- `string proxyToString(Ice::ObjectPrx prx)`  
Returns the string representation of the given proxy.
- `Ice::Identity stringToIdentity(string str)`  
Converts a string into an `Ice::Identity`.
- `Ice::ObjectPrx stringToProxy(string str)`  
Converts a string into a proxy.
- `string typeOf(val)`  
Returns the formal Slice type of the argument.

## Glacier2

Glacier2 is a lightweight firewall traversal solution for Ice applications.

We present many examples of client/server applications in this manual, most of which assume that the client and server programs are running either on the same host, or on multiple hosts with no network restrictions. We can justify this assumption because this is an instructional text, but a real-world network environment is usually much more complicated: client and server hosts with access to public networks often reside behind protective router-firewalls that not only restrict incoming connections, but also allow the protected networks to run in a private address space using Network Address Translation (NAT). These features, which are practically mandatory in today's hostile network environments, also disrupt the ideal world in which our examples are running.

## Common Firewall Traversal Issues

Let's assume that a client and server need to communicate over an untrusted network, and that the client and server hosts reside in private networks behind firewalls:

*Scenario 1: Client request in a typical network.*

Although the diagram looks fairly straightforward, there are several troublesome issues:

- A dedicated port on the server's firewall must be opened and configured to forward messages to the server.
- If the server uses multiple endpoints (e.g., to support both TCP and SSL), then a firewall port must be dedicated to each endpoint.
- The client's proxy must be configured to use the server's "public" endpoint, which is the host name and dedicated port of the firewall.
- If the server returns a proxy as the result of a request, the proxy must not contain the server's private endpoint because that endpoint is inaccessible to the client.

To complicate the scenario even further, the illustration below adds a callback from the server to the client. Callbacks imply that the client is also a server, therefore all of the issues associated with previous illustration now apply to the client as well.

*Scenario 2: Callbacks in a typical network.*

As if this was not complicated enough already, the illustration below adds multiple clients and servers. Each additional server (including clients requiring callbacks) adds more work for the firewall administrator as more ports are dedicated to forwarding requests.

*Scenario 3: Multiple clients and servers with callbacks in a typical network.*

Clearly, these scenarios do not scale well, and are unnecessarily complex. Fortunately, Ice provides a solution in [Glacier2](#).

## About Glacier2

Glacier2, the router-firewall for Ice applications, addresses [common firewall traversal issues](#) with minimal impact on clients or servers (or firewall administrators). In the illustration below, Glacier2 becomes the server firewall for Ice applications. What is not obvious in the diagram, however, is how Glacier2 eliminates much of the complexity of firewall traversal.

Complex network environments are a fact of life. Unfortunately, the cost of securing an enterprise's network is increased application complexity and administrative overhead. Glacier2 helps to minimize these costs by providing a low-impact, efficient and secure router for Ice applications.

Glacier2 has the following advantages and limitations.

### Advantages

- Clients often require only minimal changes to use Glacier2.
- Only one front-end port is necessary to support any number of servers, allowing a Glacier2 router to easily receive connections from a port-forwarding firewall.
- The number of connections to back-end servers is reduced. Glacier2 effectively acts as a connection concentrator, establishing a single connection to each back-end server to forward requests from any number of clients. Similarly, connections from back-end servers to Glacier2 for the purposes of sending callbacks are also concentrated.
- Servers are unaware of Glacier2's presence, and require no modifications whatsoever to use Glacier2. From a server's perspective, Glacier2 is just another local client, therefore servers are no longer required to advertise "public" endpoints in the proxies they create. Furthermore, back-end services such as [IceGrid](#) can continue to be used transparently via a Glacier2 router.
- [Callbacks through Glacier2](#) are supported without requiring new connections from servers to clients. In other words, a callback from a server to a client is sent over an existing connection from the client to the server, thereby eliminating the administrative requirements associated with supporting callbacks in the client firewall.
- Glacier2 requires no knowledge of the application's Slice definitions and therefore is very efficient: it routes request and reply messages without unmarshalling the message contents.
- In addition to its primary responsibility of forwarding Ice requests, Glacier2 offers support for [user-defined session management and authentication](#), [inactivity timeouts](#), and [request buffering and batching](#).

### Limitations

- Datagram protocols, such as UDP, are not supported.
- [Callback objects](#) in a client must use a Glacier2-supplied category in their identities.

- [Common Firewall Traversal Issues](#)
- [Callbacks through Glacier2](#)
- [IceGrid](#)

## How Glacier2 Works

The Ice core supports a generic router facility, represented by the `Ice::Router` interface, that allows a third-party service to "intercept" requests on a properly-configured proxy and deliver them to the intended server. Glacier2 is an implementation of this service, although other implementations are certainly possible.

Glacier2 normally runs on a host in the private network behind a [port-forwarding firewall](#), but it can also operate on a host with access to both public and private networks. In this configuration it follows that Glacier2 must have endpoints on each network.

For the sake of example, the router's public address is 5.6.7.8 and its private address is 10.0.0.1.

In the client, proxies must be configured to use Glacier2 as a router. This configuration can be done statically for all proxies created by a communicator, or programmatically for a particular proxy. A proxy configured to use a router is called a *routed proxy*.

When a client invokes an operation on a routed proxy, the client connects to one of Glacier2's client endpoints and sends the request as if Glacier2 is the server. Glacier2 then establishes an outgoing connection to the client's intended server in the private network, forwards the request to that server, and returns the reply (if any) to the client. Glacier2 is essentially acting as a local client on behalf of the remote client.

If a server returns a proxy as the result of an operation, that proxy contains the server's endpoints in the private network, as usual. (Remember, the server is unaware of Glacier2's presence, and therefore assumes that the proxy is usable by the client that requested it.) In the absence of a router, a client would receive an exception if it attempted to use such a proxy. When configured with a router, however, the client ignores the proxy's endpoints and always sends requests to the router's client endpoints instead.

Glacier2's server endpoints, which reside in the private network, are only used when a server makes a [callback to a client](#).

## Getting Started with Glacier2

On this page:

- [Using Glacier2](#)
- [Configuring the Router](#)
- [Writing a Password File](#)
  - [icehashpassword Helper Script](#)
- [Starting the Router](#)
- [Configuring a Glacier2 Client](#)
- [Glacier2 Object Identities](#)
- [Creating a Glacier2 Session](#)
- [Glacier2 Session Expiration](#)
- [Glacier2 Session Destruction](#)

## Using Glacier2

Using Glacier2 in a minimal configuration involves the following tasks:

1. Write a [configuration file](#) for the router.
2. Write a [password file](#) for the router. (Glacier2 also supports [other ways](#) to authenticate users.)
3. Decide whether to use the router's internal session manager, or supply your own [session manager](#).
4. [Start the router](#) on a host with access to the public and private networks.
5. Modify the [client configuration](#) to use the router.
6. Modify the client to create a [router session](#).
7. Ensure that the [router session remains active](#) for as long as the client requires it.

For the sake of example, the router's public address is 5.6.7.8 and its private address is 10.0.0.1.

## Configuring the Router

The following router configuration properties establish the necessary endpoint and define when a session expires due to inactivity:

```
Glacier2.Client.Endpoints=tcp -h 5.6.7.8 -p 4063
Glacier2.SessionTimeout=60
```

The endpoint defined by `Glacier2.Client.Endpoints` is used by the Ice run time in a client to interact directly with the router. It is also the endpoint where requests from routed proxies are sent. This endpoint is defined on the public network interface because it must be accessible to clients. Furthermore, the endpoint uses a fixed port because clients may be statically configured with a proxy for this endpoint. The port numbers 4063 (for TCP) and 4064 (for SSL) are reserved for Glacier2 by the Internet Assigned Numbers Authority (IANA).

This sample configuration uses TCP as the endpoint protocol, although in most cases, [SSL is preferable](#).

A client must [create a session](#) in order to use a Glacier2 router. Our setting for the `Glacier2.SessionTimeout` property causes the router to destroy sessions that have been idle for at least 60 seconds. It is not mandatory to define a timeout, but it is recommended, otherwise session state might accumulate in the router.

Note that this configuration enables the router to forward requests from clients to servers. Additional configuration is necessary to support [callbacks](#) from servers to clients.

You must also decide which authentication scheme (or schemes) to use. A [file-based](#) mechanism is available, as are [more sophisticated strategies](#).

If clients access a [location service](#) via the router, additional router configuration is typically necessary.

## Writing a Password File

The router's simplest authentication mechanism uses an access control list in a text file consisting of username and password pairs. Passwords are encoded using the `modular crypt format` (MCF).

The general structure of a MCF encoded password hash is: `$identifier$content`, where `identifier` denotes the scheme used for hashing, and `content` denotes its contents. Glacier2 supports two types of MCF encoded password hashes:

On Windows and OS X:

- PBKDF2 using SHA-1, SHA-256, or SHA-512 as the digest algorithm.

PBKDF2 does not have a standard form in the MCF specification. In this case Glacier2 uses the same format as `passlib`.

- `$pbkdf2-digest$rounds$salt$` for SHA-256 and SHA-512.
- `$pbkdf2$rounds$salt$` for SHA-1.

On Linux:

- `Crypt` using SHA-256, or SHA-512 as the digest algorithm.

The property `Glacier2.CryptPasswords` specifies the name of the password file:

```
Glacier2.CryptPasswords=passwords
```

The format of the password file is very simple. Each user name-password pair must reside on a separate line, with whitespace separating the user name from the password. For example, the following password file contains an entry for the user name `test`:

```
test
5rounds=110000$5rM9XIDChkgEu.S3$ov7yip4NOilwymAZmamEvluKPQRB0WzasoJsW
MpRT19
```

### icehashpassword Helper Script

You can use the `icehashpassword` helper script to generate these username-password pairs. This script requires `Python` and `pip` to be installed. To install this script run:

```
> pip install zeroc-icehashpassword
```

You can now use the command `icehashpassword`:

```
> icehashpassword
Password:
5rounds=110000$5rM9XIDChkgEu.S3$ov7yip4NOilwymAZmamEvluKPQRB0WzasoJsW
MpRT19
```

You may also specify several optional parameters:

- `-d MESSAGE_DIGEST_ALGORITHM, --digest=MESSAGE_DIGEST_ALGORITHM`
- `-s SALT_SIZE, --salt=SALT_SIZE`
- `-r ROUNDS, --rounds=ROUNDS`

For example,

```
> python icehashpassword.py -r 25000 -s 32 -d sha256
Password:
$pbkdf2-sha256$25000$pJSSEuKcs9aaE.J8711LyR1D6H0P4Tyn9J7znpNyLsU$Yx7NNL
DfwwLeMbZV84X2rBYBnvrXvK/TDIQiIGabQIM
```

Note that `icehashpassword` generates PBKDF2 hashes on Windows and OS X, and Crypt hashes on Linux.

This authentication scheme is intended for use in simple applications with a few users. Most applications should install their own custom [permissions verifier](#).

## Starting the Router

The router supports the following command-line options:

```
$ glacier2router -h
Usage: glacier2router [options]
Options:
-h, --help Show this message.
-v, --version Display the Ice version.
--nowarn Suppress warnings.
```

The `--nowarn` option prevents the router from displaying warning messages at startup when it is unable to contact a permissions verifier object or a session manager object specified by its configuration.

Additional command line options are supported, including those that allow the router to run as a [Windows service](#) or [Unix daemon](#), and Ice includes a [utility](#) to help you install the router as a Windows service.

Assuming our configuration properties are stored in a file named `config`, you can start the router with the following command:

```
$ glacier2router --Ice.Config=config
```

## Configuring a Glacier2 Client

The following properties configure a client to use a Glacier2 router:

```
Ice.Default.Router=Glacier2/router:tcp -h 5.6.7.8 -p 4063
Ice.RetryIntervals=-1
```

The `Ice.Default.Router` property defines the router proxy. Its endpoints must match those in `Glacier2.Client.Endpoints`.

Setting `Ice.RetryIntervals` to `-1` disables [automatic retries](#), which are not useful for proxies configured to use a Glacier2 router.

In versions prior to Ice 3.6, Glacier2 clients were required to disable [Active Connection Management](#) in order to prevent the unintentional closure of a connection to the router. This is no longer necessary as of Ice 3.6. We show how to correctly configure ACM in our discussion of [sessions](#) below.

## Glacier2 Object Identities

A Glacier2 router hosts two well-known objects. The default identities of these objects are `Glacier2/router` and `Glacier2/admin`, corresponding to the `Glacier2::Router` and `Glacier2::Admin` interfaces, respectively. If an application requires the use of multiple different (that is, not replicated) routers, it is a good idea to assign unique identities to these objects by configuring the routers with different values of the `Glacier2.InstanceName` property, as shown in the following example:

```
Glacier2.InstanceName=PublicRouter
```

This property changes the category of the object identities, which become `PublicRouter/router` and `PublicRouter/admin`. The client's configuration must also be changed to reflect the new identity:

```
Ice.Default.Router=PublicRouter/router:tcp -h 5.6.7.8 -p 4063
```

One exception to this rule is if you deploy multiple Glacier2 routers as replicas, for example, to gain redundancy or to distribute the message-forwarding load over a number of machines. In that case, all the routers must use the same instance name, and the router clients can use proxies with multiple endpoints, such as:

```
Ice.Default.Router=PublicRouter/router:tcp -h 5.6.7.8 -p 4063:tcp -h
6.10.7.8 -p 4063
```

As of Ice 3.6, a client can discover a router's proxy at run time using the [RouterFinder interface](#).

## Creating a Glacier2 Session

Session management is provided by the `Glacier2::Router` interface:

### Slice

```

module Glacier2 {
 exception PermissionDeniedException {
 string reason;
 };

 interface Router extends Ice::Router {
 Session* createSession(string userId, string password)
 throws PermissionDeniedException,
 CannotCreateSessionException;

 Session* createSessionFromSecureConnection()
 throws PermissionDeniedException,
 CannotCreateSessionException;

 idempotent string getCategoryForClient();

 void refreshSession()
 throws SessionNotExistException;

 void destroySession()
 throws SessionNotExistException;

 idempotent long getSessionTimeout();

 idempotent int getACMTimeout();
 };
};

```

The interface defines two operations for creating sessions: `createSession` and `createSessionFromSecureConnection`. The router requires each client to create a session using one of these operations; only after the session is created will the router forward requests on behalf of the client.

The `createSession` operation expects a user name and password and, depending on the [router's configuration](#), returns either a `Session` proxy or `nil`. When using the default authentication scheme, the given user name and password must match an entry in the router's password file in order to successfully create a session.

The `createSessionFromSecureConnection` operation does not require a user name and password because it authenticates the client using the credentials associated with the client's [SSL connection](#) to the router.

To create a session, the client typically obtains the router proxy from the communicator, downcasts the proxy to the `Glacier2::Router` interface, and invokes one of the `create` operations. The sample code below demonstrates how to do it in C++; the code will look very similar in the other language mappings.

**C++**

```

Ice::RouterPrx defaultRouter = communicator->getDefaultRouter();
Glacier2::RouterPrx router =
Glacier2::RouterPrx::checkedCast(defaultRouter);
string username = ...;
string password = ...;
Glacier2::SessionPrx session;
try
{
 session = router->createSession(username, password);
}
catch(const Glacier2::PermissionDeniedException& ex)
{
 cout << "permission denied:\n" << ex.reason << endl;
}
catch(const Glacier2::CannotCreateSessionException& ex)
{
 cout << "cannot create session:\n" << ex.reason << endl;
}

```

If the router is configured with a [session manager](#), the `createSession` and `createSessionFromSecureConnection` operations may return a proxy for an object implementing the `Glacier2::Session` interface (or an application-specific derived interface). The client receives a null proxy if no session manager is configured.

A non-nil session proxy returned by a `create` operation must be configured with the router that created it because the session object is only accessible via the router. If the router is configured as the client's default router at the time `createSession` or `createSessionFromSecureConnection` is invoked, as is the case in the example above, then the session proxy is already properly configured and nothing else is required. Otherwise, the client must explicitly configure the session proxy with a router using the `ice_router` proxy method.

If the client wishes to destroy the session explicitly, it must invoke `destroySession` on the router proxy. If a client does not destroy its session, the router destroys it automatically when it [expires due to inactivity](#). A client can obtain the inactivity timeout value by calling `getSessionTimeout` and keep the session alive by periodically calling `refreshSession` if necessary. An easier solution for keeping the session alive is to call `getACMTimeout` and use this value to configure the [Active Connection Management](#) behavior of the client's connection to the router:

**C++**

```

int acmTimeout = router->getACMTimeout();
if (acmTimeout > 0) {
 Ice::ConnectionPtr conn = router->ice_getCachedConnection();
 conn->setACM(acmTimeout, IceUtil::None, Ice::HeartbeatAlways);
}

```

The client calls `getACMTimeout` (new in Ice 3.6) to retrieve the router's server-side ACM timeout and passes this value to an invocation of `setACM` on its connection to the router, thereby ensuring the client and router are using a consistent setting. The client also enables automatic heartbeats so that the connection remains active and prevents the router's server-side ACM from closing the connection.

Alternatively, you could configure the client's ACM with the properties `Ice.ACM.Timeout` and `Ice.ACM.Heartbeat`. Note however that these properties affect all connections created by a client. In general, we recommend configuring the connection directly as shown above.

Whether or not you use `refreshSession` or heartbeats to keep the session alive, Glacier2 will invoke `ice_ping` on the session object for each `refreshSession` call or heartbeat received. This `ice_ping` check ensures the session is still alive in the [session manager](#). If it fails, Glacier2 destroys the session and the client is notified by the closure of the connection associated to the session.

The `getCategoryForClient` operation is used to implement [callbacks](#) over bidirectional connections.

#### Example

An example of a Glacier2 client is provided in the directory `demo/Glacier2/callback`.

## Glacier2 Session Expiration

A Glacier2 router may be configured to destroy sessions after a period of inactivity. This feature allows the router, as well as a custom [session manager](#), to reclaim resources acquired during the session, but it requires some coordination between the router and its clients.

Ideally you would select a [session timeout](#) that is long enough to accommodate the usage patterns of your clients. For example, a session timeout of thirty seconds is a reasonable choice for a client that invokes an operation on a back-end server once every five seconds. However, that timeout could disrupt a different client that has long periods of inactivity, such as when its invocations are prompted by human interaction.

If you cannot predict with certainty the usage patterns of your clients, we recommend configuring the clients so that they actively prevent their sessions from expiring. The simplest solution is to enable the heartbeat feature of [Active Connection Management](#), wherein the Ice run time automatically sends a heartbeat message at regular intervals. The Glacier2 router interprets a heartbeat message as an indication that the client is still active and wishes its session to remain alive. ACM settings can be configured for all connections created by a communicator, or individually for a particular connection. Use care to ensure the client's ACM timeout and the router's session timeout are compatible.

Ice includes [helper classes](#) that simplify the task of creating a session.

Note that if a session times out, the next client invocation raises `ConnectionLostException`. To re-establish the session, the client must explicitly re-create it. If the client uses [callbacks](#), it must also re-create the callback adapter and re-register its callback servants.

## Glacier2 Session Destruction

A router session is destroyed automatically when the [session expires](#), and when a client explicitly destroys its session. The router also destroys a session if certain connection errors occur while attempting to route a request. These errors are represented by the run-time exceptions `SocketException`, `TimeoutException`, and `ProtocolException`. In other words, if any of these exceptions occur while Glacier2 attempts to establish a connection to the target back-end server, or forward a request to the target back-end server, the router automatically destroys the session.

## Callbacks through Glacier2

Callbacks from servers to clients are commonly used in distributed applications, often to notify the client about an event such as the completion of a long-running calculation or a change to a database record. Unfortunately, supporting callbacks in a complicated network environment presents its own set of problems. Ice overcomes these obstacles using a Glacier2 router and bidirectional connections.

On this page:

- [Bidirectional Connections with Glacier2](#)
- [Callbacks and Connection Closure](#)
- [Configuring the Router for Callbacks](#)
- [Configuring the Client's Object Adapter with a Router](#)
- [Callback Object Identities](#)
- [Nested Invocations with a Router](#)
- [Handling Session Timeouts](#)

### Example

The `demo/Glacier2/callback` example illustrates the use of callbacks with Glacier2. The `README` file in the directory provides instructions on running the example, and comments in the configuration file describe the properties in detail.

## Bidirectional Connections with Glacier2

While a regular unrouted connection allows requests to flow in only one direction (from client to server), a [bidirectional connection](#) enables requests to flow in both directions. This capability is necessary to circumvent the network restrictions that commonly cause [firewall traversal issues](#), namely, client-side firewalls that prevent a server from establishing an independent connection directly to the client. By sending callback requests over the existing connection from the client to the server (more accurately, from the client to the router), we have created a virtual connection back to the client.

This diagram shows the steps involved in making a callback using Glacier2:

1. The client has a routed proxy for the server and makes an invocation. A connection is established to the router's client endpoint and the request is sent to the router.
2. The router, using information from the client's proxy, establishes a connection to the server and forwards the request. In this example, one of the arguments in the request is a proxy for a callback object in the client.
3. The server makes a callback to the client. For this to succeed, the proxy for the callback object must contain endpoints that are accessible to the server. The only path back to the client is through the router, therefore the proxy contains the [router's server endpoints](#). The server connects to the router and sends the request.
4. The router forwards the callback request to the client using the bidirectional connection established in step 1.

The arrows in the above illustration indicate the flow of requests; notice that two connections are used between the router and the server. Since the server is unaware of the router, it does not use routed proxies, and therefore does not use bidirectional connections.

It is also possible for applications to manually configure bidirectional connections without the use of a router.

## Callbacks and Connection Closure

When a client terminates, it closes its connection to the router. If a server later attempts to make a callback to the client, the attempt fails because the router has no connection to the client over which to forward the request. This situation is no worse than if the server attempted to contact the client directly, which would be prevented by the client's firewall. However, this illustrates the inherent limitation of bidirectional connections: the lifetime of a client's callback proxy is bounded by the lifetime of the client's router session.

## Configuring the Router for Callbacks

In order for the router to support callbacks from servers, it needs to have endpoints in the private network.

The configuration file shown below adds the property `Glacier2.Server.Endpoints`:

```
Glacier2.Client.Endpoints=tcp -h 5.6.7.8 -p 4063
Glacier2.Server.Endpoints=tcp -h 10.0.0.1
```

As this example shows, the server endpoint does not require a fixed port.

## Configuring the Client's Object Adapter with a Router

A client that receives callbacks is also a server, and therefore must have an object adapter. Typically, an object adapter has endpoints in the local network, but those endpoints are of no use to a server in our restricted network environment. We really want the client's callback proxy to contain the router's server endpoints, and we accomplish that by configuring the client's object adapter with a proxy for the router.

Note that multiple object adapters created by the same communicator cannot use the same router.

We supply the router's proxy by creating the object adapter with `createObjectAdapterWithRouter`, or by defining the object adapter property `adapter.Router` as shown below:

```
CallbackAdapter.Router=Glacier2/router:tcp -h 5.6.7.8 -p 4063
```

For each object adapter, the Ice run time maintains a [list of endpoints](#) that are embedded in proxies created by that adapter. Normally, this list simply contains the local endpoints defined for the object adapter but, when the adapter is configured with a router, the list only contains the router's server endpoints.

An object adapter configured in this way allows the client to receive callback requests via the router. If the client also wants to service requests via local (non-routed) endpoints, the client must [create a separate adapter](#) for these requests.

## Callback Object Identities

Glacier2 assigns a unique category to each client for use in the [identities](#) of the client's callback objects. The client creates proxies that contain this identity category and pass these proxies to back-end servers for use in making callback requests to the client. This category serves two purposes:

1. Upon receipt of a callback request from a back-end server, the router uses the request's category to identify the intended client.
2. The category is sufficiently random that, without knowing the category in advance, it is practically impossible for a misbehaving or malicious back-end server to send callback requests to an arbitrary client.

A client can obtain its assigned category by calling `getCategoryForClient` on the `Router` interface as shown in the example below:

**C++**

```
Glacier2::RouterPrx router = // ...
string category = router->getCategoryForClient();
```

## Nested Invocations with a Router

If a router client intends to receive callbacks and make nested twoway invocations, it is important that the client be configured correctly. Specifically, you must increase the size of the client thread pool to at least two threads.

## Handling Session Timeouts

If the client's session *times out*, the next invocation raises `ConnectionLostException`. The client can recover from this situation by re-creating the session, re-creating the callback adapter, and adding all the callback servants to the *Active Servant Map* (ASM) of the re-created adapter.

## Glacier2 Helper Classes

Ice includes a number of helper classes to help you build robust Glacier2 clients.

- [The Glacier2::Application Class](#)
- GUI Helper Classes
  - [The SessionFactoryHelper Class](#)
  - [The SessionHelper Class](#)
  - [The SessionCallback Interface](#)

### Compatibility Note

As of Ice 3.6, the Glacier2 helper classes use [ACM heartbeats](#) to automatically keep sessions alive. This functionality requires a Glacier2 router that also uses Ice 3.6 or later. Using an earlier version of Glacier2 will require your application to manually keep sessions alive.

## The Glacier2::Application Class

You may already be familiar with the [Ice::Application](#) class, which encapsulates some basic Ice functionality such as communicator initialization, communicator destruction, and proper handling of signals and exceptions. The [Glacier2::Application](#) extends [Ice::Application](#) to add functionality that is commonly needed by Glacier2 clients:

- Keeps a session alive by periodically sending "heartbeat" requests
- Automatically restarts a session if a failure occurs
- Optionally creates an object adapter for callbacks
- Destroys the session when the application completes

The C++ definition of [Glacier2::Application](#) is shown below. (The Java and C# versions offer identical functionality so we do not show them here.)

## C++

```

namespace Glacier2 {

class Application : public Ice::Application {
public:
 Application();
 Application(Ice::SignalPolicy policy);

 virtual int runWithSession(int argc, char* argv[]) = 0;

 virtual Glacier2::SessionPrx createSession() = 0;

 virtual void sessionDestroyed();

 static Glacier2::RouterPrx router();

 static Glacier2::SessionPrx session();

 void restart();

 std::string categoryForClient();

 Ice::Identity createCallbackIdentity(const std::string& name);

 Ice::ObjectPrx addWithUUID(const Ice::ObjectPtr& servant);

 Ice::ObjectAdapterPtr objectAdapter();
};
}

```

The class supports the following methods:

- `Application()`  
Instantiating the class using its default constructor has the same semantics as calling `Application(Ice::HandleSignals)`.
- `Application(Ice::SignalPolicy policy)`  
This constructor allows you to indicate whether the class should handle signals. The `SignalPolicy` enumeration contains two enumerators: `HandleSignals` and `NoSignalHandling`. If you specify `HandleSignals`, the class automatically shuts down or destroys its communicator upon receipt of certain signals. Refer to the `Ice::Application` documentation in the relevant language mapping chapter for more information on signal handling.
- `int runWithSession(int argc, char* argv[])`  
This method must be overridden by a subclass and represents the "main loop" of the application. It is called after the communicator has been initialized and the Glacier2 session has been established. The argument vector passed to this method contains the arguments passed to `Application::main` with all Ice-related options removed. The implementation of `runWithSession` must return zero to indicate success and non-zero to indicate failure; the value returned by `runWithSession` becomes the return value of `Application::main`.

`runWithSession` can call `restart` to restart the session. This destroys the current session, creates a new session (by calling `createSession`), and calls `runWithSession` again. The `Application` base class also restarts the session if `runWithSession` raises (or allows to be raised) any of the following exceptions:

- `Ice::ConnectionLostException`

- `Ice::ConnectionRefusedException`
- `Ice::RequestFailedException`
- `Ice::TimeoutException`
- `Ice::UnknownLocalException`

All other exceptions cause the current session to be destroyed without restarting.

- `Glacier2::SessionPrx createSession()`  
This method must be overridden by a subclass to create the application's Glacier2 session. A successful call to `createSession` is followed by a call to `runWithSession`. The application terminates if `createSession` raises (or allows to be raised) an `Ice::LocalException`.
- `void sessionDestroyed()`  
A subclass can optionally override this method to take action when connectivity with the Glacier2 router is lost.
- `Glacier2::RouterPrx router()`  
Returns the proxy for the Glacier2 router.
- `Glacier2::SessionPrx session()`  
Returns the proxy for the current session.
- `void restart()`  
Causes `Application` to destroy the current session, create a new session (by calling `createSession`), and start a new main loop (in `runWithSession`). This method does not return but rather raises a `RestartSessionException` that is trapped by `Application`.
- `std::string categoryForClient()`  
Returns the category to be used in the identities of all of the client's callback objects. Clients must use this category for the router to forward [callback requests](#) to the intended client. The method raises `SessionNotExistException` if no session is currently active.
- `Ice::Identity createCallbackIdentity(const std::string& name)`  
Creates a new Ice identity for a callback object with the given identity name.
- `Ice::ObjectPrx addWithUUID(const Ice::ObjectPtr& servant)`  
Adds a servant to the callback object adapter's Active Servant Map using a UUID for the identity name.
- `Ice::ObjectAdapterPtr objectAdapter()`  
Returns the object adapter used for callbacks, creating the object adapter if necessary.

#### Example

The Ice distribution includes an example in `demo/Glacier2/callback` that shows how to use the `Glacier2::Application` class.

## GUI Helper Classes

The "main loop" design imposed by the `Glacier2::Application` class is not suitable for graphical applications, therefore Ice also includes a collection of C++, Java and C# classes that better accommodate the needs of GUI programs:

- `SessionFactoryHelper`  
This class simplifies the task of creating a Glacier2 session. It provides overloaded `connect` methods that support the two authentication styles (user name/password and SSL credentials) accepted by the Glacier2 router, and returns an instance of `SessionHelper` for each new session.
- `SessionHelper`  
This class encapsulates a Glacier2 session and provides much of the same functionality as `Glacier2::Application`. The application must supply an instance of `SessionCallback` when creating the session; `SessionHelper` invokes this callback object when important events occur in the session's lifecycle.
- `SessionCallback`  
An application implements this interface to receive notification about session lifecycle events.

The classes reside in the `Glacier2` namespace or package. We discuss them further in the subsections below.

#### Example

You can find sample applications that make use of these classes in the `demo/Glacier2/chat` directory of your Ice distribution.

### The `SessionFactoryHelper` Class

The `SessionFactoryHelper` class provides convenience methods for configuring the settings that are commonly used to create a Glacier2 session, such as the router's host and port number. Once the application has completed its configuration, it calls one of the `connect` methods to initialize a communicator, establish a Glacier2 session, and receive a `SessionHelper` object with which it can manage the new session. An application should create a new `SessionFactoryHelper` object for each router instance that it uses.

`SessionFactoryHelper` creates an `Ice.InitializationData` object if the application does not pass one to the `SessionFactoryHelper` constructor. `SessionFactoryHelper` also creates a new property set if necessary, and then sets some configuration properties required by Glacier2 clients. The resulting `InitializationData` object is eventually used in `connect` to initialize a new communicator.

The Java definition of `SessionFactoryHelper` is shown below (the C++ and C# versions are nearly identical and not shown here):

## Java

```

package Glacier2;

public class SessionFactoryHelper {

 public SessionFactoryHelper(SessionCallback callback)
 throws Ice.InitializationException;

 public SessionFactoryHelper(Ice.InitializationData initData,
 SessionCallback callback)
 throws Ice.InitializationException;

 public SessionFactoryHelper(Ice.Properties properties,
 SessionCallback callback)
 throws Ice.InitializationException;

 public void setRouterIdentity(Ice.Identity identity);
 public Ice.Identity getRouterIdentity();

 public void setRouterHost(String hostname);
 public String getRouterHost();

 public void setProtocol(String protocol);
 public String getProtocol();

 public void setTimeout(int timeoutMillisecs);
 public int getTimeout();

 public void setPort(int port);
 public int getPort();

 public Ice.InitializationData getInitializationData();

 public void setConnectContext(java.util.Map<String, String> ctx);

 public void setUseCallbacks(boolean useCallbacks);
 public boolean getUseCallbacks();

 public SessionHelper connect();
 public SessionHelper connect(String username, String password);
}

```

The class supports the following methods:

- `SessionFactoryHelper(SessionCallback callback)`  
This constructor is useful when your application has no other configuration requirements. The constructor allocates an `InitializationData` object and a new property set. The callback argument must not be null.
- `SessionFactoryHelper(Ice.InitializationData initData, SessionCallback callback)`  
Use this constructor when you want to prepare your own instance of `InitializationData`. The callback argument must not be

null.

- `SessionFactoryHelper(Ice.Properties properties, SessionCallback callback)`  
This constructor is convenient when you wish to supply an initial set of properties. The callback argument must not be null.

- `void setRouterIdentity(Ice.Identity identity)`  
`Ice.Identity getRouterIdentity()`  
Determines the object identity of the Glacier2 router. If you don't call `setRouterIdentity` to provide an identity, the factory discovers the router's proxy by contacting the `RouterFinder` object using the endpoint information you've configured for the factory (host, port, and so on).

The factory ignores this setting if you configure `Ice.Default.Router`.

- `void setRouterHost(String hostname)`  
`String getRouterHost()`  
Determines the host name of the Glacier2 router. The default router host is `localhost`.

The factory ignores this setting if you configure `Ice.Default.Router`.

- `void setProtocol(String protocol)`  
`String getProtocol()`  
Determines the Ice protocol used for communications with the Glacier2 router. `protocol` can be `tcp`, `ssl`, `ws` or `wss`; the default protocol is `ssl`.

The factory ignores this setting if you configure `Ice.Default.Router`.

- `void setTimeout(int timeoutMillisecs)`  
`int getTimeout()`  
Determines the timeout setting (in milliseconds) for the connection to the Glacier2 router. No timeout is used if the argument is less than or equal to zero. The default timeout is 10,000 ms.

The factory ignores this setting if you configure `Ice.Default.Router`.

- `void setPort(int port)`  
`int getPort()`  
Determines the port on which the Glacier2 router is listening. The default is 4063 when the protocol is `tcp` or `ws`, and 4064 when the protocol is `ssl` or `wss`.

The factory ignores this setting if you configure `Ice.Default.Router`.

- `Ice.InitializationData getInitializationData()`  
Returns a reference to the `InitializationData` object that will be used during communicator initialization. If necessary, an application can make modifications to this object prior to calling `connect`.
- `void setConnectContext(java.util.Map<String, String> ctx)`  
Sets the request context to be used when creating a session. This method must be invoked prior to `connect`.
- `void setUseCallbacks(boolean useCallbacks)`  
`boolean getUseCallbacks()`  
Determines whether the session helper automatically creates an object adapter for callback servants. The default behavior is to create the object adapter.
- `SessionHelper connect()`  
Initializes a communicator, creates a Glacier2 session using SSL credentials, and returns a new `SessionHelper` object. The `connected` method is invoked on the session callback if the session was created successfully, otherwise the callback's `connectFailed` method is invoked.
- `SessionHelper connect(String username, String password)`

Initializes a communicator, creates a Glacier2 session using the given user name and password, and returns a new `SessionHelper` object. The `connected` method is invoked on the session callback if the session was created successfully, otherwise the callback's `connectFailed` method is invoked.

### The `SessionHelper` Class

The `SessionHelper` class encapsulates a Glacier2 session and keeps the session alive by periodically "pinging" the router. `SessionHelper` also provides several convenience methods for common session-related actions:

```

Java

package Glacier2;

public class SessionHelper {

 public void destroy();

 public Ice.Communicator communicator();

 public String categoryForClient()
 throws SessionNotExistException;

 public Ice.ObjectPrx addWithUUID(Ice.Object servant)
 throws SessionNotExistException;

 public Glacier2.SessionPrx session()
 throws SessionNotExistException;

 public boolean isConnected();

 public Ice.ObjectAdapter objectAdapter()
 throws SessionNotExistException;
}

```

The class supports the following methods:

- `void destroy()`  
Initiates the destruction of the Glacier2 session, including the communicator created by the `SessionHelper`. This is a non-blocking method that spawns a background thread to perform potentially blocking activities. `SessionHelper` invokes the `disconnected` method on the application's callback object to indicate the completion of the `destroy` request. If the session has already been destroyed when `destroy` is called, the method does nothing.
- `Ice.Communicator communicator()`  
Returns the communicator created by the `SessionHelper`.
- `String categoryForClient()`  
Returns the category that must be used in the identities of all callback objects. Raises `SessionNotExistException` if no session is currently active.
- `Ice.ObjectPrx addWithUUID(Ice.Object servant)`  
Adds a servant to the callback object adapter using a UUID for the identity name. Raises `SessionNotExistException` if no session is currently active.
- `Glacier2.SessionPrx session()`  
Returns a proxy for the Glacier2 session. Raises `SessionNotExistException` if no session is currently active.
- `boolean isConnected()`

Returns true if the session is currently active, false otherwise.

- `Ice.ObjectAdapter objectAdapter()`  
Returns the callback object adapter. This object adapter is only created if the session factory was configured to do so using `setUseCallbacks`. Raises `SessionNotExistException` if no session is currently active.

The Java implementation of `SessionHelper` installs a JVM shutdown hook that calls `destroy` when the application is about to exit.

### The `SessionCallback` Interface

An application must supply an instance of `SessionCallback` when instantiating a `SessionFactoryHelper` object. The callback methods allow the application to receive notification about events in the lifecycle of the session:

**Java**

```
package Glacier2;

public interface SessionCallback {

 void createdCommunicator(SessionHelper session);

 void connected(SessionHelper session)
 throws SessionNotExistException;

 void disconnected(SessionHelper session);

 void connectFailed(SessionHelper session, Throwable ex);
}
```

The following callback methods are supported:

- `void createdCommunicator(SessionHelper session)`  
Called after successfully initializing a communicator.
- `void connected(SessionHelper session)`  
Called after successfully establishing the Glacier2 session. The method can raise `SessionNotExistException` to force the new session to be destroyed.
- `void disconnected(SessionHelper session)`  
Called after the Glacier2 session is destroyed.
- `void connectFailed(SessionHelper session, Throwable ex)`  
Called if a failure occurred while attempting to establish a Glacier2 session.

## Securing a Glacier2 Router

As a firewall, a Glacier2 router represents a doorway into a private network, and in most cases that doorway should have a good lock. The obvious first step is to use [SSL](#) for the router's client endpoints. This allows you to secure the message traffic and restrict access to clients having the proper credentials. However, the router takes security even further by providing access control and filtering capabilities.

### Glacier2 Access Control

The authentication capabilities of SSL may not be sufficient for all applications: the certificate validation phase of the SSL handshake verifies that the user is who he says he is, but how do we know that he should be allowed to use the router? Glacier2 addresses this issue through the use of an access control facility that supports two forms of authentication: passwords and certificates. You can configure the router to use whichever authentication method is most appropriate for your application, or you can configure both methods in the same router.

#### Password Authentication

The router verifies the user name and password arguments to its `createSession` operation before it forwards any requests on behalf of the client. Given that the password is sent "in the clear," it is important to protect these values by using an SSL connection with the router.

There are two ways for the router to verify a user name and password. By default, the router uses a file-based access control list, but you can override this behavior by installing a proxy for an application-defined verifier object. Configuration properties define the password file name or the verifier proxy; if you install a verifier proxy, the password file is ignored. Since we have already discussed the [password file](#), we will focus on the custom verifier interface here.

An application that has special requirements can implement the interface `Glacier2::PermissionsVerifier` to gain programmatic control over access to a router. This can be especially useful in situations where a repository of account information already exists (such as an LDAP directory), in which case duplicating that information in another file would be tedious and error-prone.

The Slice definition for the interface contains just one operation:

**Slice**

```

module Glacier2 {
 interface PermissionsVerifier {
 idempotent bool checkPermissions(string userId, string password,
 out string reason)
 throws PermissionDeniedException;
 };
};

```

The router invokes `checkPermissions` on the verifier object, passing it the user name and password arguments that were given to `createSession`. The operation must return true if the arguments are valid, and false otherwise. If the operation returns false, a reason can be

provided in the output parameter. Starting with Ice 3.5, `checkPermissions` can also throw `Glacier2::PermissionDeniedException`. Glacier2 forwards this exception as-is to the client, which means the verifier can raise a subclass of `PermissionDeniedException` in order to provide more information to the client.

To configure a router with a custom verifier, set the configuration property `Glacier2.PermissionsVerifier` with the proxy for the object.

In situations where authentication is not necessary, such as during development or when running in a trusted environment, you can use Glacier2's built-in "null" permissions verifier. This object accepts any combination of user name and password, and you can enable it with the following property definition:

```
Glacier2.PermissionsVerifier=Glacier2/NullPermissionsVerifier
```

Note that the category of the object's identity (`Glacier2` in this example) must match the value of the property `Glacier2.InstanceName`.

#### Example

A sample implementation of the `PermissionsVerifier` interface is provided in the `demo/Glacier2/callback` directory.

## Certificate Authentication

The `createSessionFromSecureConnection` operation does not require a user name or password because the client's SSL connection to the router already supplies the credentials necessary to sufficiently identify the client, in the form of X.509 certificates.

It is up to you to decide what constitutes sufficient identification. For example, a single certificate could be shared by all clients if there is no need to distinguish between them, or you could generate a unique certificate for each client or a group of clients. Glacier2 does not enforce any particular policy, but simply delegates the decision of whether to accept the client's credentials to an application-defined object that implements the `Glacier2::SSLPermissionsVerifier` interface:

```

Slice

module Glacier2 {
 interface SSLPermissionsVerifier {
 idempotent bool authorize(SSLInfo info, out string reason)
 throws PermissionDeniedException;
 };
};

```

Router clients may only use `createSessionFromSecureConnection` if the router is configured with a proxy for an `SSLPermissionsVerifier` object. The implementation of `authorize` must return true to allow the client to establish a session. To reject the session, `authorize` must return false and may optionally provide a value for `reason`, which is returned to the client as a member of `PermissionDeniedException`. Starting with Ice 3.5, it can also throw `Glacier2::PermissionDeniedException`. Glacier2 forwards this exception as-is to the client, which means the verifier can raise a subclass of `PermissionDeniedException` in order to provide more information to the client.

The verifier examines the members of `SSLInfo` to authenticate a client:

### Slice

```

module Glacier2 {
 struct SSLInfo {
 string remoteHost;
 int remotePort;
 string localHost;
 int localPort;
 string cipher;
 Ice::StringSeq certs;
 };
};

```

The structure includes address information about the remote and local hosts, and a string that describes the ciphersuite negotiated for the SSL connection between the client and the router. These values are generally of interest for logging purposes, whereas the `certs` member supplies the information the verifier needs to make its decision. The client's certificate chain is represented as a sequence of strings that use the Privacy Enhanced Mail (PEM) encoding.

The first element of the sequence corresponds to the client's certificate, followed by its signing certificates. The certificate of the root Certificate Authority (CA) is the last element of the sequence. An empty sequence indicates that the client did not supply a certificate chain.

Although the certificate chain has already been validated by the SSL implementation, a verifier implementation typically needs to examine it in detail before making its decision. As a result, the verifier will need to convert the contents of `certs` into a more usable form. Some Ice platforms, such as Java and .NET, already provide certificate abstractions, and IceSSL supplies its own for C++ users. IceSSL for Java and .NET defines the method `IceSSL.Util.createCertificate`, which accepts a PEM-encoded string and returns an instance of the platform's certificate class. In C++, the class `IceSSL::Certificate` has a constructor that accepts a PEM-encoded string.

In addition to examining certificate attributes such as the distinguished name of the subject and issuer, it is also important that a verifier consider the [length of the certificate chain](#).

To install your verifier, set the `Glacier2.SSLPermissionsVerifier` property with the proxy of your verifier object.

In situations where authentication is not necessary, such as during development or when running in a trusted environment, you can use Glacier2's built-in "null" permissions verifier. This object accepts the credentials of any client, and you can enable it with the following property definition:

```
Glacier2.SSLPermissionsVerifier=Glacier2/NullSSLPermissionsVerifier
```

Note that the category of the object's identity (`Glacier2` in this example) must match the value of the property `Glacier2.InstanceName`.

### Interaction with a Permissions Verifier

The router attempts to contact the configured permissions verifiers at startup. If an object is unreachable, the router logs a warning message but continues its normal operation (you can suppress the warning using the `--nowarn` option.) The router does not contact a verifier again until it needs to invoke an operation on the object. For example, when a client asks the router to create a new session, the router makes another attempt to contact the verifier; if the object is still unavailable, the router logs a message and returns `PermissionDeniedException` to the client.

### Obtaining SSL Credentials for a Router Client

Servers that wish to receive information about a client's SSL connection to the router can define the `Glacier2.AddConnectionContext` property. When enabled, the router adds several entries to the request context of each invocation it forwards to a server, providing

information such as the client's encoded certificate (if supplied) and addressing details. If the client's connection uses SSL, the router defines the `_con.peerCert` entry in the context. A server can check for the presence of this entry and also extract additional context entries as shown below in this example:

```
C++
```

```

void unlockDoor(string id, const Ice::Current& curr)
{
 Ice::Context::const_iterator i = curr.ctx.find("_con.peerCert");
 if (i != curr.ctx.end()) {
 string certPEM;
 certPEM = i->second;
 cout << "Client address = "
 << curr.ctx["_con.remoteAddress"]
 << ":" << curr.ctx["_con.remotePort"] << endl;
 ...
 }
 ...
}

```

If the client supplied a certificate, the server can decode and examine it using the techniques discussed for [IceSSL](#).

## Request Filtering

The Glacier2 router is capable of filtering requests based on a variety of criteria, which helps to ensure that clients do not gain access to unintended objects.

### Address Filters

To prevent a client from accessing arbitrary back-end hosts or ports, you can configure a Glacier2 router to validate the address information in each proxy that the client attempts to use. Two properties determine the router's filtering behavior:

- `Glacier2.Filter.Address.Accept`  
An address is accepted if it matches an entry in this property and does not match an entry in `Glacier2.Filter.Address.Reject`.
- `Glacier2.Filter.Address.Reject`  
An address is rejected if it matches an entry in this property.

The value of each property is a list of *address:port* pairs separated by spaces, as shown in the example below:

```
Glacier2.Filter.Address.Accept=192.168.1.5:4063 192.168.1.6:4063
```

This configuration allows clients to use only two hosts in the back-end network, and only one port on each host. A client that attempts to use a proxy containing any other host or port receives an `ObjectNotExistException` on its initial request.

You can also use ranges, groups and wildcards when defining your address filters. For example, the following property value shows how to use an address range:

```
Glacier2.Filter.Address.Accept=192.168.1.[5-6]:4063
```

This property is equivalent to the first example, but the range notation allows us to define the filter more concisely. Similarly, we can restate the property using the group notation by separating values with a comma:

```
Glacier2.Filter.Address.Accept=192.168.1.[5,6]:4063
```

The wildcard notation uses the `*` character to substitute for a value:

```
Glacier2.Filter.Address.Accept=10.0.*.1:4063
```

The range, group, and wildcard notation is also supported when specifying ports, as shown below:

```
Glacier2.Filter.Address.Accept=192.168.1.[5,6]:[10000-11000]
Glacier2.Filter.Address.Reject=192.168.1.[5,6]:[10500,10501]
```

In this configuration, the router allows clients to access all of the ports in the range 10000 to 11000, except for the two ports 10500 and 10501.

At first glance, you might think that the following property definition is pointless because it would prevent clients from accessing any back-end server:

```
Glacier2.Filter.Address.Reject=*
```

In reality, this configuration only prevents clients from accessing servers using direct proxies, that is, proxies that contain endpoints. As a result, the property causes Glacier2 to accept only [indirect proxies](#).

By default, a Glacier2 router forwards requests for any address, which is equivalent to defining the property `Glacier2.Filter.Address.Accept=*`.

## Category Filters

The `Ice::Identity` type contains two string members: `category` and `name`. You can configure a router with a list of valid identity categories, in which case it only routes requests for objects in those categories. The configuration property `Glacier2.Filter.Category.Accept` supplies the category list:

```
Glacier2.Filter.Category.Accept=cat1 cat2
```

This property does not affect the routing of [callback requests](#) from back-end servers to router clients.

By default a Glacier2 router forwards requests for any category.

If a category contains spaces, you can enclose the value in single or double quotes. If a category contains a quote character, it must be escaped with a leading backslash.

Glacier2 can optionally manipulate the category filter automatically. When you set `Glacier2.Filter.Category.AcceptUser` to a value of 1, the router adds the session's user name (for password authentication) or distinguished name (for SSL authentication) to the list of accepted categories. To ensure the uniqueness of your categories, you may prefer setting the property to a value of 2, which causes the router to prepend an underscore to the user name or distinguished name before adding it to the list.

A session manager can also configure category filters [dynamically](#) using Glacier2's `SessionControl` interface.

## Identity Filters

The ability to filter on identity categories, as described in the previous section, is a convenient way to limit clients to particular groups of objects. For even stricter control over the identities that clients are allowed to access, you can use the `Glacier2.Filter.Identity.Accept` property. The value of this property is a list of identities, separated by whitespace, representing the *only* objects the router's clients may use.

If an identity contains spaces, you can enclose the value in single or double quotes. If an identity contains a quote character, it must be escaped with a leading backslash.

Clearly, specifying a static list of identities is only practical for a small set of objects. Furthermore, in many applications, the complete set of identities cannot be known in advance, such as when objects are created on a per-session basis and use UUIDs in their identities. For these situations, category-based filtering is generally sufficient. However, a session manager can also use Glacier2's [dynamic filtering](#) interface, `SessionControl`, to manage the set of valid identities at run time.

## Adapter Filters

Applications often use `IceGrid` in their back-end network to simplify server administration and take advantage of the benefits offered by indirect proxies. Once you have configured Glacier2 with an appropriate [locator proxy](#), clients can use indirect proxies to refer to objects in `IceGrid`-managed servers. Indirect proxies come in two forms: one that contains only an identity, and one that contains an identity and an object adapter identifier. You can use the category and identity filters described in previous sections to control identity-only proxies, and you can use the property `Glacier2.Filter.AdapterId.Accept` to enforce restrictions on indirect proxies that use an object adapter identifier.

For example, the following property definition allows a client to use the proxy `factory@WidgetAdapter` but not the proxy `factory@SecretAdapter`:

```
Glacier2.Filter.AdapterId.Accept=WidgetAdapter
```

If an adapter identifier contains spaces, you can enclose the value in single or double quotes. If an adapter identifier contains a quote character, it must be escaped with a leading backslash.

A session manager can also configure this filter [dynamically](#) using Glacier2's `SessionControl` interface.

## Proxy Filters

The Glacier2 router maintains an internal routing table that contains an entry for each proxy used by a router client; the size of the routing table grows in proportion to the number of clients and their proxy usage. Furthermore, the amount of memory that the routing table consumes is affected by the number of endpoints in each proxy. Glacier2 provides two properties that you can use to limit the size of the routing table and defend against malicious router clients.

The property `Glacier2.RoutingTable.MaxSize` specifies the maximum number of entries allowed in the routing table. If the size of the table exceeds the value of this property, the router evicts older entries on a least-recently-used basis. (Eviction of proxies from the routing table is transparent to router clients.) The default size of the routing table is 1000, but you may need to define a different value depending on the needs of your application. While experimenting with different values, you may find it useful to define the property `Glacier2.Trace.RoutingTable` to see a log of the router's activities with respect to the routing table.

The property `Glacier2.Filter.ProxySizeMax` sets a limit on the size of a stringified proxy. The Ice run time places no limits on the size of proxy components such as identities and host names, but a malicious client could manufacture very large proxies in a denial-of-service attack on a Glacier2 router. By setting this property to a reasonably small value, you can prevent proxies from consuming excessive memory in the router process.

### Client Impact

The Glacier2 router immediately terminates a client's session if it attempts to use a proxy that is rejected by an address filter or exceeds the size limit defined by the property `Glacier2.Filter.ProxySizeMax`. The Ice run time in the client responds by raising `ConnectionLostException` to the application.

For category, identity, and adapter identifier filters, the router raises `ObjectNotExistException` if any of the filters rejects a proxy and none of the filters accepts it.

To obtain more information on the router's reasons for terminating a session or rejecting a request, set the following property and examine the router's log output:

```
Glacier2.Client.Trace.Reject=1
```

### Glacier2 Routing Table

The Glacier2 router maintains an internal routing table for each session. The routing table holds every proxy used by its session. Consequently, the size of the routing table grows in proportion to the number of proxies used by a session. Furthermore, the amount of memory that all of the routing tables consume grows with the number of active sessions.

The property `Glacier2.RoutingTable.MaxSize` allows you to specify an upper limit on the number of entries in the routing table. If the size of the table exceeds the value of this property, the router evicts older entries on a least-recently-used basis. (Eviction of proxies from the routing table is transparent to router clients.) The default size of the routing table is 1000, but you may need to define a different value depending on the needs of your application. While experimenting with different values, you may find it useful to define the property `Glacier2.Trace.RoutingTable` to see a log of the router's activities with respect to the routing table.

The router does not remove entries from a session's routing table except when evicting an old entry to make room for a new one. In particular, an exception that occurs while routing a request for a proxy does *not* cause that proxy to be removed from the routing table. Note however that the routing table is destroyed upon session destruction.

### Glacier2 Administrative Interface

Glacier2 supports an administrative interface that allows you to shut down a router programmatically:

```

Slice

module Glacier2 {
 interface Admin {
 idempotent void shutdown();
 };
};
```

To prevent unwanted clients from using the `Admin` interface, the object is only accessible on the endpoints defined by the `Glacier2.Admin.Endpoints` property. This property has no default value, meaning you must define the property in order to make the `Admin` object accessible.

If you decide to define `Glacier2.Admin.Endpoints`, choose your endpoints carefully. We generally recommend the use of endpoints that are accessible only from behind a firewall.

## Glacier2 Session Management

A Glacier2 router requires a client to [create a session](#) and forwards requests on behalf of the client until its session expires. A session expires when it is explicitly destroyed, or when it times out due to inactivity.

You can configure a router to use a custom session manager if your application needs to track the router's session activities. For example, your application may need to acquire resources and initialize the state of back-end services for each new session, and later reclaim those resources when the session expires.

As with the [authentication facility](#), Glacier2 provides two session manager interfaces that an application can implement. The `SessionManager` interface receives notifications about sessions that use password authentication, while the `SSLSessionManager` interface is for sessions authenticated using SSL certificates.

On this page:

- [Glacier2 Session Manager Interfaces](#)
- [Glacier2 Session Timeouts](#)
- [Connection Timeouts on Routed Proxies](#)
- [Connection Caching for Session Managers](#)

## Glacier2 Session Manager Interfaces

The relevant Slice definitions are shown below:

Slice
<pre> module Glacier2 {     exception CannotCreateSessionException {         string reason;     };      interface Session {         void destroy();     };      interface SessionManager {         Session* create(string userId, SessionControl* control)             throws CannotCreateSessionException;     };      interface SSLSessionManager {         Session* create(SSLInfo info, SessionControl* control)             throws CannotCreateSessionException;     }; }; </pre>

When a client [creates a session](#) by invoking `createSession` on the `Router` interface, the router validates the client's user name and password and then calls `SessionManager::create`. Similarly, a call to `createSessionFromSecureConnection` causes the router to invoke `SSLSessionManager::create`. The `SSLInfo` structure provides details about the client's SSL connection. The second argument to the `create` operations is a proxy for a `SessionControl` object, which a session can use to perform [dynamic filtering](#).

The `create` operations must return the proxy of a new `Session` object, or raise `CannotCreateSessionException` and provide an appropriate reason. The `Session` proxy returned by `create` is ultimately returned to the client as the result of `createSession` or `createSessionFromSecureConnection`.

Glacier2 invokes the `destroy` operation on a `Session` proxy when the session expires, giving a custom session manager the opportunity to reclaim resources that were acquired for the session during `create`.

The `create` operations may be called with information that identifies an existing session. For example, this can occur when a client loses its connection to the router but its previous session has not yet expired (and therefore the router has not yet invoked `destroy` on its `Session` proxy). A session manager implementation must be prepared to handle this situation.

To configure the router with a custom session manager, define the properties `Glacier2.SessionManager` or `Glacier2.SSLSessionManager` with the proxies of the session manager objects. If necessary, you can configure a router with proxies for both types of session managers. If a session manager proxy is not supplied, the call to `createSession` or `createSessionFromSecureConnection` always returns a null proxy.

The router attempts to contact the configured session manager at startup. If the object is unreachable, the router logs a warning message but continues its normal operation (you can suppress the warning using the `--nowarn` option). The router does not contact the session manager again until it needs to invoke an operation on the object. For example, when a client asks the router to create a new session, the router makes another attempt to contact the session manager; if the session manager is still unavailable, the router logs a message and returns `CannotCreateSessionException` to the client.

#### Example

A sample implementation of the `SessionManager` interface is provided in the `demo/Glacier2/callback` directory.

## Glacier2 Session Timeouts

The value of the `Glacier2.SessionTimeout` property specifies the number of seconds a session must be inactive before it expires. This property is not defined by default, which means sessions never expire due to inactivity. If a non-zero value is specified, it's very important that the application chooses a value that does not result in premature session expiration. For example, if it's normal for a client to create a session and then have long periods of inactivity, then a suitably long timeout must be chosen, or the connection must have periodic activity, or timeouts must be disabled altogether. `Callbacks` from a server to the client also keep a session alive, in which case Glacier2 automatically destroys the session if a failure occurs while forwarding a server callback to the client.

Once a session has expired (or been destroyed for some other reason), the client will no longer be able to send requests via the router and receives a `ConnectionLostException` for each subsequent invocation. The client must explicitly create a new session in order to continue using the router.

In general, we recommend the use of an appropriate session timeout, otherwise resources created for each session will accumulate in the router.

The easiest way for a client to keep a session alive is to enable `ACM heartbeats`.

## Connection Timeouts on Routed Proxies

The timeout for a client's connection to a Glacier2 router works the same as any other `connection timeout`: in addition to the timeout specified in a proxy's endpoints, several properties can also influence the timeout. For the sake of this discussion, let's ignore the properties and focus on the proxy endpoints.

Before we discuss timeouts, we need to briefly review some Glacier2 concepts. When a Glacier2 client `configures a router proxy`, normally by setting `Ice.Default.Router`, it causes all proxies to become *routed proxies*. For an invocation on a routed proxy, the Ice run time in the client ignores that proxy's endpoints and instead forwards the invocation to the router for delivery.

There are two kinds of proxies here: the router proxy, and routed proxies. It's important to recognize this distinction in order to understand the following timeout semantics:

- The endpoint timeout in the **router proxy** determines the connection timeout for the connection between the client and the router. Suppose we use the following settings:

```
Ice.Default.Router=Glacier2/router:tcp -h routerHost -p 4063 -t
10000
MyProxy=hello:tcp -h backEndHost -p 8888 -t 5000
```

This setting configures a ten second timeout for the client's connection to the router. Endpoint timeouts in routed proxies have no effect on this connection.

- The endpoint timeout in a **routed proxy** affects the router's connection to a back-end server. The Ice run time in the client internally registers routed proxies with the router because the router uses these proxies when it forwards invocations from the client to the desired back-end server. For the routed proxy `MyProxy` in the example above, the router would establish its own connection to port 8888 on `backEndHost` and configure a timeout of five seconds for that connection.

Again, it's critically important that the client's connection to the router remain open for as long as the client requires its session, as closing this connection effectively terminates the session. Since Ice interprets the occurrence of a [connection timeout](#) as a hard error and closes the offending connection, select your timeout for the router proxy with care.

As of Ice 3.6, a Glacier2 client can safely use [invocation timeouts](#) and [active connection management](#).

For invocations made by Glacier2 to a back-end server, whatever timeout value is set on the *first* proxy that is used to make an invocation applies to all proxies for the same object. This is necessary because Glacier2 adds the proxy to its routing table during the first invocation and, thereafter, reuses that cached proxy for all invocations to the same object identity. Here is an example to illustrate this:

### C++

```
// 10-second timeout for the connection to the router.
ObjectPrx router = communicator->stringToProxy("Glacier2/router:tcp -h
routerHost -p 4063 -t 10000");
communicator->setDefaultRouter(RouterPrx::uncheckedCast(router));

// Ping back-end server with 20-second timeout
communicator->stringToProxy("id:tcp -h backEndHost -p 8888 -t
20000")->ice_ping();

// Ping back-end server with 30-second timeout
communicator->stringToProxy("id:tcp -h backEndHost -p 8888 -t
30000")->ice_ping();
```

The first call to `ice_ping`, when forwarded by Glacier2 to the server, establishes a connection with a 20-second timeout. The second call to `ice_ping` reuses the existing connection with a 20-second timeout, even though the proxy specifies a 30-second timeout.

## Connection Caching for Session Managers

You can distribute the load among multiple session manager objects by configuring the router with a session manager proxy that contains multiple endpoints. Glacier2 disables [connection caching](#) on this proxy so that each invocation on a session manager attempts to use a different endpoint.

This behavior achieves a basic form of load balancing without depending on the [replication](#) features provided by IceGrid. Be aware that including an invalid endpoint in your session manager proxy, such as the endpoint of a session manager server that is not currently running, can cause router clients to experience delays during session creation.

If your session managers are in an IceGrid replica group, refer to [IceGrid and Glacier2 Integration](#) for more information on the router's caching behavior.

## Dynamic Request Filtering with Glacier2

Glacier2 can be [statically configured](#) to filter requests, and also allows a session manager to customize filters for each session at run time via its `SessionControl` interface:

Slice
<pre> module Glacier2 {     interface SessionControl {         StringSet* categories();         StringSet* adapterIds();         IdentitySet* identities();         void destroy();     }; }; </pre>

The router creates a `SessionControl` object for each client session and supplies a proxy for the object to the session manager `create` operations. Note that the `SessionControl` proxy is null unless the router is [configured with server endpoints](#).

Invoking the `destroy` operation causes the router to destroy the client's session, which eventually results in an invocation of `destroy` on the application-defined `Session` object, if one was provided.

The interface operations `categories`, `adapterIds`, and `identities` return proxies to objects representing the modifiable filters for the session. The router initializes these filters using their respective static configuration properties.

The `SessionControl` object uses a `StringSet` to manage the category and adapter identifier filters:

Slice
<pre> module Glacier2 {     interface StringSet {         idempotent void add(Ice::StringSeq additions);         idempotent void remove(Ice::StringSeq deletions);         idempotent Ice::StringSeq get();     }; }; </pre>

Similarly, the `IdentitySet` interface manages the identity filters:

Slice
<pre> module Glacier2 {     interface IdentitySet {         idempotent void add(Ice::IdentitySeq additions);         idempotent void remove(Ice::IdentitySeq deletions);         idempotent Ice::IdentitySeq get();     }; }; </pre>

In both interfaces, the `add` operation silently ignores duplicates, and the `remove` operation silently ignores non-existent entries.

Dynamic filtering is often necessary when each session must be restricted to a particular group of objects. Upon session creation, a session manager typically allocates a number of objects in back-end servers for that session to use. To prevent other sessions from accessing these objects (intentionally or not), the session manager can configure the session's filters so that it is only permitted to use the objects that were created for it.

For example, a session manager can retain the `SessionControl` proxy and add a new identity to the `IdentitySet` as each new object is created for the session. A simpler solution is to create a unique category for the session, add it to the session's category filter, and use that category in the identities of all objects accessible to that session. Using a category filter in this way reserves an identity namespace for each session and avoids the need to update the filter for each new object.

To aid in logging and debugging, you can select a category that identifies the client, such as the user name that was supplied during session creation, or an attribute of the client's certificate such as the common name, as long as the selected category is sufficiently unique that it will not conflict with another client's session. You must also ensure that the categories you assign to sessions never match the categories of back-end objects that are not meant to be accessed by router clients. As an example, consider the following session manager implementation:

### C++

```
class SessionManagerI : public Glacier2::SessionManager
{
public:

 virtual Glacier2::SessionPrx
 create(const string& username, const Glacier2::SessionControlPrx&
 ctrl,
 const Ice::Current& curr)
 {
 string category = "_" + username;
 ctrl->categories()->add(category);
 // ...
 }
};
```

This session manager derives a category for the session by prepending an underscore to the user name and then adds this category to the session's filter. As long as our back-end objects do not use a leading underscore in their identity categories, this strategy guarantees that a session's category can never match the category of a back-end object.

For your convenience, Glacier2 already includes support for [automatic category filtering](#).

## Glacier2 Request Buffering

A Glacier2 router can forward requests in buffered or unbuffered mode. In addition, the buffering mode can be set independently for each direction (client-to-server and server-to-client).

The configuration properties `Glacier2.Client.Buffered` and `Glacier2.Server.Buffered` govern the buffering behavior. The former affects buffering of requests from clients to servers, and the latter affects buffering of requests from servers to clients. If a property is not specified, the default value is 1, which enables buffering. A property value of 0 selects the unbuffered mode.

The primary difference between the two modes is in the way requests are forwarded:

- **Buffered**  
The router queues incoming requests and outgoing replies for delivery in a separate thread.
- **Unbuffered**  
The router forwards requests in the same thread that received the request.

Although unbuffered mode consumes fewer resources than buffered mode, certain features such as [request overriding](#) and [request batching](#) are available only in buffered mode.

### See Also

- [How Glacier2 uses Request Contexts](#)

## How Glacier2 uses Request Contexts

The Glacier2 router examines the [context](#) of an incoming request for special keys that affect how the router forwards the request. These contexts have the same semantics regardless of whether the request is sent from client to server or from server to client.

On this page:

- [The `\_fwd` Context](#)
- [The `\_ovrd` Context](#)
- [Forwarding Batch Requests](#)
- [Context Forwarding](#)

### The `_fwd` Context

The `_fwd` context determines the proxy mode that the router uses when forwarding the request. The value associated with the `_fwd` key must be a string containing one or more of the characters shown in the following table:

Value	Mode
d	datagram
D	Batch datagram
o	Oneway
O	Batch oneway
s	Secure
t	Twoway
z	Compress

*Legal values for the `_fwd` context key.*

These characters match the corresponding [stringified proxy options](#).

For requests whose `_fwd` context specify a batch mode, the forwarding behavior of the router depends on whether it is [batching requests](#).

If the `_fwd` key is not present in a request context, the mode used by the router to forward that request depends on the mode used by the client's proxy as well as the router's own configuration:

- If the client used twoway mode, the router also uses twoway mode.
- If the client sent the request as a oneway or batch oneway, the router's behavior is determined by its [configuration properties](#).

### The `_ovrd` Context

In buffered mode, the router allows a new incoming request to override any pending requests that are still in the router's queue, effectively replacing any pending requests with the new request.

For a new request to override a pending request, both requests must meet the following criteria:

- they specify the `_ovrd` key in the request context with the same value
- they are oneway requests
- they are requests on the same object.

This feature is intended to be used by clients that are sending frequent oneway requests in which the most recent request takes precedence. This feature minimizes the number of requests that are forwarded to the server when requests are sent frequently enough that they accumulate in the router's queue before the router has a chance to process them.

Note that the properties `Glacier2.Client.SleepTime` and `Glacier2.Server.SleepTime` can be used to add a delay to the router once it has sent all pending requests. Setting a delay increases the likelihood of overrides actually taking effect. These properties are described in the next section.

## Forwarding Batch Requests

Clients can direct the router to forward oneway requests in batches by including the `D` or `O` characters in the `_fwd` context. If the router is configured for buffered mode and several such requests accumulate in its queue, the router forwards them together in a `batch` rather than as individual requests.

In addition, the properties `Glacier2.Client.AlwaysBatch` and `Glacier2.Server.AlwaysBatch` determine whether oneway requests are always batched regardless of the `_fwd` context. The former property affects requests from clients to servers, while the latter affects requests from servers to clients. If a property is defined with a non-zero value, then all requests whose `_fwd` context includes the `o` character or were sent as oneway invocations are treated as if `O` were specified instead, and are batched when possible. Likewise, requests whose `_fwd` context includes the `d` character or were sent as datagram invocations are treated as if `D` were specified. If a property is not defined, the router only batches requests if specifically directed to do so by the `_fwd` context.

The configuration properties `Glacier2.Client.SleepTime` and `Glacier2.Server.SleepTime` can be used to force the router's delivery threads to sleep for the specified number of milliseconds after the router has sent all of its pending requests. (Incoming requests are queued during this period.) The delay is useful to increase the effectiveness of batching because it makes it more likely for additional requests to accumulate in a batch before the batch is sent. If these properties are not defined, or their value is zero, the corresponding thread does not sleep after sending queued requests.

## Context Forwarding

The configuration properties `Glacier2.Client.ForwardContext` and `Glacier2.Server.ForwardContext` determine whether the router includes the context when forwarding a request. The former property affects requests from clients to servers, while the latter affects requests from servers to clients. If a property is not defined or has the value zero, the router does not include the context when forwarding requests.

## Configuring Glacier2 behind an External Firewall

The Glacier2 router requires only one external port to receive connections from clients and therefore can easily coexist with a network firewall device.

For example, consider the network shown in the following illustration:

The Glacier2 router in the example above has both of its endpoints in the private network and its host requires only one IP address, unlike the example we showed in the discussion of [bidirectional connections](#) in which the Glacier2 host straddled both networks.

We assume that the firewall has been configured to forward connections from port 4064 to the router's client endpoint at port 9998. Meanwhile, the client must be configured to use the firewall's address information in its router proxy, as shown below:

```
Ice.Default.Router=Glacier2/router:ssl -h 5.6.7.8 -p 4064
```

The Glacier2 router configuration for this example requires the following properties:

```
Glacier2.Client.Endpoints=ssl -h 10.0.0.1 -p 9998
Glacier2.Client.PublishedEndpoints=ssl -h 5.6.7.8 -p 4064
Glacier2.Server.Endpoints=tcp -h 10.0.0.1 -p 9999
```

We need to specify [published endpoints](#) for the client object adapter because the router is located behind a firewall. Without this property, any proxies that the router creates would use the endpoints specified in `Glacier2.Client.Endpoints`, but of course those endpoints are inaccessible to clients outside the firewall. The `PublishedEndpoints` property forces the Ice run time to use the given endpoints in proxies created by the client object adapter.

Note also that the server endpoint in this example includes a fixed port (9999), but a fixed port is not required in the server endpoint for the router to operate properly.

## Advanced Glacier2 Client Configurations

This section details strategies that Glacier2 clients can use to address more advanced requirements.

On this page:

- [Callback Strategies with Multiple Object Adapters](#)
- [Using Multiple Routers](#)
- [Using the RouterFinder Interface](#)

### Callback Strategies with Multiple Object Adapters

An application that needs to support callback requests from a router as well as requests from local clients should use multiple object adapters to ensure that proxies created by these object adapters contain the appropriate endpoints. For example, suppose we have the network configuration as shown in the following illustration:

Notice that the two local area networks use the same private network addresses, which is not an unrealistic scenario.

Now, if the callback client were to use a single object adapter for handling both callback requests and local requests, then any proxies created by that object adapter would contain the application's local endpoints as well as the router's server endpoints. As you might imagine, this could cause some subtle problems.

1. When the local client attempts to establish a connection to the callback client via one of these proxies, it might arbitrarily select one of the router's server endpoints to try first. Since the router's server endpoints use addresses in the same network, the local client attempts to make a connection over the local network, with two possible outcomes: the connection attempts to those endpoints fail, in which case they are skipped and the real local endpoints are attempted; or, even worse, one of the endpoints might accidentally be valid in the local network, in which case the local client has just connected to some unintended server.
2. The server may encounter similar problems when attempting to establish a local connection to the router in order to make a callback request.

The solution is to dedicate an object adapter solely to handling callback requests, and another one for servicing local clients. The object adapter dedicated to callback requests must be [configured with the router proxy](#).

### Using Multiple Routers

A client is not limited to using only one router at a time: the [proxy method](#) `ice_router` allows a client to configure its routed proxies as necessary. With respect to callbacks, a client must create a new callback object adapter for each router that can forward callback requests to the client. A client must also be aware of the [object identities](#) in use by the routers.

### Using the RouterFinder Interface

A router's identity can be changed by setting the `Glacier2.InstanceName` property, which affects the category portion of the identity. The default identity of a Glacier2 router is `Glacier2/Router`, but we can change it to `Production/Router` with the following setting:

```
Glacier2.InstanceName=Production
```

A client could configure its corresponding router proxy as follows:

```
Ice.Default.Router=Production/Glacier2:tcp -p 4063 -h prodhost
```

In most cases the client can statically configure the router's proxy as we've shown here. For clients that need to discover a router's proxy at run time, Ice also requires router implementations to support the `RouterFinder` interface:

### Slice

```
module Ice {
 interface RouterFinder {
 Router* getRouter();
 };
};
```

An object supporting this interface must be available with the identity `Ice/RouterFinder`. By knowing the host and port of a router's client endpoints, a client can discover the router's proxy with a call to `getRouter`:

### C++

```
Ice::ObjectPrx prx = communicator->stringToProxy("Ice/RouterFinder:tcp
-p 4063 -h prodhost");
Ice::RouterFinderPrx finder = Ice::RouterFinderPrx::checkedCast(prx);
Ice::RouterPrx router = finder->getRouter();
communicator->setDefaultRouter(router);
```

The `RouterFinder` interface was added in Ice 3.6.

## IceGrid and Glacier2 Integration

IceGrid is a server activation and location service. This section describes the ways in which you can integrate Glacier2 and IceGrid.

On this page:

- [Configuring Router Clients for IceGrid](#)
- [Using Replicated Session Managers](#)

### Configuring Router Clients for IceGrid

It is not uncommon for a Glacier2 client to require access to a locator service such as IceGrid. In the absence of Glacier2, a locator client would typically define the property `Ice.Default.Locator` with a stringified proxy for the `locator` service. However, when that locator service is accessed via a Glacier2 router, the configuration requirements are slightly different. It is no longer necessary for the client's configuration to include `Ice.Default.Locator`; this property must be defined in the router's configuration instead.

For example, consider the following network architecture:

In this case the Glacier2 router's configuration must include the property shown below:

```
Ice.Default.Locator=IceGrid/Locator:tcp -h 10.0.0.2 -p 4061
```

### Using Replicated Session Managers

An IceGrid application might want to use [replication](#) to increase the availability of Glacier2 session managers. When you configure an indirect proxy for a session manager (and [configure Glacier2 with a locator proxy](#)), the Ice run time in the router queries the locator to obtain a proxy for a session manager replica.

By default, this proxy is cached for 10 minutes, meaning the router uses the same session manager proxy to create sessions for a 10-minute period, after which it queries the locator again. If you want to distribute the session-creation load among the session manager replicas more evenly, you can decrease the locator cache timeout using configuration properties.

For example, the following settings use a timeout of 30 seconds:

```
Glacier2.SessionManager.LocatorCacheTimeout=30
Glacier2.SSLSessionManager.LocatorCacheTimeout=30
```

As you can see, timeouts are specified individually for the `SessionManager` and `SSLSessionManager` proxies. You can also disable

caching completely by using a value of 0, in which case the router queries the locator before every invocation on a session manager. See the discussion of [session management](#) for more details.

## Glacier2 Metrics

You can monitor Glacier2 using the [Administrative Facility](#) and the [Metrics Facet](#). Glacier2 provides a metrics class to monitor session related metrics. The Glacier2 session metrics class is defined in `Glacier2/Metrics.ice` and is shown below.

**Slice**

```

namespace IceMX {
class SessionMetrics extends Metrics {
 int forwardedClient = 0;
 int forwardedServer = 0;
 int routingTableSize = 0;
 int queuedClient = 0;
 int queuedServer = 0;
 int overriddenClient = 0;
 int overriddenServer = 0;
};
};

```

Glacier2 records session metrics in the `Session` metrics map, the metrics objects contained in this map are instances of the `IceMX::SessionMetrics` class show above. To configure a metrics view to record Glacier2 session metrics you can use [metrics properties](#) with the `IceMX.Metrics.view-name.Map.Session` prefix, for example:

- `IceMX.Metrics.SessionView.Map.Session.GroupBy=id` to configure a view containing one metrics object per session.
- `IceMX.Metrics.SessionView.Map.Session.GroupBy=none` to configure a view containing a single metrics object with metrics for all the sessions.

You can use the following attributes when configuring the Glacier2 Session metrics map:

Name	Description
id	A unique identifier to identify the session. This corresponds to the user Id for sessions created with a username/password and to the subject DN for sessions created from SSL.
parent	The Glacier2 router instance name.
none	The empty string.
endpoint	The stringified endpoint.
endpointType	The endpoint numerical type as defined in <code>Ice/Endpoint.ice</code> .
endpointIsDatagram	A boolean indicating if the endpoint is a datagram endpoint.
endpointIsSecure	A boolean indicating if the endpoint is secure.
endpointTimeout	The endpoint timeout.
endpointCompress	A boolean indicating if the endpoint requires compression.
endpointHost	The endpoint host.
endpointPort	The endpoint port.
connection	The connection description.
incoming	A boolean indicating if the connection is a server or client connection.

adapterName	If the connection is a server connection, adapterName will return the name of the adapter which created the connection, it will contain the empty string otherwise.
connectionId	The ID of the connection if one is set, the empty string otherwise.
localAddress	The connection's local address.
localPort	The connection's local port.
remoteAddress	The connection's remote address.
remotePort	The connection's remote port.
mcastAddress	The connection's multicast address.
mcastPort	The connection's multicast port.
state	The state of the connection.

The connection and endpoint attributes are for the connection tied to the Glacier2 session.

## IceGrid

IceGrid is a location and activation service for Ice applications. For the purposes of this discussion, we can loosely define *grid computing* as the use of a network of relatively inexpensive computers to perform the computational tasks that once required costly "big iron." Developers familiar with distributed computing technologies may not consider the notion of grid computing to be particularly revolutionary; after all, distributed applications have been running on networks for years, and the definition of grid computing is sufficiently vague that practically any server environment could be considered a "grid."

One possible grid configuration is a homogeneous collection of computers running identical programs. Each computer in the grid is essentially a clone of the others, and all are equally capable of handling a task. As a developer, you need to write the code that runs on the grid computers, and Ice is ideally suited as the infrastructure that enables the components of a grid application to communicate with one another. However, writing the application code is just the first piece of the puzzle. Many other challenges remain:

- How do I install and update this application on all of the computers in the grid?
- How do I keep track of the servers running on the grid?
- How do I distribute the load across all the computers?
- How do I migrate a server from one computer to another one?
- How can I quickly add a new computer to the grid?

Of course, these are issues faced by most distributed applications. As you learn more about IceGrid's capabilities, you will discover that it offers solutions to these challenges. To get you started, we have summarized IceGrid's feature set below:

- **Location service**  
As an implementation of an Ice [location service](#), IceGrid enables clients to bind indirectly to their servers, making applications more flexible and resilient to changing requirements. ([IceDiscovery](#) is an alternate, lightweight location service implementation for applications that don't require IceGrid's additional features.)
- **On-demand server activation**  
Starting an Ice server process is called *server activation*. IceGrid can be given responsibility for activating a server on demand, that is, when a client attempts to access an object hosted by the server. Activation usually occurs as a side effect of indirect binding, and is completely transparent to the client.
- **Application distribution**  
IceGrid provides a convenient way to distribute your application to a set of computers, without the need for a shared file system or complicated scripts. Simply configure an [IcePatch2](#) server and let IceGrid download the necessary files and keep them synchronized.
- **Replication and load balancing**  
IceGrid supports replication by grouping the object adapters of several servers into a single virtual object adapter. During indirect binding, a client can be bound to an endpoint of any of these adapters. Furthermore, IceGrid monitors the load on each computer and can use that information to decide which of the endpoints to return to a client.
- **Sessions and resource allocation**  
An IceGrid client establishes a session in order to allocate a resource such as an object or a server. IceGrid prevents other clients from using the resource until the client releases it or the session expires. Sessions enhance security through the use of an authentication mechanism that can be integrated with a [Glacier2 router](#).
- **Automatic failover**  
Ice supports automatic retry and failover in any proxy that contains multiple endpoints. When combined with IceGrid's support for replication and load balancing, automatic failover means that a failed request results in a client transparently retrying the request on the next endpoint with the lowest load.
- **Dynamic queries**  
In addition to transparent binding, applications can interact directly with IceGrid to locate objects in a variety of ways.
- **Status monitoring**  
IceGrid supports Slice interfaces that allow applications to monitor its activities and receive notifications about significant events, enabling the development of custom tools or the integration of IceGrid status events into an existing management framework.
- **Administration**  
IceGrid includes command-line and graphical administration tools. They are available on all supported platforms and allow you to start, stop, monitor, and reconfigure any server managed by IceGrid.
- **Deployment**  
Using XML files, you can describe the servers to be deployed on each computer. Templates simplify the description of identical servers.

As grid computing enters the mainstream and compute servers become commodities, users expect more value from their applications. IceGrid, in cooperation with the Ice run time, relieves you of these low-level tasks to accelerate the construction and simplify the administration of your distributed applications.

## IceGrid Architecture

An IceGrid domain consists of a *registry* and any number of *nodes*. Together, the registry and nodes cooperate to manage the information and server processes that comprise *applications*. Each application assigns servers to particular nodes. The registry maintains a persistent record of this information, while the nodes are responsible for starting and monitoring their assigned server processes. In a typical configuration, one node runs on each computer that hosts Ice servers. The registry does not consume much processor time, so it commonly runs on the same computer as a node; in fact, the registry and a node can run in the same process if desired. If fault tolerance is desired, the registry supports replication using a master-slave design.

On this page:

- [Architecture of a Simple IceGrid Application](#)
- [Server Replication with IceGrid](#)
- [Deploying an IceGrid Application](#)

### Architecture of a Simple IceGrid Application

As an example, this illustration shows a very simple IceGrid application running on a network of three computers. The IceGrid registry is the only process of interest on host PC1, while IceGrid nodes are running on the hosts PC2 and PC3. In this sample application, one server has been assigned to each node.

*Simple IceGrid application.*

From a client application's perspective, the primary responsibility of the registry is to resolve indirect proxies as an Ice [location service](#). As such, this contribution is largely transparent: when a client first attempts to use an indirect proxy, the Ice run time in the client contacts the registry to convert the proxy's symbolic information into endpoints that allow the client to [establish a connection](#).

Although the registry might sound like nothing more than a simple lookup table, reality is quite different. For example, behind the scenes, a locate request might prompt a node to start the target server automatically, or the registry might select appropriate endpoints based on load statistics from each computer.

This also illustrates the benefits of indirect proxies: the location service can provide a great deal of functionality without any special action by the client and, unlike with direct proxies, the client does not need advance knowledge of the address and port of a server. The extra level of indirection adds some latency to the client's first use of a proxy; however, all subsequent interactions occur directly between client and server, so the cost is negligible. Furthermore, indirection allows servers to migrate to different computers without the need to update proxies held by clients.

### Server Replication with IceGrid

IceGrid's flexibility allows an endless variety of configurations. For example, suppose we have a grid network and want to replicate a server on each blade, as shown below:

*Replicated server on grid network.*

Replication in Ice is based on [object adapters](#), not servers. Any object adapter in any server could participate in replication, but it is far more likely that all of the [replicated object adapters](#) are created by instances of the same server executable that is running on each computer. We are using this configuration in the example shown above, but IceGrid requires each server to have a unique name. `Server 1` and `Server 2` are our unique names for the same executable.

The binding process works somewhat differently when replication is involved, since the registry now has multiple object adapters to choose from. The description of the IceGrid application drives the registry's decision about which object adapter (or object adapters) to use. For example, the registry could consider the system load of each computer (as periodically reported by the nodes) and return the endpoints of the object adapter on the computer with the lowest load. It is also possible for the registry to combine the endpoints of several object adapters, in which case the Ice run time in the client would select the endpoint for the initial connection attempt.

## Deploying an IceGrid Application

In IceGrid, *deployment* is the process of describing an application to the registry. This description includes the following information:

- **Replica groups**  
A *replica group* is the term for a collection of [replicated object adapters](#). An application can create any number of replica groups. Each group requires a unique identifier.
- **Nodes**  
An application must assign its servers to one or more nodes.
- **Servers**  
A server's description includes a unique name and the path to its executable. It also lists the object adapters it creates.
- **Object adapters**  
Information about an object adapter includes its endpoints and any well-known objects it advertises. If the object adapter is a member of a replica group, it must also supply that group's identifier.
- **Objects**  
A *well-known object* is one that is known solely by its identity. The registry maintains a global list of such objects for use during locate requests.

IceGrid uses the term *descriptor* to refer to the description of an application and its components; deploying an application involves creating its descriptors in the registry. There are several ways to accomplish this:

- You can use a [command-line tool](#) that reads a file containing an XML representation of the descriptors.
- You can create descriptors interactively with the [graphical administration tool](#).
- You can create descriptors programmatically via IceGrid's [administrative interface](#).

The registry server must be running in order to deploy an application, but it is not necessary for nodes to be active. Nodes that are started after deployment automatically retrieve the information they need from the registry. Once deployed, you can update the application at any time.

## Getting Started with IceGrid

This page introduces a sample application that will help us demonstrate IceGrid's capabilities.

On this page:

- [The Ripper Application](#)
- [Initial Ripper Architecture](#)
- [Ripper Registry Configuration](#)
- [Ripper Client Configuration](#)
- [Ripper Server Configuration](#)
- [Starting the Registry for the Ripper Application](#)
- [Starting the Ripper Server](#)
- [Ripper Progress Review](#)

## The Ripper Application

Our application "rips" music tracks from a compact disc (CD) and encodes them as MP3 files, as shown below:

*Overview of sample application.*

Ripping an entire CD usually takes several minutes because the MP3 encoding requires lots of CPU cycles. Our distributed ripper application accelerates this process by taking advantage of powerful CPUs on remote Ice servers, enabling us to process many songs in parallel.

The Slice interface for the MP3 encoder is straightforward:

### Slice

```

#include <Ice/BuiltinSequences.ice>
module Ripper {
exception EncodingFailedException {
 string reason;
};

sequence<short> Samples;

interface Mp3Encoder {
 // Input: PCM samples for left and right channels
 // Output: MP3 frame(s).
 Ice::ByteSeq encode(Samples leftSamples, Samples rightSamples)
 throws EncodingFailedException;

 // You must flush to get the last frame(s). Flush also
 // destroys the encoder object.
 Ice::ByteSeq flush()
 throws EncodingFailedException;
};

interface Mp3EncoderFactory
{
 Mp3Encoder* createEncoder();
};
};

```

The implementation of the encoding algorithm is not relevant for the purposes of this discussion. Instead, we will focus on incrementally improving the application as we discuss IceGrid features.

### Initial Ripper Architecture

The initial architecture for our application is intentionally simple, consisting of an IceGrid registry and a server that we start manually. This illustration shows how the client's invocation on its `EncoderFactory` proxy causes an implicit locate request:

Initial architecture for the ripper application.

The corresponding C++ code for the client is presented below:

```
C++
```

```
Ice::ObjectPrx proxy =
communicator->stringToProxy("factory@EncoderAdapter");
Ripper::MP3EncoderFactoryPrx factory =
Ripper::MP3EncoderFactoryPrx::checkedCast(proxy);
Ripper::MP3EncoderPrx encoder = factory->createEncoder();
```

Notice that the client uses an indirect proxy for the `MP3EncoderFactory` object. This stringified proxy can be read literally as "the object with identity `factory` in the object adapter identified as `EncoderAdapter`." The encoding server creates this object adapter and ensures that the object adapter uses this identifier. Since each object adapter must be uniquely identified, the registry can easily determine the server that created the adapter and return an appropriate endpoint to the client.

The client's call to `checkedCast` is the first remote invocation on the factory object, and therefore the `locate` request is performed during the completion of this invocation. The subsequent call to `createEncoder` is sent directly to the server without further involvement by IceGrid.

## Ripper Registry Configuration

The registry needs a subdirectory in which to create its databases, and we will use `/opt/ripper/registry` for this purpose (the directory must exist before starting the registry). We also need to create an Ice configuration file to hold [properties](#) required by the registry. The file `/opt/ripper/registry.cfg` contains the following properties:

```
IceGrid.Registry.Client.Endpoints=tcp -p 4061
IceGrid.Registry.Server.Endpoints=tcp
IceGrid.Registry.Internal.Endpoints=tcp
IceGrid.Registry.AdminPermissionsVerifier=IceGrid/NullPermissionsVerifi
er
IceGrid.Registry.Data=/opt/ripper/registry
IceGrid.Registry.DynamicRegistration=1
```

Several of the properties define endpoints, but only the value of `IceGrid.Registry.Client.Endpoints` needs a fixed port. This property specifies the endpoints of the IceGrid locator service; IceGrid clients must include these endpoints in their definition of `Ice.Default.Locator`, as discussed in the next section. The TCP port number (4061) used in this example has been reserved by the [Internet Assigned Numbers Authority](#) (IANA) for the IceGrid registry, along with SSL port number 4062.

Several other properties are worth mentioning:

- `IceGrid.Registry.AdminPermissionsVerifier`  
Controls access to the registry's [administrative functionality](#).
- `IceGrid.Registry.Data`  
Specifies the registry's database directory.
- `IceGrid.Registry.DynamicRegistration`  
If set to a non-zero value, allows servers to register their object adapters. Dynamic registration is explained in more detail below.

By default, IceGrid will not permit a server to register its object adapters without using IceGrid's [deployment facility](#). In some situations, such as in this sample application, you may want a client to be able to bind indirectly to a server without having to first deploy the server. That is, simply starting the server should be sufficient to make the server register itself with IceGrid and be reachable from clients.

You can achieve this by running the registry with the property `IceGrid.Registry.DynamicRegistration` set to a non-zero value. With this setting, IceGrid permits an adapter to register itself upon activation even if it has not been previously deployed. To force the server to

register its adapters, you must define `Ice.Default.Locator` (so the server can find the registry) and, for each adapter that you wish to register, you must set `<adapter-name>.AdapterId` to an identifier that is unique within the registry. Setting the `<adapter-name>.AdapterId` property also causes the adapter to no longer create direct proxies but rather to create indirect proxies that clients must resolve via the registry.

## Ripper Client Configuration

The client requires only minimal configuration, namely a value for the property `Ice.Default.Locator`. This property supplies the Ice run time with the proxy for the locator service. In IceGrid, the locator service is implemented by the registry, and the locator object is available on the registry's client endpoints. The property `IceGrid.Registry.Client.Endpoints` defined above provides most of the information we need to construct the proxy. The missing piece is the identity of the locator object, which defaults to `IceGrid/Locator` but may change based on the registry's configuration:

```
Ice.Default.Locator=IceGrid/Locator:tcp -h registryhost -p 4061
```

The use of a locator service allows the client to take advantage of indirect binding and avoid static dependencies on server endpoints. However, the locator proxy must have a fixed port, otherwise the client has a bootstrapping problem: it cannot resolve indirect proxies without knowing the endpoints of the locator service.

`IceLocatorDiscovery` eliminates the need for a client to define the `Ice.Default.Locator` property by using UDP multicast to discover registries at run time.

## Ripper Server Configuration

We use `/opt/ripper/server.cfg` as the server's configuration file. It contains the following properties:

```
EncoderAdapter.AdapterId=EncoderAdapter
EncoderAdapter.Endpoints=tcp
Ice.Default.Locator=IceGrid/Locator:tcp -h registryhost -p 4061
```

The properties are described below:

- `EncoderAdapter.AdapterId`  
This property supplies the object adapter identifier that the client uses in its indirect proxy (e.g., `factory@EncoderAdapter`).
- `EncoderAdapter.Endpoints`  
This property defines the [object adapter's endpoint](#). Notice that the value does not contain any port information, meaning that the adapter uses a system-assigned port. Without IceGrid, the use of a system-assigned port would pose a significant problem: how would a client create a direct proxy if the adapter's port could change every time the server is restarted? IceGrid solves this problem nicely because clients can use indirect proxies that contain no endpoint dependencies. The registry resolves indirect proxies using the endpoint information supplied by object adapters each time they are activated.
- `Ice.Default.Locator`  
The server requires a value for this property in order to register its object adapter.

## Starting the Registry for the Ripper Application

Now that the configuration file is written and the directory structure is prepared, we are ready to start the IceGrid registry:

```
$ icegridregistry --Ice.Config=/opt/ripper/registry.cfg
```

Additional `command line options` are supported, including those that allow the registry to run as a Windows service or Unix daemon.

## Starting the Ripper Server

With the registry up and running, we can now start the server. At a command prompt, we run the program and pass an `--Ice.Config` option indicating the location of the configuration file:

```
$ /opt/ripper/bin/server --Ice.Config=/opt/ripper/server.cfg
```

## Ripper Progress Review

This example demonstrated how to use IceGrid's location service, which is a core component of IceGrid's feature set. By incorporating IceGrid into our application, the client is now able to locate the `MP3EncoderFactory` object using only an indirect proxy and a value for `Ice.Default.Locator`. Furthermore, we can reconfigure the application in any number of ways without modifying the client's code or configuration.

For some applications, the functionality we have already achieved using IceGrid may be entirely sufficient. However, we have only just begun to explore IceGrid's capabilities, and there is much we can still do to improve our application. The next section shows how we can avoid the need to start our server manually by deploying our application onto an IceGrid node.

## Using IceGrid Deployment

Here we extend the capabilities of our [sample application](#) using IceGrid's deployment facility.

On this page:

  - [Descriptor Changes](#)
  - [Configuration Changes](#)
  - [Redeploying the Application](#)
  - [Client Changes](#)

### Ripper Architecture using Deployment

The revised architecture for our application consists of a single IceGrid node responsible for our encoding server that runs on the computer named `ComputeServer`. The illustration below shows the client's initial invocation on its indirect proxy and the actions that IceGrid takes to make this invocation possible:

*Architecture for deployed ripper application.*

In contrast to the [initial architecture](#), we no longer need to manually start our server. In this revised application, the client's locate request prompts the registry to query the node about the server's state and start it if necessary. Once the server starts successfully, the locate request completes and subsequent client communication occurs directly with the server.

### Ripper Deployment Descriptors

We can deploy our application using the [icegridadmin command line utility](#), but first we must define our descriptors in XML. The descriptors are quite brief:

## XML

```

<icegrid>
 <application name="Ripper">
 <node name="Node1">
 <server id="EncoderServer" exe="/opt/ripper/bin/server"
activation="on-demand">
 <adapter name="EncoderAdapter" id="EncoderAdapter"
endpoints="tcp"/>
 </server>
 </node>
 </application>
</icegrid>

```

For IceGrid's purposes, we have named our application `Ripper`. It consists of a single server, `EncoderServer`, assigned to the node `Node1`.

Since a computer typically runs only one node process, you might be tempted to give the node a name that identifies its host (such as `ComputeServerNode`). However, this naming convention becomes problematic as soon as you need to migrate the node to another host.

The server's `exe` attribute supplies the pathname of its executable, and the `activation` attribute indicates that the server should be **activated on demand** when necessary.

The object adapter's descriptor is the most interesting. As you can see, the `name` and `id` attributes both specify the value `EncoderAdapter`. The value of `name` reflects the adapter's name in the server process (i.e., the argument passed to `createObjectAdapter`) that is used for configuration purposes, whereas the value of `id` uniquely identifies the adapter within the registry and is used in indirect proxies. These attributes are not required to have the same value. Had we omitted the `id` attribute, IceGrid would have composed a unique value by combining the server name and adapter name to produce the following identifier:

```
EncoderServer.EncoderAdapter
```

The `endpoints` attribute defines one or more **endpoints** for the adapter. As explained [earlier](#), these endpoints do not require a fixed port.

Refer to the [XML reference](#) for detailed information on using XML to define descriptors.

## Ripper Registry and Node Configuration

In our [initial registry configuration](#), we created the directory `/opt/ripper/registry` for use by the registry. The node also needs a subdirectory for its own purposes, so we will use `/opt/ripper/node`. Again, these directories must exist before starting the registry and node.

We also need to create an Ice configuration file to hold [properties](#) required by the registry and node. The file `/opt/ripper/config` contains the following properties:

```

Registry properties
IceGrid.Registry.Client.Endpoints=tcp -p 4061
IceGrid.Registry.Server.Endpoints=tcp
IceGrid.Registry.Internal.Endpoints=tcp
IceGrid.Registry.AdminPermissionsVerifier=IceGrid/NullPermissionsVerifi
er
IceGrid.Registry.Data=/opt/ripper/registry

Node properties
IceGrid.Node.Endpoints=tcp
IceGrid.Node.Name=Node1
IceGrid.Node.Data=/opt/ripper/node
IceGrid.Node.CollocateRegistry=1
Ice.Default.Locator=IceGrid/Locator:tcp -p 4061

```

The registry and node can share this configuration file. In fact, by enabling `IceGrid.Node.CollocateRegistry`, we have indicated that the registry and node should run in the same process.

One difference from our [initial configuration](#) is that we no longer define `IceGrid.Registry.DynamicRegistration`. By omitting this property, we force the registry to reject the registration of object adapters that have not been deployed.

The node properties are explained below:

- `IceGrid.Node.Endpoints`  
This property specifies the node's endpoints. A fixed port is not required.
- `IceGrid.Node.Name`  
This property defines the unique name for this node. Its value must match the descriptor we wrote above.
- `IceGrid.Node.Data`  
This property specifies the node's data directory.
- `Ice.Default.Locator`  
This property is defined for use by the `icegridadmin` tool. The node would also require this property if the registry is not collocated. Refer to our discussion of the [ripper client configuration](#) for more information on this setting.

## Ripper Server Configuration using Deployment

Server configuration is accomplished using descriptors. During deployment, the node creates a subdirectory tree for each server. Inside this tree the node creates a configuration file containing properties derived from the server's descriptors. For instance, the adapter's [descriptor](#) generates the following properties in the server's configuration file:

```

Server configuration
Ice.Admin.ServerId=EncoderServer
Ice.Admin.Endpoints=tcp -h 127.0.0.1
Ice.ProgramName=EncoderServer
Object adapter EncoderAdapter
EncoderAdapter.Endpoints=tcp
EncoderAdapter.AdapterId=EncoderAdapter
Ice.Default.Locator=IceGrid/Locator:default -p 4061

```

As you can see, the configuration file that IceGrid generates from the descriptor resembles the [initial configuration](#), with two additional properties:

- `Ice.Admin.ServerId`
- `Ice.Admin.Endpoints`

The `Ice.Admin.Endpoints` property enables the [administrative facility](#) that, among other features, allows an IceGrid node to gracefully deactivate the server.

Using the directory structure we established for our ripper application, the configuration file for `EncoderServer` has the file name shown below:

```
/opt/ripper/node/servers/EncoderServer/config/config
```

Note that this file should not be edited directly because any changes you make are lost the next time the node regenerates the file. The correct way to add properties to the file is to include property definitions in the server's descriptor. For example, we can add the property `Ice.Trace.Network=1` by modifying the server descriptor as follows:

```
<icegrid>
 <application name="Ripper">
 <node name="Node1">
 <server id="EncoderServer" exe="/opt/ripper/bin/server"
activation="on-demand">
 <adapter name="EncoderAdapter" id="EncoderAdapter"
endpoints="tcp"/>
 <property name="Ice.Trace.Network" value="1"/>
 </server>
 </node>
 </application>
</icegrid>
```

When a node activates a server, it passes the location of the server's configuration file using the `--Ice.Config` command-line argument. If you start a server manually from a command prompt, you must supply this argument yourself.

## Starting the Node for the Ripper Application

Now that the configuration file is written and the directory structure is prepared, we are ready to start the IceGrid registry and node. Using a collocated registry and node, we only need to use one command:

```
$ icegridnode --Ice.Config=/opt/ripper/config
```

Additional command line options are supported, including those that allow the node to run as a Windows service or Unix daemon.

## Deploying the Ripper Application

With the registry up and running, it is now time to deploy our application. Like our client, the `icegridadmin` utility also requires a definition for the `Ice.Default.Locator` property. We can start the utility with the following command:

```
$ icegridadmin --Ice.Config=/opt/ripper/config
```

After confirming that it can contact the registry, `icegridadmin` provides a command prompt at which we deploy our application. Assuming our descriptor is stored in `/opt/ripper/app.xml`, the deployment command is shown below:

```
>>> application add "/opt/ripper/app.xml"
```

Next, confirm that the application has been deployed:

```
>>> application list
Ripper
```

You can start the server using this command:

```
>>> server start EncoderServer
```

Finally, you can retrieve the current endpoints of the object adapter:

```
>>> adapter endpoints EncoderAdapter
```

If you want to experiment further using `icegridadmin`, issue the `help` command and review the [available commands](#).

## Ripper Progress Review

We have deployed our first IceGrid application, but you might be questioning whether it was worth the effort. Even at this early stage, we have already gained several benefits:

- We no longer need to manually start the encoder server before starting the client, because the IceGrid node automatically starts it if it is not active at the time a client needs it. If the server happens to terminate for any reason, such as an IceGrid administrative action or a server programming error, the node restarts it without intervention on our part.
- We can manage the application remotely using one of the IceGrid administration tools. The ability to remotely modify applications, start and stop servers, and inspect every aspect of your configuration is a significant advantage.

Admittedly, we have not made much progress yet in our stated goal of improving the performance of the ripper over alternative solutions that are restricted to running on a single computer. Our client now has the ability to easily delegate the encoding task to a server running on another computer, but we have not achieved the parallelism that we really need. For example, if the client created a number of encoders and used them simultaneously from multiple threads, the encoding performance might actually be *worse* than simply encoding the data directly in the client, as the remote computer would likely slow to a crawl while attempting to task-switch among a number of processor-intensive tasks.

## Adding Nodes to the Ripper Application

Adding more nodes to our environment would allow us to distribute the encoding load to more compute servers. Using the techniques we

have learned so far, let us investigate the impact that adding a node would have on our descriptors, configuration, and client application.

## Descriptor Changes

The addition of a node is mainly an exercise in cut and paste:

**XML**

```

<icegrid>
 <application name="Ripper">
 <node name="Node1">
 <server id="EncoderServer1" exe="/opt/ripper/bin/server"
activation="on-demand">
 <adapter name="EncoderAdapter" endpoints="tcp"/>
 </server>
 </node>
 <node name="Node2">
 <server id="EncoderServer2" exe="/opt/ripper/bin/server"
activation="on-demand">
 <adapter name="EncoderAdapter" endpoints="tcp"/>
 </server>
 </node>
 </application>
</icegrid>

```

Note that we now have two `node` elements instead of a single one. You might be tempted to simply use the host name as the node name. However, in general, that is not a good idea. For example, you may want to run several IceGrid nodes on a single machine (for example, for testing). Similarly, you may have to rename a host at some point, or need to migrate a node to a different host. But, unless you also rename the node, that leads to the situation where you have a node with the name of a (possibly obsolete) host when the node in fact is not running on that host. Obviously, this makes for a confusing configuration — it is better to use abstract node names, such as `Node1`.

Aside from the new `node` element, notice that the server identifiers must be unique. The adapter name, however, can remain as `EncoderAdapter` because this name is used only for local purposes within the server process. In fact, using a different name for each adapter would actually complicate the server implementation, since it would somehow need to discover the name it should use when creating the adapter.

We have also removed the `id` attribute from our adapter descriptors; the [default values](#) supplied by IceGrid are sufficient for our purposes.

## Configuration Changes

We can continue to use the configuration file we created [earlier](#) for our combined registry-node process. We need a separate configuration file for `Node2`, primarily to define a different value for the property `IceGrid.Node.Name`. However, we also cannot have two nodes configured with `IceGrid.Node.CollocateRegistry` because only one master registry is allowed, so we must remove this property:

```

IceGrid.Node.Endpoints=tcp
IceGrid.Node.Name=Node2
IceGrid.Node.Data=/opt/ripper/node

Ice.Default.Locator=IceGrid/Locator:tcp -h registryhost -p 4061

```

We assume that `/opt/ripper/node` refers to a local file system directory on the computer hosting `Node2`, and not a shared volume, because two nodes must not share the same data directory.

We have also modified the locator proxy to include the address of the host on which the registry is running.

Using `IceLocatorDiscovery` allows a node to discover its registry at run time without the need to define `Ice.Default.Locator`.

## Redeploying the Application

After saving the new descriptors, you need to redeploy the application. Using `icegridadmin`, issue the following command:

```
$ icegridadmin --Ice.Config=/opt/ripper/config
>>> application update "/opt/ripper/app.xml "
```

If an update affects any of the application's servers that are currently running, IceGrid automatically stops those servers prior to performing the update and restarts them again after the update is complete. We can determine whether an update would require any restarts using the `application diff` command:

```
$ icegridadmin --Ice.Config=/opt/ripper/config
>>> application diff --servers "/opt/ripper/app.xml "
```

To ensure that our update does not impact any active servers, we can use the `--no-restart` option:

```
$ icegridadmin --Ice.Config=/opt/ripper/config
>>> application update --no-restart "/opt/ripper/app.xml "
```

With this option, the update would fail if any servers required a restart.

## Client Changes

We have added a new node, but we still need to modify our client to take advantage of it. As it stands now, our client can delegate an encoding task to one of the two `MP3EncoderFactory` objects. The client selects a factory by using the appropriate indirect proxy:

- `factory@EncoderServer1.EncoderAdapter`
- `factory@EncoderServer2.EncoderAdapter`

In order to distribute the tasks among both factories, the client could use a random number generator to decide which factory receives the next task:

**C++**

```

string adapter;
if ((rand() % 2) == 0)
 adapter = "EncoderServer1.EncoderAdapter";
else
 adapter = "EncoderServer2.EncoderAdapter";
Ice::ObjectPrx proxy =
communicator->stringToProxy("factory@" + adapter);
Ripper::MP3EncoderFactoryPrx factory =
Ripper::MP3EncoderFactoryPrx::checkedCast(proxy);
Ripper::MP3EncoderPrx encoder = factory->createEncoder();

```

There are a few disadvantages in this design:

- The client application must be modified each time a new compute server is added or removed because it knows all of the adapter identifiers.
- The client cannot distribute the load intelligently; it is just as likely to assign a task to a heavily-loaded computer as it is an idle one.

We describe better solutions in the sections that follow.

  - [Ripper Progress Review](#)

### Overview of Well-Known Objects

There are two types of [indirect proxies](#): one specifies an identity and an object adapter identifier, while the other contains only an identity. The latter type of indirect proxy is known as a [well-known proxy](#). A well-known proxy refers to a well-known object, that is, its identity alone is sufficient to allow the client to locate it. Ice requires all object identities in an application to be unique, but typically only a select few objects are able to be located only by their identities.

In earlier sections we showed the relationship between indirect proxies containing an object adapter identifier and the IceGrid configuration. Briefly, in order for a client to use a proxy such as `factory@EncoderAdapter`, an object adapter must be given the identifier `EncoderAdapter`.

A similar requirement exists for well-known objects. The registry maintains a table of these objects, which can be populated in a number of ways:

- statically in descriptors,
- programmatically using IceGrid's administrative interface,
- dynamically using an IceGrid administration tool.

The registry's database maps an object identity to a proxy. A locate request containing only an identity prompts the registry to consult this database. If a match is found, the registry examines the associated proxy to determine if additional work is necessary. For example, consider the well-known objects in the following table.

Identity	Proxy
Object1	Object1:tcp -p 10001
Object2	Object2@TheAdapter
Object3	Object3

The proxy associated with `Object1` already contains endpoints, so the registry can simply return this proxy to the client.

For `Object2`, the registry notices the adapter ID and checks to see whether it knows about an adapter identified as `TheAdapter`. If it does, it attempts to obtain the endpoints of that adapter, which may cause its server to be started. If the registry is successfully able to determine the adapter's endpoints, it returns a direct proxy containing those endpoints to the client. If the registry does not recognize `TheAdapter` or cannot obtain its endpoints, it returns the indirect proxy `Object2@TheAdapter` to the client. Upon receipt of another indirect proxy, the Ice run time in the client will try once more to resolve the proxy, but generally this will not succeed and the Ice run time in the client will raise a `NoEndpointException` as a result.

Finally, `Object3` represents a hopeless situation: how can the registry resolve `Object3` when its associated proxy refers to itself? In this case, the registry returns the proxy `Object3` to the client, which causes the client to raise `NoEndpointException`. Clearly, you should avoid this situation.

### Well-Known Object Types

The registry's database not only associates an identity with a proxy, but also a type. Technically, the "type" is an arbitrary string but, by convention, that string represents the most-derived Slice type of the object. For example, the Slice [type ID](#) of the encoder factory in our ripper application is `::Ripper::MP3EncoderFactory`.

Object types are useful when performing [queries](#).

## Deploying Well-Known Objects

The `object` descriptor adds a well-known object to the registry. It must appear within the context of an adapter descriptor, as shown in the XML example below:

XML
<pre> &lt;icegrid&gt;   &lt;application name="Ripper"&gt;     &lt;node name="Node1"&gt;       &lt;server id="EncoderServer" exe="/opt/ripper/bin/server" activation="on-demand"&gt;         &lt;adapter name="EncoderAdapter" id="EncoderAdapter" endpoints="tcp"&gt;           &lt;object identity="EncoderFactory" type="::Ripper::MP3EncoderFactory"/&gt;         &lt;/adapter&gt;       &lt;/server&gt;     &lt;/node&gt;   &lt;/application&gt; &lt;/icegrid&gt; </pre>

During deployment, the registry associates the identity `EncoderFactory` with the indirect proxy `EncoderFactory@EncoderAdapter`. If the adapter descriptor had omitted the adapter ID, the registry would have generated a unique identifier by combining the server ID and the adapter name.

In this example, the object's `type` is specified explicitly.

## Adding Well-Known Objects Programmatically

The `IceGrid::Admin` interface defines several operations that manipulate the registry's database of well-known objects:

### Slice

```

module IceGrid {
interface Admin {
 ...
 void addObject(Object* obj)
 throws ObjectExistsException,
 DeploymentException;
 void updateObject(Object* obj)
 throws ObjectNotRegisteredException,
 DeploymentException;
 void addObjectWithType(Object* obj, string type)
 throws ObjectExistsException,
 DeploymentException;
 void removeObject(Ice::Identity id)
 throws ObjectNotRegisteredException,
 DeploymentException;
 ...
};
};

```

- **addObject**  
The `addObject` operation adds a new object to the database. The proxy argument supplies the identity of the well-known object. If an object with the same identity has already been registered, the operation raises `ObjectExistsException`. Since this operation does not accept an argument supplying the object's type, the registry invokes `ice_id` on the given proxy to determine its most-derived type. The implication here is that the object must be available in order for the registry to obtain its type. If the object is not available, `addObject` raises `DeploymentException`.
- **updateObject**  
The `updateObject` operation supplies a new proxy for the well-known object whose identity is encapsulated by the proxy. If no object with the given identity is registered, the operation raises `ObjectNotRegisteredException`. The object's type is not modified by this operation.
- **addObjectWithType**  
The `addObjectWithType` operation behaves like `addObject`, except the object's type is specified explicitly and therefore the registry does not attempt to invoke `ice_id` on the given proxy (even if the type is an empty string).
- **removeObject**  
The `removeObject` operation removes the well-known object with the given identity from the database. If no object with the given identity is registered, the operation raises `ObjectNotRegisteredException`.

The following C++ example produces the same result as the [descriptor](#) we deployed earlier:

**C++**

```

Ice::ObjectAdapterPtr adapter =
communicator->createObjectAdapter("EncoderAdapter");
Ice::Identity ident = communicator->stringToIdentity("EncoderFactory");
FactoryPtr f= new FactoryI;
Ice::ObjectPrx factory = adapter->add(f, ident);
IceGrid::AdminPrx admin = // ...
try {
 admin->addObject(factory); // OOPS!
} catch (const IceGrid::ObjectExistsException &) {
 admin->updateObject(factory);
}

```

After obtaining a proxy for the `IceGrid::Admin` interface, the code invokes `addObject`. Notice that the code traps `ObjectExistsException` and calls `updateObject` instead when the object is already registered.

There is one subtle problem in this code: calling `addObject` causes the registry to invoke `ice_id` on our factory object, but we have not yet activated the object adapter. As a result, our program will hang indefinitely at the call to `addObject`. One solution is to activate the adapter prior to the invocation of `addObject`; another solution is to use `addObjectWithType` as shown below:

**C++**

```

Ice::ObjectAdapterPtr adapter =
communicator->createObjectAdapter("EncoderAdapter");
Ice::Identity ident = communicator->stringToIdentity("EncoderFactory");
FactoryPtr f = new FactoryI;
Ice::ObjectPrx factory = adapter->add(f, ident);
IceGrid::AdminPrx admin = // ...
try {
 admin->addObjectWithType(factory, factory->ice_id());
} catch (const IceGrid::ObjectExistsException &) {
 admin->updateObject(factory);
}

```

### Adding Well-Known Objects with `icegridadmin`

The `icegridadmin` utility provides commands that are the functional equivalents of the Slice operations for managing well-known objects. We can use the utility to manually register the `EncoderFactory` object from our [descriptors](#):

```

$ icegridadmin --Ice.Config=/opt/ripper/config
>>> object add "EncoderFactory@EncoderAdapter"

```

Use the `object list` command to verify that the object was registered successfully:

```
>>> object list
EncoderFactory
IceGrid/Query
IceGrid/Locator
IceGrid/Registry
IceGrid/InternalRegistry-Master
```

To specify the object's type explicitly, append it to the `object add` command:

```
>>> object add "EncoderFactory@EncoderAdapter"
"::Ripper::MP3EncoderFactory"
```

Finally, the object is removed from the registry like this:

```
>>> object remove "EncoderFactory"
```

## Querying Well-Known Objects

The registry's database of well-known objects is not used solely for resolving indirect proxies. The database can also be queried interactively to find objects in a variety of ways. The `IceGrid::Query` interface supplies this functionality:

Slice
<pre>module IceGrid { enum LoadSample {     LoadSample1,     LoadSample5,     LoadSample15 };  interface Query {     idempotent Object* findObjectById(Ice::Identity id);     idempotent Object* findObjectByType(string type);     idempotent Object* findObjectByTypeOnLeastLoadedNode(string type, LoadSample sample);     idempotent Ice::ObjectProxySeq findAllObjectsByType(string type);     idempotent Ice::ObjectProxySeq findAllReplicas(Object* proxy); }; };</pre>

- `findObjectById`  
The `findObjectById` operation returns the proxy associated with the given identity of a well-known object. It returns a null proxy if no match was found.
- `findObjectByType`  
The `findObjectByType` operation returns a proxy for an object registered with the given type. If more than one object has the

same type, the registry selects one at random. The operation returns a null proxy if no match was found.

- `findObjectByTypeOnLeastLoadedNode`  
The `findObjectByTypeOnLeastLoadedNode` operation considers the system load when selecting one of the objects with the given type. If the registry is unable to determine which node hosts an object (for example, because the object was registered with a direct proxy and not an adapter ID), the object is considered to have a load value of 1 for the purposes of this operation. The sample argument determines the interval over which the loads are averaged (one, five, or fifteen minutes). The operation returns a null proxy if no match was found.
- `findAllObjectsByType`  
The `findAllObjectsByType` operation returns a sequence of proxies representing the well-known objects having the given type. The operation returns an empty sequence if no match was found.
- `findAllReplicas`  
Given an indirect proxy for a replicated object, the `findAllReplicas` operation returns a sequence of proxies representing the individual replicas. An application can use this operation when it is necessary to communicate directly with one or more replicas.

Be aware that the operations accepting a `type` parameter are not equivalent to invoking `ice_isA` on each object to determine whether it supports the given type, a technique that would not scale well for a large number of registered objects. Rather, the operations simply compare the given type to the object's [registered type](#) or, if the object was registered without a type, to the object's most-derived Slice type as determined by the registry.

## Using Well-Known Objects in the Ripper Application

Well-known objects are another IceGrid feature we can incorporate into our ripper application.

### Adding Well-Known Objects to the Ripper Deployment

First we'll modify the descriptors to add two well-known objects:

XML
<pre> &lt;icegrid&gt;   &lt;application name="Ripper"&gt;     &lt;node name="Node1"&gt;       &lt;server id="EncoderServer1" exe="/opt/ripper/bin/server" activation="on-demand"&gt;         &lt;adapter name="EncoderAdapter" endpoints="tcp"&gt;           &lt;object identity="EncoderFactory1" type="::Ripper::MP3EncoderFactory"/&gt;         &lt;/adapter&gt;       &lt;/server&gt;     &lt;/node&gt;     &lt;node name="Node2"&gt;       &lt;server id="EncoderServer2" exe="/opt/ripper/bin/server" activation="on-demand"&gt;         &lt;adapter name="EncoderAdapter" endpoints="tcp"&gt;           &lt;object identity="EncoderFactory2" type="::Ripper::MP3EncoderFactory"/&gt;         &lt;/adapter&gt;       &lt;/server&gt;     &lt;/node&gt;   &lt;/application&gt; &lt;/icegrid&gt; </pre>

At first glance, the addition of the well-known objects does not appear to simplify our client very much. Rather than selecting which of the two

adapters receives the next task, we now need to select one of the well-known objects.

### Querying Ripper Objects with `findAllObjectsByType`

The `IceGrid::Query` interface provides a way to eliminate the client's dependency on object adapter identifiers and object identities. Since our factories are registered with the same type, we can search for all objects of that type:

```

C++
Ice::ObjectPrx proxy = communicator->stringToProxy("IceGrid/Query");
IceGrid::QueryPrx query = IceGrid::QueryPrx::checkedCast(proxy);
Ice::ObjectProxySeq seq;
string type = Ripper::MP3EncoderFactory::ice_staticId();
seq = query->findAllObjectsByType(type);
if (seq.empty()) {
 // no match
}
Ice::ObjectProxySeq::size_type index = ... // random number
Ripper::MP3EncoderFactoryPrx factory =
Ripper::MP3EncoderFactoryPrx::checkedCast(seq[index]);
Ripper::MP3EncoderPrx encoder = factory->createEncoder();
```

This example invokes `findAllObjectsByType` and then randomly selects an element of the sequence.

### Querying Ripper Objects with `findObjectByType`

We can simplify the client further using `findObjectByType` instead, which performs the randomization for us:

```

C++
Ice::ObjectPrx proxy = communicator->stringToProxy("IceGrid/Query");
IceGrid::QueryPrx query = IceGrid::QueryPrx::checkedCast(proxy);
Ice::ObjectPrx obj;
string type = Ripper::MP3EncoderFactory::ice_staticId();
obj = query->findObjectByType(type);
if (!obj) {
 // no match
}
Ripper::MP3EncoderFactoryPrx factory =
Ripper::MP3EncoderFactoryPrx::checkedCast(obj);
Ripper::MP3EncoderPrx encoder = factory->createEncoder();
```

### Querying Ripper Objects with `findObjectByTypeOnLeastLoadedNode`

So far the use of `IceGrid::Query` has allowed us to simplify our client, but we have not gained any functionality. If we replace the call to `findObjectByType` with `findObjectByTypeOnLeastLoadedNode`, we can improve the client by distributing the encoding tasks more intelligently. The change to the client's code is trivial:

**C++**

```

Ice::ObjectPrx proxy = communicator->stringToProxy("IceGrid/Query");
IceGrid::QueryPrx query = IceGrid::QueryPrx::checkedCast(proxy);
Ice::ObjectPrx obj;
string type = Ripper::MP3EncoderFactory::ice_staticId();
obj = query->findObjectByTypeOnLeastLoadedNode(type,
 IceGrid::LoadSample1);
if (!obj) {
 // no match
}
Ripper::MP3EncoderFactoryPrx factory =
Ripper::MP3EncoderFactoryPrx::checkedCast(obj);
Ripper::MP3EncoderPrx encoder = factory->createEncoder();

```

**Ripper Progress Review**

Incorporating intelligent load distribution is a worthwhile enhancement and is a capability that would be time consuming to implement ourselves. However, our current design uses only well-known objects in order to make queries possible. We do not really need the encoder factory object on each compute server to be individually addressable as a well-known object, a fact that seems clear when we examine the identities we assigned to them: `EncoderFactory1`, `EncoderFactory2`, and so on. IceGrid's [replication features](#) give us the tools we need to improve our design.

## IceGrid Templates

IceGrid templates simplify the task of creating the descriptors for an application. A template is a parameterized descriptor that you can instantiate as often as necessary, and they are descriptors in their own right. Templates are components of an IceGrid application and therefore they are stored in the registry's database. As such, their use is not restricted to XML files; templates can also be created and instantiated interactively using the [graphical administration tool](#).

You can define templates for server and service descriptors. The focus of this section is server templates; we discuss service descriptors and templates in the context of [IceBox integration](#).

On this page:

- [Server Templates](#)
- [Template Parameters](#)
- [Adding Properties to a Server Instance](#)
- [Default Templates](#)
- [Using Templates with icegridadmin](#)

## Server Templates

You may recall from a [previous example](#) that the XML description of our sample application defined two nearly identical servers:

**XML**

```

<icegrid>
 <application name="Ripper">
 <node name="Node1">
 <server id="EncoderServer1" exe="/opt/ripper/bin/server"
activation="on-demand">
 <adapter name="EncoderAdapter" endpoints="tcp"/>
 </server>
 </node>
 <node name="Node2">
 <server id="EncoderServer2" exe="/opt/ripper/bin/server"
activation="on-demand">
 <adapter name="EncoderAdapter" endpoints="tcp"/>
 </server>
 </node>
 </application>
</icegrid>

```

This example is an excellent candidate for a server template. Equivalent definitions that incorporate a template are shown below:

## XML

```

<icegrid>
 <application name="Ripper">
 <server-template id="EncoderServerTemplate">
 <parameter name="index"/>
 <server id="EncoderServer${index}"
exe="/opt/ripper/bin/server" activation="on-demand">
 <adapter name="EncoderAdapter" endpoints="tcp"/>
 </server>
 </server-template>
 <node name="Node1">
 <server-instance template="EncoderServerTemplate"
index="1"/>
 </node>
 <node name="Node2">
 <server-instance template="EncoderServerTemplate"
index="2"/>
 </node>
 </application>
</icegrid>

```

We have defined a [server template](#) named `EncoderServerTemplate`. Nested within the `server-template` element is a [server descriptor](#) that defines an encoder server. The only difference between this `server` element and our previous example is that it is now parameterized: the template parameter `index` is used to form unique identifiers for the server and its adapter. The symbol `${index}` is replaced with the value of the `index` parameter wherever it occurs.

The template is instantiated by a `server-instance` element, which may be used anywhere that a `server` element is used. The [server instance descriptor](#) identifies the template to be instantiated, and supplies a value for the `index` parameter.

Although we have not significantly reduced the length of our XML file, we have made it more readable. And more importantly, deploying this server on additional nodes has become much easier.

## Template Parameters

Parameters enable you to customize each instance of a template as necessary. The example [above](#) defined the `index` parameter with a different value for each instance to ensure that identifiers are unique. A parameter may also declare a default value that is used in the template if no value is specified for it. In our sample application the `index` parameter is considered mandatory and therefore should not have a default value, but we can illustrate this feature in another way. For example, suppose that the path name of the server's executable may change on each node. We can supply a default value for this attribute and override it when necessary:

## XML

```

<icegrid>
 <application name="Ripper">
 <server-template id="EncoderServerTemplate">
 <parameter name="index"/>
 <parameter name="exepath" default="/opt/ripper/bin/server"/>
 <server id="EncoderServer${index}" exe="${exepath}"
activation="on-demand">
 <adapter name="EncoderAdapter" endpoints="tcp"/>
 </server>
 </server-template>
 <node name="Node1">
 <server-instance template="EncoderServerTemplate"
index="1"/>
 </node>
 <node name="Node2">
 <server-instance template="EncoderServerTemplate" index="2"
exepath="/opt/ripper-test/bin/server"/>
 </node>
 </application>
</icegrid>

```

As you can see, the instance on `Node1` uses the default value for the new parameter `exepath`, but the instance on `Node2` defines a different location for the server's executable.

Understanding the semantics of [descriptor variables and parameters](#) will help you add flexibility to your own IceGrid applications.

## Adding Properties to a Server Instance

As we saw in the preceding section, template parameters allow you to customize each instance of a server template, and template parameters with default values allow you to define commonly used configuration options. However, you might want to have additional configuration properties for a given instance without having to add a parameter. For example, to debug a server instance on a specific node, you might want to start the server with the `Ice.Trace.Network` property set; it would be inconvenient to have to add a parameter to the template just to set that property.

To cater for such scenarios, it is possible to specify additional properties for a server instance without modifying the template. You can define such properties in the `server-instance` element, for example:

## XML

```

<icegrid>
 <application>
 ...
 <node name="Node2">
 <server-instance template="EncoderServerTemplate"
index="2">
 <properties>
 <property name="Ice.Trace.Network" value="2"/>
 </properties>
 </server-instance>
 </node>
 </application>
</icegrid>

```

This sets the `Ice.Trace.Network` property for a specific server.

## Default Templates

The IceGrid registry can be configured to supply any number of default template descriptors for use in your applications. The configuration property `IceGrid.Registry.DefaultTemplates` specifies the path name of an XML file containing template definitions. One such template file is provided in the Ice distribution as `config/templates.xml`, which contains helpful templates for deploying Ice services such as `IcePatch2` and `Glacier2`.

The template file must use the structure shown below:

## XML

```

<icegrid>
 <application name="DefaultTemplates">
 <server-template id="EncoderServerTemplate">
 ...
 </server-template>
 </application>
</icegrid>

```

The name you give to the application is not important, and you may only define `server` and `service` templates within it. After configuring the registry to use this file, your default templates become available to every application that imports them.

The descriptor for each application indicates whether the default templates should be imported. (By default they are not imported.) If the templates are imported, they are essentially copied into the application descriptor and treated no differently than templates defined by the application itself. As a result, changes to the file containing default templates have no effect on existing application descriptors. In XML, the attribute `import-default-templates` determines whether the default templates are imported, as shown in the following example:

## XML

```
<icegrid>
 <application name="Ripper" import-default-templates="true">
 ...
 </application>
</icegrid>
```

### Using Templates with icegridadmin

The IceGrid administration tools allow you to inspect templates and instantiate new servers dynamically. First, let us ask icegridadmin to describe the server template we created earlier:

```
$ icegridadmin --Ice.Config=/opt/ripper/config
>>> server template describe Ripper EncoderServerTemplate
```

This command generates the following output:

```
server template `EncoderServerTemplate'
{
 parameters = `index exepath'
 server `EncoderServer${index}'
 {
 exe = `${exepath}'
 activation = `on-demand'
 properties
 {
 EncoderAdapter.Endpoints = `tcp'
 }
 adapter `EncoderAdapter'
 {
 id = `EncoderAdapter${index}'
 replica group id =
 endpoints = `tcp'
 register process = `false'
 server lifetime = `true'
 }
 }
}
```

Notice that the server ID is a parameterized value; it cannot be evaluated until the template is instantiated with values for its parameters.

Next, we can use icegridadmin to create an instance of the encoder server template on a new node:

```
>>> server template instantiate Ripper Node3 EncoderServerTemplate
index=3
```

The command requires that we identify the application, node and template, as well as supply any parameters needed by the template. The new server instance is permanently added to the registry's database, but if we intend to keep this configuration it is a good idea to update the XML description of our application to reflect these changes and avoid potential synchronization issues.

## IceBox Integration with IceGrid

IceGrid makes it easy to configure an [IceBox](#) server with one or more services.

On this page:

- [Deploying an IceBox Server](#)
- [Service Templates](#)
- [Advanced Service Templates](#)

### Deploying an IceBox Server

An IceBox server shares many of the same characteristics as other servers, but its special requirements necessitate a new [descriptor](#). Unlike other servers, an IceBox server generally hosts multiple independent services, each requiring its own communicator instance and configuration file.

As an example, the following application deploys an IceBox server containing one service:

**XML**

```

<icegrid>
 <application name="IceBoxDemo">
 <node name="Node">
 <icebox id="IceBoxServer" exe="/opt/Ice/bin/icebox"
activation="on-demand">
 <service name="ServiceA" entry="servicea:create">
 <adapter name="{service}" endpoints="tcp"/>
 </service>
 </icebox>
 </node>
 </application>
</icegrid>

```

It looks very similar to a server descriptor. The most significant difference is the [service descriptor](#), which is constructed much like a server in that you can declare its attributes such as object adapters and configuration properties. The order in which services are defined determines the order in which they are loaded by the IceBox server.

The value of the adapter's `name` attribute needs additional explanation. The symbol `service` is one of the names [reserved by IceGrid](#). In the context of a service descriptor, `{service}` is replaced with the service's name, and so the object adapter is also named `ServiceA`.

### Service Templates

If you are familiar with [templates](#) in general, an IceBox [service template](#) is readily understandable:

## XML

```

<icegrid>
 <application name="IceBoxApp">
 <service-template id="ServiceTemplate">
 <parameter name="name"/>
 <service name="\${name}" entry="DemoService:create">
 <adapter name="\${service}" endpoints="default"/>
 <property name="\${service}.Identity"
value="\${server}-\${service}"/>
 </service>
 </service-template>
 <node name="Node1">
 <icebox id="IceBoxServer" endpoints="default"
exe="/opt/Ice/bin/icebox" activation="on-demand">
 <service-instance template="ServiceTemplate"
name="Service1"/>
 </icebox>
 </node>
 </application>
</icegrid>

```

In this application, an IceBox server is deployed on a node and has one service instantiated from the service template. Of particular interest is the `property` descriptor, which uses another `reserved name` `server` to form the property value. When the template is instantiated by the `service instance descriptor`, the symbol `\${server}` is replaced with the name of the enclosing server, so the property definition expands as follows:

```
Service1.Identity=IceBoxServer-Service1
```

As with server instances, you can specify additional properties for the service instance without modifying the template. These properties can be defined in the `service-instance` element, as shown below:

**XML**

```
<icegrid>
 <application name="IceBoxApp">
 ...
 <node name="Node1">
 <icebox id="IceBoxServer" endpoints="default"
 exe="/opt/Ice/bin/icebox" activation="on-demand">
 <service-instance template="ServiceTemplate"
name="Service1">
 <properties>
 <property name="Ice.Trace.Network" value="1"/>
 </properties>
 </service-instance>
 </icebox>
 </node>
 </application>
</icegrid>
```

**Advanced Service Templates**

A more sophisticated use of templates involves instantiating a service template in a [server template](#):

## XML

```

<icegrid>
 <application name="IceBoxApp">
 <service-template id="ServiceTemplate">
 <parameter name="name"/>
 <service name="{name}" entry="DemoService:create">
 <adapter name="{service}" endpoints="default"/>
 <property name="{name}.Identity"
value="{server}-{name}"/>
 </service>
 </service-template>
 <server-template id="ServerTemplate">
 <parameter name="id"/>
 <icebox id="{id}" endpoints="default"
exe="/opt/Ice/bin/icebox" activation="on-demand">
 <service-instance template="ServiceTemplate"
name="Service1"/>
 </icebox>
 </server-template>
 <node name="Node1">
 <server-instance template="ServerTemplate"
id="IceBoxServer"/>
 </node>
 </application>
</icegrid>

```

This application is equivalent to our first example of [service templates](#). Now, however, the process of deploying an identical server on several nodes has become much simpler.

If you need the ability to customize the configuration of a particular service instance, your server instance can define a [property set](#) that applies only to the desired service:

## XML

```

<icegrid>
 <application name="IceBoxApp">
 <node name="Node1">
 <server-instance template="ServerTemplate"
id="IceBoxServer">
 <properties service="Service1">
 <property name="Ice.Trace.Network" value="1"/>
 </properties>
 </server-instance>
 </node>
 </application>
</icegrid>

```

As this example demonstrates, the `service` attribute of the property set denotes the name of the target service.

## Object Adapter Replication

As an implementation of an Ice location service, IceGrid supports [object adapter replication](#). An application defines its replica groups and their participating object adapters using descriptors, and IceGrid generates the server configurations automatically.

On this page:

- [Deploying a Replica Group](#)
- [Replica Group Membership](#)
- [Using Replica Groups in the Ripper Application](#)
  - [Adding a Replica Group to the Ripper Deployment](#)
  - [Using a Replica Group in the Ripper Client](#)

### Deploying a Replica Group

The [descriptor](#) that defines a [replica group](#) can optionally declare [well-known objects](#) as well as configure the group to determine its behavior during locate requests. Consider this example:

**XML**

```

<icegrid>
 <application name="ReplicaApp">
 <replica-group id="ReplicatedAdapter">
 <object identity="TheObject" type="::Demo::ObjectType"/>
 </replica-group>
 <node name="Node">
 <server id="ReplicaServer" activation="on-demand"
exe="/opt/replica/bin/server">
 <adapter name="TheAdapter" endpoints="default"
replica-group="ReplicatedAdapter"/>
 </server>
 </node>
 </application>
</icegrid>

```

The adapter's descriptor declares itself to be a member of the replica group `ReplicatedAdapter`, which must have been previously created by a replica group descriptor.

The replica group `ReplicatedAdapter` declares a well-known object so that an indirect proxy of the form `TheObject` is equivalent to the indirect proxy `TheObject@ReplicatedAdapter`. Since this trivial example defines only one adapter in the replica group, the proxy `TheObject` is also equivalent to `TheObject@TheAdapter`.

### Replica Group Membership

An object adapter participates in a replica group by specifying the group's ID in the adapter's `ReplicaGroupId` configuration property. Identifying the replica group in the IceGrid descriptor for an object adapter causes the node to include the equivalent `ReplicaGroupId` property in the configuration file it generates for the server.

By default, the IceGrid registry requires the membership of a replica group to be statically defined. When you create a descriptor for an object adapter that identifies a replica group, the registry adds that adapter to the group's list of valid members. During an adapter's activation, when it describes its endpoints to the registry, an adapter that also claims membership in a replica group is validated against the registry's internal list.

In a properly configured IceGrid application, this activity occurs without incident, but there are situations in which validation can fail. For example, adapter activation fails if an adapter's ID is changed without notifying the registry, such as by manually modifying the server configuration file that was generated by a node.

It is also possible for activation to fail when the IceGrid registry is being used solely as a location service, in which case descriptors have not been created and therefore the registry has no advance knowledge of the replica groups or their members. In this situation, adapter activation causes the server to receive `NotRegisteredException` unless the registry is configured to allow dynamic registration, which you can do by defining the following property:

```
IceGrid.Registry.DynamicRegistration=1
```

With this configuration, a replica group is created implicitly as soon as an adapter declares membership in it, and any adapter is allowed to participate.

The use of dynamic registration often leads to the accumulation of obsolete replica groups and adapters in the registry. The [IceGrid administration tools](#) allow you to inspect and clean up the registry's state.

## Using Replica Groups in the Ripper Application

Replication is a perfect fit for the ripper application. The collection of encoder factory objects should be treated as a single logical object, and replication makes that possible.

### Adding a Replica Group to the Ripper Deployment

Adding a replica group descriptor to our application is very straightforward:

## XML

```

<icegrid>
 <application name="Ripper">
 <replica-group id="EncoderAdapters">
 <object identity="EncoderFactory"
type="::Ripper::MP3EncoderFactory"/>
 </replica-group>
 <server-template id="EncoderServerTemplate">
 <parameter name="index"/>
 <parameter name="exepath" default="/opt/ripper/bin/server"/>
 <server id="EncoderServer${index}" exe="${exepath}"
activation="on-demand">
 <adapter name="EncoderAdapter"
replica-group="EncoderAdapters"
 endpoints="tcp"/>
 </server>
 </server-template>
 <node name="Node1">
 <server-instance template="EncoderServerTemplate"
index="1"/>
 </node>
 <node name="Node2">
 <server-instance template="EncoderServerTemplate"
index="2"/>
 </node>
 </application>
</icegrid>

```

The new descriptor adds the replica group called `EncoderAdapters` and registers a well-known object with the identity `EncoderFactory`. The adapter descriptor in the server template has been changed to declare its membership in the replica group.

### Using a Replica Group in the Ripper Client

In comparison to the examples that demonstrated [querying for well-known objects](#), the new version of our client has become much simpler:

```

Ice::ObjectPrx obj = communicator->stringToProxy("EncoderFactory");
Ripper::MP3EncoderFactoryPrx factory =
Ripper::MP3EncoderFactoryPrx::checkedCast(obj);
Ripper::MP3EncoderPrx encoder = factory->createEncoder();

```

The client no longer needs to use the `IceGrid::Query` interface, but simply creates a proxy for a well-known object and lets the Ice run time transparently interact with the location service. In response to a locate request for `EncoderFactory`, the registry returns a proxy containing the endpoints of both object adapters. The Ice run time in the client selects one of the endpoints at random, meaning we have now lost some functionality compared to the prior example in which system load was considered when selecting an endpoint. We will learn how to rectify this situation in our discussion of [load balancing](#).

**See Also**

- [Terminology](#)
- [Replica-Group Descriptor Element](#)
- [Object Descriptor Element](#)
- [Well-Known Objects](#)
- [Load Balancing](#)

## Load Balancing

[Replication](#) is an important IceGrid feature but, when combined with load balancing, replication becomes even more useful.

IceGrid nodes regularly report the system load of their hosts to the registry. The replica group's configuration determines whether the registry actually considers system load information while processing a locate request. Its configuration also specifies how many replicas to include in the registry's response.

IceGrid's load balancing capability assists the client in obtaining an initial set of endpoints for the purpose of [establishing a connection](#). Once a client has established a connection, all subsequent requests on the proxy that initiated the connection are normally sent to the same server without further consultation with the registry. As a result, the registry's response to a locate request can only be viewed as a snapshot of the replicas at a particular moment. If system loads are important to the client, it must take steps to periodically contact the registry and [update its endpoints](#).

On this page:

- [Replica Group Load Balancing](#)
- [Load Balancing Types](#)
- [Using Load Balancing in the Ripper Application](#)
- [Interacting with Object Replicas](#)
- [Custom Load Balancing Strategies](#)
  - [Overview of Custom Load Balancing](#)
    - [The Registry Plug-in Facade Object](#)
    - [Implementing a Registry Plug-in](#)
    - [Installing a Registry Plug-in](#)
    - [Filter Implementation Techniques](#)
  - [Implementing a Custom Replica Group Filter](#)
  - [Implementing a Custom Type Filter](#)

## Replica Group Load Balancing

A [replica group descriptor](#) optionally contains a [load balancing descriptor](#) that determines how system loads are used in locate requests. The load balancing descriptor specifies the following information:

- [Type](#)  
Several [load balancing types](#) are supported.
- [Sampling interval](#)  
One of the load balancing types considers system load statistics, which are reported by each node at regular intervals. The replica group can specify a sampling interval of one, five, or fifteen minutes. Choosing a sampling interval requires balancing the need for up-to-date load information against the desire to minimize transient spikes. On Unix platforms, the node reports the system's load average for the selected interval, while on Windows the node reports the CPU utilization averaged over the interval.
- [Number of replicas](#)  
The replica group can instruct the registry to return the endpoints of one (the default) or more object adapters. If the specified number  $N$  is larger than one, the proxy returned in response to a locate request contains the endpoints of at most  $N$  object adapters. If  $N$  is 0, the proxy contains the endpoints of all the object adapters. The Ice run time in the client selects one of these endpoints at random when [establishing a connection](#).

For example, the descriptor shown below uses adaptive load balancing to return the endpoints of the two least-loaded object adapters sampled with five-minute intervals:

**XML**

```
<replica-group id="ReplicatedAdapter">
 <load-balancing type="adaptive" load-sample="5" n-replicas="2"/>
</replica-group>
```

The type must be specified, but the remaining attributes are optional.

As of Ice 3.5, IceGrid ignores the object adapters of a [disabled server](#) when executing a locate request, meaning the client that initiated the locate request will not receive the endpoints for any of these object adapters.

As of Ice 3.6, you can optionally use custom load balancing strategies by installing [replica group filters](#).

## Load Balancing Types

A replica group can select one of the following load balancing types:

- **Random**  
Random load balancing selects the requested number of object adapters at random. The registry does not consider system load for a replica group with this type.
- **Adaptive**  
Adaptive load balancing uses system load information to choose the least-loaded object adapters over the requested sampling interval. This is the only load balancing type that uses sampling intervals.
- **Round Robin**  
Round robin load balancing returns the least recently used object adapters. The registry does not consider system load for a replica group with this type. Note that the round-robin information is not shared between registry replicas; each replica maintains its own notion of the "least recently used" object adapters.
- **Ordered**  
Ordered load balancing selects the requested number of object adapters by priority. A priority can be set for each object adapter member of the replica group. If you define several object adapters with the same priority, IceGrid will order these object adapters according to their order of appearance in the descriptor.

Choosing the proper type of load balancing is highly dependent on the needs of client applications. Achieving the desired load balancing and fail-over behavior may also require the cooperation of your clients. To that end, it is very important that you understand how and when the Ice run time uses a [locator to resolve indirect proxies](#).

## Using Load Balancing in the Ripper Application

The only change we need to make to the ripper application is the addition of a load balancing descriptor:

## XML

```

<icegrid>
 <application name="Ripper">
 <replica-group id="EncoderAdapters">
 <load-balancing type="adaptive"/>
 <object identity="EncoderFactory"
type="::Ripper::MP3EncoderFactory"/>
 </replica-group>
 <server-template id="EncoderServerTemplate">
 <parameter name="index"/>
 <parameter name="exepath" default="/opt/ripper/bin/server"/>
 <server id="EncoderServer${index}" exe="${exepath}"
activation="on-demand">
 <adapter name="EncoderAdapter"
replica-group="EncoderAdapters"
 endpoints="tcp"/>
 </server>
 </server-template>
 <node name="Node1">
 <server-instance template="EncoderServerTemplate"
index="1"/>
 </node>
 <node name="Node2">
 <server-instance template="EncoderServerTemplate"
index="2"/>
 </node>
 </application>
</icegrid>

```

Using adaptive load balancing, we have regained the functionality we forfeited when we [introduced replica groups](#). Namely, we now select the object adapter on the least-loaded node, and no changes are necessary in the client.

## Interacting with Object Replicas

In some applications you may have a need for interacting directly with the replicas of an object. You might be tempted to call `ice_getEndpoints` on the proxy of a replicated object in an effort to obtain the endpoints of all replicas, but that is not the correct solution because the proxy is indirect and therefore contains no endpoints. The proper approach is to [query well-known objects](#) using the `findAllReplicas` operation.

## Custom Load Balancing Strategies

As of Ice 3.6, the IceGrid registry allows you to plug in custom load balancing implementations that the registry invokes to filter its query results. Two kinds of filters are supported:

- **Replica group filter**  
The registry invokes a replica group filter each time a client requests the endpoints of a replica group or object adapter, as well as for calls to `findAllReplicas`. The registry passes information about the query that the filter can use in its implementation,

including the list of object adapters participating in the replica group whose nodes are active at the time of the request. The object adapter list is initially ordered using the [load balancing type](#) configured for the replica group; the filter can modify this list however it chooses.

- **Type filter**

The registry invokes a type filter for each query that a client issues to [find a well-known object by type](#) using the operations `findObjectByType`, `findAllObjectsByType`, and `findObjectByTypeOnLeastLoadedNode`. Included in the information passed to the filter is a list of proxies for the matching well-known objects; the filter implementation decides which of these proxies are returned to the client.

In the sections below we describe how to implement these filters.

## Overview of Custom Load Balancing

Filters are installed into the IceGrid registry using the standard Ice [plug-in facility](#). The registry is implemented in C++, therefore the filters must be implemented in C++.

### *The Registry Plug-in Facade Object*

During initialization, your plug-in will obtain a reference to a facade object with which it can register one or more filters. A filter typically retains a reference to this facade object because it offers a number of useful methods that the filter might need during its implementation. The `RegistryPluginFacade` class provides the following methods:

## C++

```

namespace IceGrid {
class RegistryPluginFacade : virtual public Ice::LocalObject {
public:
 void addReplicaGroupFilter(const std::string& id, const
IceGrid::ReplicaGroupFilterPtr& filter);
 bool removeReplicaGroupFilter(const std::string& id, const
IceGrid::ReplicaGroupFilterPtr& filter);

 void addTypeFilter(const std::string& id, const
IceGrid::TypeFilterPtr& filter);
 bool removeTypeFilter(const std::string& id, const
IceGrid::TypeFilterPtr& filter);

 IceGrid::ApplicationInfo getApplicationInfo(const std::string& name)
const;

 IceGrid::ServerInfo getServerInfo(const std::string& serverId)
const;

 std::string getAdapterServer(const std::string& adapterId) const;
 std::string getAdapterApplication(const std::string& adapterId)
const;
 std::string getAdapterNode(const std::string& adapterId) const;
 IceGrid::AdapterInfoSeq getAdapterInfo(const std::string& adapterId)
const;
 std::string getPropertyForAdapter(const std::string& adapterId,
const std::string& name) const;

 IceGrid::ObjectInfo getObjectInfo(const Ice::Identity& id) const;

 IceGrid::NodeInfo getNodeInfo(const std::string& name) const;
 IceGrid::LoadInfo getNodeLoad(const std::string& name) const;
};
typedef ... RegistryPluginFacadePtr;

RegistryPluginFacadePtr getRegistryPluginFacade();
}

```

There are methods for adding and removing replica group and type filters, along with a number of methods for obtaining information about the deployment. As you can see, a great deal of information is available to a filter implementation for use in making its decisions. The data structures returned by these methods correspond directly to their [XML descriptors](#); you can also review the Slice definitions of the IceGrid data types for more information.

The methods are described below:

- `void addReplicaGroupFilter(const std::string& id, const IceGrid::ReplicaGroupFilterPtr& filter)`  
Adds a replica group filter with the given identifier. The identifier must match the `filter` attribute of a [replica-group descriptor](#). The registry maintains a list of filters for each identifier. If you register more than one filter with the same identifier, the registry invokes each one in turn, in the order of registration. To add a replica group filter for dynamically registered replica groups, you should use the empty string for the identifier.

- `bool removeReplicaGroupFilter(const std::string& id, const IceGrid::ReplicaGroupFilterPtr& filter)`  
Removes an existing replica group filter that matches the given identifier and smart pointer. Returns true if a match was found, false otherwise.
- `void addTypeFilter(const std::string& id, const IceGrid::TypeFilterPtr& filter)`  
Adds a type filter with the given identifier. The registry maintains a list of filters for each identifier. If you register more than one filter with the same identifier, the registry invokes each one in turn, in the order of registration.
- `bool removeTypeFilter(const std::string& id, const IceGrid::TypeFilterPtr& filter)`  
Removes an existing type filter that matches the given identifier and smart pointer. Returns true if a match was found, false otherwise.
- `IceGrid::ApplicationInfo getApplicationInfo(const std::string& name) const`  
Returns the descriptor for the application with the given name. Raises `IceGrid::ApplicationNotExistException` if no match is found.
- `IceGrid::ServerInfo getServerInfo(const std::string& serverId) const`  
Returns the descriptor for the server with the given identifier. Raises `IceGrid::ServerNotExistException` if no match is found.
- `std::string getAdapterServer(const std::string& adapterId) const`  
Returns the identifier of the server hosting the object adapter with the given adapter identifier. Returns an empty string if no match is found.
- `std::string getAdapterApplication(const std::string& adapterId) const`  
Returns the name of the application containing the given object adapter identifier. Returns an empty string if no match is found.
- `std::string getAdapterNode(const std::string& adapterId) const`  
Returns the name of the node containing the given object adapter identifier. Returns an empty string if no match is found.
- `IceGrid::AdapterInfoSeq getAdapterInfo(const std::string& adapterId) const`  
If `adapterId` is a replica group identifier, this method returns a sequence of adapter descriptors for all of the replicas. Otherwise, this method returns a sequence containing one descriptor for the given object adapter. Raises `IceGrid::AdapterNotExistException` if no match is found.
- `std::string getPropertyForAdapter(const std::string& adapterId, const std::string& name) const`  
Obtains the value of a server configuration property with the key name for the server hosting the object adapter identified by `adapterId`. Returns an empty string if no match is found.
- `IceGrid::ObjectInfo getObjectInfo(const Ice::Identity& id) const`  
Returns information about an object with the given identity. Raises `IceGrid::ObjectNotRegisteredException` if no match is found.
- `IceGrid::NodeInfo getNodeInfo(const std::string& name) const`  
Returns the descriptor for the node with the given name. Raises `IceGrid::NodeNotExistException` if no match is found.
- `IceGrid::LoadInfo getNodeLoad(const std::string& name) const`  
Returns load information for the node with the given name. Raises `IceGrid::NodeNotExistException` if no match is found.

Methods that require access to deployment information raise `IceGrid::RegistryUnreachableException` if called before the registry has fully initialized itself.

### ***Implementing a Registry Plug-in***

The [API](#) for creating an Ice plug-in using C++ requires a factory function with external linkage, along with a class that implements the `Ice::Plugin` local Slice interface. We can use the code from the example in `demo/IceGrid/customLoadBalancing` to illustrate these points. First, the factory function instantiates and returns the plug-in:

**C++**

```
extern "C" {
ICE_DECLSPEC_EXPORT Ice::Plugin*
createRegistryPlugin(const Ice::CommunicatorPtr& communicator, const
string&, const Ice::StringSeq&)
{
 return new RegistryPluginI(communicator);
}
}
```

The plug-in class is straightforward:

**C++**

```
class RegistryPluginI : public Ice::Plugin {
public:
 RegistryPluginI(const Ice::CommunicatorPtr& communicator) :
 _communicator(communicator) {}

 virtual void initialize()
 {
 IceGrid::RegistryPluginFacadePtr facade =
IceGrid::getRegistryPluginFacade();
 if(facade)
 {
 facade->addReplicaGroupFilter("filterByCurrency", new
ReplicaGroupFilterI(facade));
 }
 }

 virtual void destroy() {}

private:
 const Ice::CommunicatorPtr _communicator;
};
```

The `initialize` method calls `getRegistryPluginFacade` to obtain a smart pointer for the registry's `facade` object. The plug-in uses this object to install a replica group filter.

We describe filter implementations in more detail below.

### ***Installing a Registry Plug-in***

Continuing with our example from `demo/IceGrid/customLoadBalancing`, we use the following property to install our plug-in in the `IceGrid` registry:

```
Ice.Plugin.RegistryPlugin=RegistryPlugin:createRegistryPlugin
```

The `Ice.Plugin` property must be defined in the registry's configuration file.

Make sure to configure all of the replicas to load the same registry plug-ins, otherwise a client could get different behavior depending on which replica it's currently using.

### Filter Implementation Techniques

A filter may require client-specific information in order to assemble its list of results. We recommend using [request contexts](#) for this purpose. Briefly, a request context is a dictionary of key/value string pairs that a client can configure and send along as "out of band" metadata accompanying a request. Ice provides several ways for a client to establish a request context:

- Implicit - provides a default request context for every request on all proxies
- Per-proxy - configures a default request context for every request on a particular proxy
- Explicit - specifies a request context at the time of invocation, overriding any default context

Our goal here is to transfer information from a client to a filter. Consequently, we don't recommend using implicit contexts because the context will add overhead to every invocation the client makes, not just the ones that involve the filter. To decide whether to use per-proxy or explicit contexts, we first must understand the circumstances in which each kind of filter receives a request context:

- Replica group filter

Most invocations involving a replica group filter occur when the Ice run time in a client issues requests on a registry. This internal activity is triggered by the client's invocation on a proxy, but Ice doesn't use the client's proxy or the request context that the client may have configured for its proxy or passed explicitly to the invocation. Rather, the Ice run time uses the locator that the client configured for its proxy or communicator. As a result, the request contexts passed to a replica group filter are those configured for the *locator* proxy. (The only exception is when a client invokes `findAllReplicas` directly on the registry via its `Query` interface; refer to the discussion of type filters below for more details.)

There are several ways you can configure a request context for the locator proxy. If a client configures its locator proxy statically using properties, the simplest solution is to add [Context properties](#) to the client's configuration, such as:

```
Ice.Default.Locator=...
Ice.Default.Locator.Context.someKey=someValue
```

If you need to define the context at run time, you can obtain the locator proxy by calling `getDefaultLocator` on the communicator, create a new locator proxy with the desired context by calling `ice_context`, and then replace the locator proxy by calling `setDefaultLocator`.

Both of these approaches are examples of per-proxy request contexts.

- Type filter

Invocations involving type filters occur when a client invokes directly on the registry using its `Query` interface. To use per-proxy request contexts, configure the `Query` proxy as necessary. Explicit request contexts can also be used when querying the registry.

So far we've discussed how client-specific information can be passed to a filter, but what if the filter needs to obtain more information about the object adapters (in the case of a replica group filter) or objects (in the case of a type filter) in order to perform its duties? This is where the registry's [facade object](#) comes in handy, as with it the filter can retrieve information about the deployment. For example, a replica group filter can use server-specific properties as a form of metadata. The registry supplies the filter with a list of object adapter identifiers; each object adapter is hosted by a server, and the filter can look up property values for that server using the facade. The sample filter in `demo/IceGrid/customLoadBalancing` uses this technique, and we describe it in more detail below.

### Implementing a Custom Replica Group Filter

A replica group filter must define a subclass of `ReplicaGroupFilter`:

**C++**

```

namespace IceGrid {
class ReplicaGroupFilter : virtual public Ice::LocalObject {
public:
 virtual Ice::StringSeq filter(const std::string& id,
 const Ice::StringSeq& adapters,
 const Ice::ConnectionPtr& connection,
 const Ice::Context& context);
};
}

```

The registry passes the following arguments to the `filter` method:

- `id`  
The replica group identifier involved in this request.
- `adapters`  
A sequence of object adapter identifiers denoting the object adapters participating in the replica group whose nodes are active at the time of the request. The object adapter list is initially ordered using the [load balancing type](#) configured for the replica group.
- `connection`  
The incoming connection from the client to the registry.
- `context`  
The [request context](#) that accompanied the request.

The implementation returns a sequence containing zero or more object adapter identifiers. The registry may truncate this list if the filter supplies more object adapters than the `n-replicas` value configured for the replica group's load balancing policy, but the registry will not change the ordering.

The `filter` implementation must not block.

The C++ example in `demo/IceGrid/customLoadBalancing` uses a replica group filter to select only those object adapters that support the currency requested by the client. The replica group's descriptor specifies the filter:

```

<replica-group id="ReplicatedPricingAdapter" filter="filterByCurrency">
 <load-balancing type="random"/>
 <object identity="pricing" type="::Demo::PricingEngine"/>
</replica-group>

```

Notice that the filter identifier `filterByCurrency` matches that used when the plug-in [registered the filter](#).

In this example, the client uses a [request context](#) to indicate the desired currency. The context is configured on the locator proxy in the client's configuration file:

```

Ice.Default.Locator=...
Ice.Default.Locator.Context.currency=USD

```

Here we use the `Context` proxy property to statically assign a request context to the locator proxy, which means every invocation on the locator proxy includes the key/value pair `currency/USD`.

In addition to configuring the replica group filter, the deployment descriptor plays another important role here by defining server-specific

properties that the filter uses in its implementation:

```

<server-template id="PricingServer">
 <parameter name="index"/>
 <parameter name="currencies"/>
 <server id="PricingServer- $\{\text{index}\}$ " exe="./server"
activation="on-demand">
 <adapter name="Pricing" endpoints="tcp -h localhost"
replica-group="ReplicatedPricingAdapter"/>
 <property name="Identity" value="pricing"/>
 <property name="Currencies" value=" $\{\text{currencies}\}$ " />
 ...
</server>
</server-template>

<node name="node1">
 <server-instance template="PricingServer" index="1" currencies="EUR,
GBP, JPY"/>
 <server-instance template="PricingServer" index="2" currencies="USD,
GBP, AUD"/>
 <server-instance template="PricingServer" index="3" currencies="EUR,
USD, INR"/>
 <server-instance template="PricingServer" index="4" currencies="JPY,
GBP, AUD"/>
 <server-instance template="PricingServer" index="5" currencies="GBP,
AUD"/>
 <server-instance template="PricingServer" index="6" currencies="EUR,
USD"/>
</node>

```

As a convenience, the descriptor file uses a server template to define several servers, with each server supporting a specific set of currencies. The template adds to the property set of each server a property named `Currencies` representing the currencies that the server supports.

Finally, you can see how all of this ties together in the filter implementation:

```

Ice::StringSeq
ReplicaGroupFilterI::filter(const string& replicaGroupId,
 const Ice::StringSeq& adapters,
 const Ice::ConnectionPtr& connection,
 const Ice::Context& ctx)
{
 Ice::Context::const_iterator p = ctx.find("currency");
 if(p == ctx.end())
 {
 return adapters;
 }

 string currency = p->second;

 Ice::StringSeq filteredAdapters;
 for(Ice::StringSeq::const_iterator p = adapters.begin(); p !=
adapters.end(); ++p)
 {
 if(_facade->getPropertyForAdapter(*p,
"Currencies").find(currency) != string::npos)
 {
 filteredAdapters.push_back(*p);
 }
 }
 return filteredAdapters;
}

```

The code first checks the request context for a value associated with the key `currency` and returns the adapter list unmodified if no entry is found. Next, the method builds a new list of adapters by iterating over the adapter list in its existing order and calling `getPropertyForAdapter` on the facade for each adapter. This method uses the registry's deployment information to find the server hosting the given adapter and then searches the server's configuration properties for one matching the given property name. If the `Currencies` property contains the client's specified currency, the adapter is added to the list that is eventually returned by the filter.

As this example demonstrates, request contexts are a convenient way to supply a filter with client-specific information, and server properties can serve as a simple database when a filter needs to tailor its results based on server attributes.

### Implementing a Custom Type Filter

A replica group filter must define a subclass of `TypeFilter`:

**C++**

```

namespace IceGrid {
class TypeFilter : virtual public Ice::LocalObject {
public:
 virtual Ice::ObjectProxySeq filter(const std::string& type,
 const Ice::ObjectProxySeq&
proxies,
 const Ice::ConnectionPtr&
connection,
 const Ice::Context& context);
};
}

```

The registry passes the following arguments to the `filter` method:

- `type`  
The type identifier involved in this request.
- `proxies`  
A sequence of proxies denoting the objects that matched the type.
- `connection`  
The incoming connection from the client to the registry.
- `context`  
The [request context](#) that accompanied the request.

The implementation returns a sequence containing zero or more proxies.

The `filter` implementation must not block.

Refer to the previous section for more information on implementing a filter.

## Resource Allocation using IceGrid Sessions

IceGrid provides a resource allocation facility that coordinates access to the objects and servers of an IceGrid application. To allocate a resource for exclusive use, a client must first establish a session by authenticating itself with the IceGrid registry or a Glacier2 router, after which the client may reserve objects and servers that the application indicates are allocatable. The client should release the resource when it is no longer needed, otherwise IceGrid reclaims it when the client's session terminates or expires due to inactivity.

An allocatable server offers at least one allocatable object. The server is considered to be allocated when its first allocatable object is claimed, and is not released until all of its allocated objects are released. While the server is allocated by a client, no other clients can allocate its objects.

On this page:

- [Creating an IceGrid Session](#)
- [Controlling Access to IceGrid Sessions](#)
- [Allocating Objects with an IceGrid Session](#)
- [Allocating Servers with an IceGrid Session](#)
- [Security Considerations for Allocated Resources](#)
- [Deploying Allocatable Resources](#)
- [Using Resource Allocation in the Ripper Application](#)

### Creating an IceGrid Session

A client must create an IceGrid session before it can allocate objects. If you have configured a Glacier2 router to use [IceGrid's session managers](#), the client's [router session](#) satisfies this requirement.

In the absence of Glacier2, an IceGrid client invokes `createSession` or `createSessionFromSecureConnection` on IceGrid's `Registry` interface to create a session:

## Slice

```

module IceGrid {
 exception PermissionDeniedException {
 string reason;
 };

 interface Session extends Glacier2::Session {
 idempotent void keepAlive();
 ...
 };

 interface Registry {
 Session* createSession(string userId, string password)
 throws PermissionDeniedException;

 Session* createSessionFromSecureConnection()
 throws PermissionDeniedException;

 idempotent int getSessionTimeout();

 idempotent int getACMTimeout();

 ...
 };
};

```

The `createSession` operation expects a username and password and returns a session proxy if the client is allowed to create a session. By default, IceGrid does not allow the creation of sessions. You must define the registry property `IceGrid.Registry.PermissionsVerifier` with the proxy of a permissions verifier object to [enable session creation](#) with `createSession`.

The `createSessionFromSecureConnection` operation does not require a username and password because it uses the credentials supplied by an SSL connection to authenticate the client. As with `createSession`, you must [enable session creation](#) by configuring the proxy of a permissions verifier object so that clients can use `createSessionFromSecureConnection` to create a session. In this case, the property is `IceGrid.Registry.SSLPermissionsVerifier`.

To create a session, the client obtains the registry proxy by converting the well-known proxy string `"IceGrid/Registry"` to a proxy object with the communicator, downcasts the proxy to the `IceGrid::Registry` interface, and invokes one of the operations. The sample code below demonstrates how to do it in C++; the code will look very similar in other language mappings.

**C++**

```
Ice::ObjectPrx base = communicator->stringToProxy("IceGrid/Registry");
IceGrid::RegistryPrx registry =
IceGrid::RegistryPrx::checkedCast(base);
string username = ...;
string password = ...;
IceGrid::SessionPrx session;
try {
 session = registry->createSession(username, password);
} catch (const IceGrid::PermissionDeniedException & ex) {
 cout << "permission denied:\n" << ex.reason << endl;
}
}
```

The [identity of the registry object](#) may change based on its configuration settings.

After creating the session, the client must keep it alive to prevent it from expiring. You have two options for keeping a session alive:

1. Call `Registry::getSessionTimeout` and periodically invoke `Session::keepAlive` every *timeout* (or less) seconds
2. Call `Registry::getACMTimeout` and configure [ACM settings](#) on the connection

We recommend using the second approach, which you can implement as follows:

**C++**

```
int acmTimeout = registry->getACMTimeout();
if (acmTimeout > 0) {
 Ice::ConnectionPtr conn = session->ice_getCachedConnection();
 conn->setACM(acmTimeout, IceUtil::None, Ice::HeartbeatAlways);
}
}
```

Enabling heartbeats on the connection causes Ice to automatically send a heartbeat message at regular intervals determined by the given timeout value. The server ignores these messages, but they serve the purpose of keeping the session alive.

The ACM features shown here were introduced in Ice 3.6.

If a session times out, or if the client explicitly terminates the session by invoking its `destroy` operation, IceGrid automatically releases all objects allocated using that session.

## Controlling Access to IceGrid Sessions

As described above, you must configure the IceGrid registry with the proxy of at least one permissions verifier object to enable session creation:

- `IceGrid.Registry.PermissionsVerifier`  
This property supplies the proxy of an object that implements the interface `Glacier2::PermissionsVerifier`. Defining this property allows clients to create sessions using `createSession`.

- `IceGrid.Registry.SSLPermissionsVerifier`

This property supplies the proxy of an object that implements the interface `Glacier2::SSLPermissionsVerifier`. Defining this property allows clients to create sessions using `createSessionFromSecureConnection`.

IceGrid supplies built-in permissions verifier objects:

- A null permissions verifier for TCP/IP. This object accepts any username and password and should only be used in a secure environment where no access control is necessary. You select this verifier object by defining the following configuration property:

```
IceGrid.Registry.PermissionsVerifier=<instance-name>/NullPermissionsVerifier
```

Note that you have to substitute the correct `instance name` for the object identity category.

- A null permissions verifier for SSL, analogous to the one for TCP/IP. You select this verifier object by defining the following configuration property:

```
IceGrid.Registry.SSLPermissionsVerifier=<instance-name>/NullSSLPermissionsVerifier
```

- A file-based permissions verifier. This object uses an access control list in a file that contains username-password pairs. The format of the password file is the same as the format of [Glacier2 password files](#). You enable this verifier implementation by defining the configuration property `IceGrid.Registry.CryptPasswords` with the pathname of the password file. Note that this property is ignored if you specify the proxy of a permissions verifier object using `IceGrid.Registry.PermissionsVerifier`.

You can also [implement your own permissions verifier object](#).

## Allocating Objects with an IceGrid Session

A client allocates objects using the session proxy returned from `createSession` or `createSessionFromSecureConnection`. The proxy supports the `Session` interface shown below:

## Slice

```

module IceGrid {
 exception ObjectNotRegisteredException {
 Ice::Identity id;
 };

 exception AllocationException {
 string reason;
 };

 exception AllocationTimeoutException
 extends AllocationException {
 };

 interface Session extends Glacier2::Session {

 idempotent void keepAlive();

 Object* allocateObjectById(Ice::Identity id)
 throws ObjectNotRegisteredException,
 AllocationException;

 Object* allocateObjectByType(string type)
 throws AllocationException;

 void releaseObject(Ice::Identity id)
 throws ObjectNotRegisteredException,
 AllocationException;

 idempotent void setAllocationTimeout(int timeout);
 };
};

```

The client is responsible for keeping the session alive by periodically invoking `keepAlive`, as discussed [earlier](#).

The `allocateObjectById` operation allocates and returns the proxy for the allocatable object with the given identity. If no allocatable object with the given identity is registered, the client receives `ObjectNotRegisteredException`. If the object cannot be allocated, the client receives `AllocationException`. An allocation attempt can fail for the following reasons:

- the object is already allocated by the session
- the object is allocated by another session and did not become available during the configured allocation timeout period
- the session was destroyed.

The `allocateObjectByType` operation allocates and returns a proxy for an allocatable object registered with the given type. If more than one allocatable object is registered with the given type, the registry selects one at random. The client receives `AllocationException` if no objects with the given type could be allocated. An allocation attempt can fail for the following reasons:

- no objects are registered with the given type
- all objects with the given type are already allocated (either by this session or other sessions) and none became available during the configured allocation timeout period
- the session was destroyed.

The `releaseObject` operation releases an object allocated by the session. The client receives `ObjectNotRegisteredException` if no allocatable object is registered with the given identity and `AllocationException` if the object is not allocated by the session. Upon session destruction, IceGrid automatically releases all allocated objects.

The `setAllocationTimeout` operation configures the timeout used by the allocation operations. If no allocatable objects are available when the client invokes `allocateObjectById` or `allocateObjectByType`, IceGrid waits for the specified timeout period for an allocatable object to become available. If the timeout expires, the client receives `AllocationTimeoutException`.

## Allocating Servers with an IceGrid Session

A client does not need to explicitly allocate a server. If a server is allocatable, IceGrid implicitly allocates it to the first client that claims one of the server's allocatable objects. Likewise, IceGrid releases the server when all of its allocatable objects are released.

Server allocation is useful in two situations:

- Only allocatable servers can use the `session` activation mode, in which the server is activated on demand when allocated by a client and deactivated upon release.
- An allocatable server can be secured with IceSSL or Glacier2 so that its objects can only be invoked by the client that allocated it.

## Security Considerations for Allocated Resources

IceGrid's resource allocation facility allows clients to coordinate access to objects and servers but does not place any restrictions on client invocations to allocated objects; any client that has a proxy for an allocated object could conceivably invoke an operation on it. IceGrid assumes that clients are cooperating with each other and respecting allocation semantics.

To prevent unauthorized clients from invoking operations on an allocated object or server, you can use [IceSSL](#) or [Glacier2](#):

- Using IceSSL, you can secure access to a server or a particular object adapter with the properties `IceSSL.TrustOnly.Server` or `IceSSL.TrustOnly.Server.AdapterName`. For example, if you configure a server with the session activation mode, you can set one of the `IceSSL.TrustOnly` properties to the `${session.id}` variable, which is substituted with the session ID when the server is activated for the session. If the IceGrid session was created from a secure connection, the session ID will be the distinguished name associated with the secure connection, which effectively restricts access to the server or one of its adapters to the client that established the session with IceGrid.
- With Glacier2, you can secure access to an allocated object or the object adapters of an allocated server with the Glacier2 [filtering mechanism](#). By default, IceGrid sessions created with a Glacier2 router are [automatically](#) given access to allocated objects, allocatable objects, certain well-known objects, and the object adapters of allocated servers.

## Deploying Allocatable Resources

Allocatable objects are registered using a descriptor that is similar to [well-known object descriptors](#). Allocatable objects cannot be replicated and therefore can only be specified within an object adapter descriptor.

Servers can be specified as allocatable by setting the server descriptor's `allocatable` attribute.

As an example, the following application defines an allocatable server and an [allocatable object](#):

## XML

```

<icegrid>
 <application name="Ripper">
 <node name="Node1">
 <server id="EncoderServer"
 exe="/opt/ripper/bin/server"
 activation="on-demand"
 allocatable="true">
 <adapter name="EncoderAdapter" id="EncoderAdapter" endpoints="tcp">
 <allocatable identity="EncoderFactory" type="::Ripper::MP3EncoderFactory"/>
 </adapter>
 </server>
 </node>
 </application>
</icegrid>

```

### Using Resource Allocation in the Ripper Application

We can use the allocation facility in our MP3 encoder factory to coordinate access to the MP3 encoder factories. First we need to modify the descriptors to define an allocatable object:

## XML

```

<icegrid>
 <application name="Ripper">
 <server-template id="EncoderServerTemplate">
 <parameter name="index"/>
 <server id="EncoderServer${index}"
 exe="/opt/ripper/bin/server"
 activation="on-demand">
 <adapter name="EncoderAdapter" endpoints="tcp">
 <allocatable identity="EncoderFactory${index}"
 type="::Ripper::MP3EncoderFactory"/>
 </adapter>
 </server>
 </server-template>
 <node name="Node1">
 <server-instance template="EncoderServerTemplate" index="1"
 />
 </node>
 <node name="Node2">
 <server-instance template="EncoderServerTemplate" index="2"
 />
 </node>
 </application>
</icegrid>

```

Next, the client needs to create a session and allocate a factory:

## C++

```

Ice::ObjectPrx obj = session->allocateObjectByType(Ripper::MP3EncoderFactory::ice_staticId());
try {
 Ripper::MP3EncoderPrx encoder = factory->createEncoder();
 // Use the encoder to encode a file ...
}
catch (const Ice::LocalException & ex) {
 // There was a problem with the encoding, we catch the
 // exception to make sure we release the factory.
}
session->releaseObject(obj->ice_getIdentity());

```

It is important to release an allocated object when it is no longer needed so that other clients may use it. If you forget to release an object, it remains allocated until the session is destroyed.

## Registry Replication

The failure of an IceGrid registry or registry host can have serious consequences. A client can continue to use an existing connection to a server without interruption, but any activity that requires interaction with the registry is vulnerable to a single point of failure. As a result, the IceGrid registry supports replication using a master-slave configuration to provide high availability for applications that require it.

### Registry Replication Architecture

In IceGrid's registry replication architecture, there is one master replica and any number of slave replicas. The master synchronizes its deployment information with the slaves so that any replica is capable of responding to locate requests, managing nodes, and starting servers on demand. Should the master registry or its host fail, properly configured clients transparently fail over to one of the slaves.

Each replica has a unique name. The name `Master` is reserved for the master replica, while replicas can use any name that can legally appear in an object identity.

The figure below illustrates the underlying concepts of registry replication:

*Overview of registry replication.*

1. The slave replica contacts the master replica at startup and synchronizes its databases. Any subsequent modifications to the deployed applications are made via the master replica, which distributes them to all active slaves.
2. The nodes contact the master replica at startup to notify it about their availability.
3. The master replica provides a list of slave replicas to the nodes so that the nodes can also notify the slaves.
4. The client's configuration determines which replica it contacts initially. In this example, it contacts the master replica.
5. In the case of a failure, the client automatically fails over to the slave. If the master registry's host has failed, then `Node1` and any

servers that were active on this host also become unavailable. The use of [object adapter replication](#) allows the client to transparently reestablish communication with a server on `Node2`.

## Capabilities of a Registry Replica

A master registry replica has a number of responsibilities, only some of which are supported by slaves. The master replica knows all of its slaves, but the slaves are not in contact with one another. If the master replica fails, the slaves can perform several vital functions that should keep most applications running without interruption. Eventually, however, a new master replica must be started to restore full registry functionality. For a slave replica to become the master, the slave must be restarted.

### Locate Requests

One of the most important functions of a registry replica is responding to locate requests from clients, and every replica has the capability to service these requests. Slaves synchronize their databases with the master so that they have all of the information necessary to transform object identities, object adapter identifiers, and replica group identifiers into an appropriate set of endpoints.

### Server Activation

Nodes establish sessions with each active registry replica so that any of the replicas are capable of activating a server on behalf of a client.

### Queries

Replicating the registry also replicates the object that supports the `IceGrid::Query` interface used to [query well-known objects](#). A client that resolves the `IceGrid/Query` object identity receives the endpoints of all active replicas, any of which can execute the client's requests.

### Allocation

A client that needs to allocate a resource must establish a session with the master replica.

### Administration

The state of an IceGrid registry is accessible via the `IceGrid::Admin` interface or (more commonly) using an [administrative tool](#) that encapsulates this interface. Modifications to the registry's state, such as deploying or updating an application, can only be done using the master replica. Administrative access to slave replicas is allowed but restricted to read-only operations. The administrative utilities provide mechanisms for you to select a particular replica to contact.

For programmatic access to a replica's administrative interface, the `IceGrid/Registry` identity corresponds to the master replica and the identity `IceGrid/Registry-name` corresponds to the slave with the given name.

### Glacier2 Support

The registry implements the session manager interfaces required for [integration with a Glacier2 router](#). The master replica supports the object identities `IceGrid/SessionManager` and `IceGrid/AdminSessionManager`. The slave replicas offer support for read-only administrative sessions using the object identity `IceGrid/AdminSessionManager-name`.

## Configuring Registry Replication

Incorporating registry replication into an application is primarily accomplished by modifying your IceGrid configuration settings.

### Replicas

Each replica must specify a unique name in its configuration property `IceGrid.Registry.ReplicaName`. The default value of this property is `Master`, therefore the master replica can omit this property if desired.

At startup, a slave replica attempts to register itself with its master in order to synchronize its databases and obtain the list of active nodes. The slave uses the proxy supplied by the `Ice.Default.Locator` property to find the master. At a minimum, this proxy should contain the

endpoint of a replica that is connected to the master.

For better reliability if a failure occurs, we recommend that you also include the endpoints of all slave replicas in the `Ice.Default.Locator` property. There is no harm in adding the slave's own endpoints to the proxy in `Ice.Default.Locator`; in fact, it makes configuration simpler because all of the slaves can share the same property definition. Although slaves do not communicate with each other, it is possible for one of the slaves to be promoted to the master, therefore supplying the endpoints of all slaves minimizes the chance of a communication failure.

Shown below is an example of the configuration properties for a master replica:

```
IceGrid.InstanceName=DemoIceGrid
IceGrid.Registry.Client.Endpoints=default -p 12000
IceGrid.Registry.Server.Endpoints=default
IceGrid.Registry.Internal.Endpoints=default
IceGrid.Registry.Data=db/master
...
```

You can configure a slave replica to use this master with the following settings:

```
Ice.Default.Locator=DemoIceGrid/Locator:default -p 12000
IceGrid.Registry.Client.Endpoints=default -p 12001
IceGrid.Registry.Server.Endpoints=default
IceGrid.Registry.Internal.Endpoints=default
IceGrid.Registry.Data=db/replica1
IceGrid.Registry.ReplicaName=Replica1
...
```

Configuring [IceLocatorDiscovery](#) in the replicas allows them to discover the master at run time without the need to define `Ice.Default.Locator`.

## Clients

The endpoints contained in the `Ice.Default.Locator` property determine which registry replicas the client can use when issuing locate requests. If high availability is important, this property should include the endpoints of at least two (and preferably all) replicas. Not only does this increase the reliability of the client, it also distributes the work load of responding to locate requests among all of the replicas.

Continuing the example from the previous section, you can configure a client with the `Ice.Default.Locator` property as shown below:

```
Ice.Default.Locator=DemoIceGrid/Locator:default -p 12000:default -p 12001
```

Configuring [IceLocatorDiscovery](#) in a client allows it to discover the replicas at run time without the need to define `Ice.Default.Locator`.

## Nodes

As with slave replicas and clients, an IceGrid node should be configured with an `Ice.Default.Locator` property that contains the endpoint of at least one replica and preferably all the replicas. A node needs to notify each of the registry replicas about its presence, thereby enabling the replicas to activate its servers and obtain the endpoints of its object adapters. Only the master replica knows the list of active replica slaves so it's important that the node connects to the master on startup to retrieve the list of all the active replicas. If the master is down when the node starts, the node will try to obtain the list of the registry replicas from the replicas specified in its `Ice.Default.Locator` proxy.

The following properties demonstrate how to configure a node with a replicated registry:

```
Ice.Default.Locator=DemoIceGrid/Locator:default -p 12000:default -p 12001
IceGrid.Node.Name=node1
IceGrid.Node.Endpoints=default
IceGrid.Node.Data=db/node1
```

Configuring `IceLocatorDiscovery` in a node allows it to discover the replicas at run time without the need to define `Ice.Default.Locator`.

## Diagnostics

You can use several configuration properties to enable trace messages that may help in diagnosing registry replication issues:

- `IceGrid.Registry.Trace.Replica`  
Displays information about the sessions established between master and slave replicas.
- `IceGrid.Registry.Trace.Node`  
`IceGrid.Node.Trace.Replica`  
Displays information about the sessions established between replicas and nodes.

## Using Registry Replication with External Load Balancing

As explained earlier, we recommend including the endpoints of all replicas in the `Ice.Default.Locator` property. However, doing so might not always be convenient in large deployments, as it can require modifying many configuration files whenever you add or remove a registry replica. There are two ways to simplify your configuration:

- **Use a DNS name bound to multiple address (A) records**  
Configure the DNS name to point to the IP addresses of each of the registry replicas. You can then define the `Ice.Default.Locator` property with a single endpoint that embeds the DNS name. The Ice run time in the client randomly picks one of these IP addresses when it resolves the DNS name. All replicas must use the same port.
- **Use a TCP load balancer**  
Configure the load balancer to redirect traffic to the registry replicas and define the `Ice.Default.Locator` property with an endpoint that embeds the IP address and port of the TCP load balancer. The Ice run time in the client connects to the load balancer and the load balancer forwards the traffic to an active registry replica.

For maximum reliability, the DNS server or TCP load balancer should also be replicated.

When using such a configuration for the `Ice.Default.Locator` property of registry slaves, special care needs to be taken when initially starting the IceGrid registry replicas. Since the `Ice.Default.Locator` property no longer includes the endpoint of the master replica, a slave replica won't be able to contact the master if it's started when no master is running. You must first start the master and then the slaves to prevent this from happening. Once a replica slave connects successfully to the master, it saves the endpoint of the master and the other slaves in its database, so this is really only an issue when starting a slave with an empty database.

### Using IcePatch2 to Distribute Applications

In the section so far, "deployment" has meant the creation of descriptors in the registry. A broader definition involves a number of other tasks:

- Writing IceGrid configuration files and preparing data directories on each computer
- Installing the IceGrid binaries and dependent libraries on each computer
- Starting the registry and/or node on each computer, and possibly configuring the systems to launch them automatically
- Distributing your server executables, dependent libraries and supporting files to the appropriate nodes.

The first three tasks are the responsibility of the system administrator, but IceGrid can help with the fourth. Using an [IcePatch2](#) server, you can configure the nodes to download servers automatically and patch them at any time. The illustration below shows the interactions of the components:

*Overview of application distribution.*

As you can see, deploying an IceGrid application has greater significance when IcePatch2 is also involved. After deployment, the [administrative tool](#) initiates a patch, causing the registry to notify all active nodes that are configured for application distribution to begin the patching process. Since each IceGrid node is an IcePatch2 client, the node performs the patch just like any IcePatch2 client: it downloads everything if no local copy of the distribution exists, otherwise it does an incremental patch in which it downloads only new files and those whose signatures have changed.

The benefits of this feature are clear:

- The distribution files are maintained in a central location
- Updating a distribution on all of the nodes is a simple matter of preparing the master distribution and letting IceGrid do the rest
- Manually transferring executables and supporting files to each computer is avoided, along with the mistakes that manual intervention sometimes introduces.

### Deploying an IcePatch2 Server

If you plan to use IceGrid's distribution capabilities, we generally recommend deploying an IcePatch2 server along with your application. Doing so gives you the same benefits as any other IceGrid server, including on-demand activation and remote administration. We will only use one server in our sample application, but you might consider replicating a number of IcePatch2 servers in order to balance the patching load for large distributions.

### Patching Considerations

Deploying an IcePatch2 server with your application presents a chicken-and-egg dilemma: how do the nodes download their distributions if the IcePatch2 server is included in the deployment? To answer this question, we need to learn more about IceGrid's behavior.

Deploying and patching are treated as two separate steps: first you deploy the application, then you initiate the patching process. The `icegridadmin` utility combines these steps into one command (`application add`), but also provides an option to disable the patching step if so desired.

Let's consider the state of the application after deployment but before patching: we have described the servers that run on each node, including file system-dependent attributes such as the pathnames of their executables and default working directories. If these pathnames refer to directories in the distribution, and the distribution has not yet been downloaded to that node, then clearly we cannot attempt to use those servers until patching has completed. Similarly, we cannot deploy an `IcePatch2` server whose executable resides in the distribution to be downloaded.

We are ignoring the case where a temporary `IcePatch2` server is used to bootstrap other `IcePatch2` servers.

For these reasons, we assume that the `IcePatch2` server and supporting libraries are distributed by the system administrator along with the IceGrid registry and nodes to the appropriate computers. The server should be configured for on-demand activation so that its node starts it automatically when patching begins. If the server is configured for manual activation, you must start it prior to patching.

### IcePatch2 Server Template

The Ice distribution includes an `IcePatch2` [server template](#) that simplifies the inclusion of `IcePatch2` in your application. The relevant portion from the file `config/templates.xml` is shown below:

**XML**

```

<server-template id="IcePatch2">
 <parameter name="instance-name" default="{application}.IcePatch2"/>
 <parameter name="endpoints" default="default"/>
 <parameter name="directory"/>

 <server id="{instance-name}" exe="icepatch2server"
 application-distrib="false" activation="on-demand">
 <adapter name="IcePatch2" endpoints="{endpoints}">
 <object identity="{instance-name}/server"
type="::IcePatch2::FileServer"/>
 </adapter>
 <adapter name="IcePatch2.Admin" id=" "
endpoints="tcp -h 127.0.0.1"/>
 <property name="IcePatch2.InstanceName"
value="{instance-name}"/>
 <property name="IcePatch2.Directory" value="{directory}"/>
 </server>
 </server-template>

```

Notice that the server's pathname is `icepatch2server`, meaning the program must be present in the node's executable search path. The only mandatory parameter is `directory`, which specifies the server's data directory and becomes the value of the `IcePatch2.Directory` property. The value of the `instance-name` parameter is used as the server's identifier when the template is instantiated; its default value includes the name of the application in which the template is used. This identifier also affects the identities of the two well-known objects declared by the server.

Consider the following sample application:

## XML

```
<icegrid>
 <application name="PatchDemo">
 <node name="Node">
 <server-instance template="IcePatch2"
directory="/opt/icepatch2/data"/>
 ...
 </node>
 </application>
</icegrid>
```

Instantiating the `IcePatch2` template creates a server identified as `PatchDemo.IcePatch2` (as determined by the default value for the `instance-name` parameter). The well-known objects use this value as the category in their identities, such as `PatchDemo.IcePatch2/server`.

In order to refer to the `IcePatch2` template in your application, you must have already configured the registry to use the `config/templates.xml` file as your [default templates](#), or copied the template into the XML file describing your application.

## Adding Distribution to a Deployment

A [distribution descriptor](#) provides the details that a node requires in order to download the necessary files. Specifically, the descriptor supplies the proxy of the `IcePatch2` server and the names of the subdirectories comprising the distribution, all of which are optional. If the descriptor does not define the proxy, the following default value is used instead:

```
${application}.IcePatch2/server
```

You may recall that this value matches the default identity configured by the `IcePatch2` server template described [above](#). Also notice that this is an indirect proxy, implying that the `IcePatch2` server was deployed with the application and can be started on-demand if necessary.

If the descriptor does not select any subdirectories, the node downloads the entire contents of the `IcePatch2` data directory.

In XML, a descriptor having the default behavior as described above can be written as shown below:

## XML

```
<distrib/>
```

To specify a proxy, use the `icepatch` attribute:

## XML

```
<distrib icepatch="PatchDemo.IcePatch2/server"/>
```

Finally, select subdirectories using a nested element:

**XML**

```
<distrib>
 <directory>dir1</directory>
 <directory>dir2/subdir</directory>
</distrib>
```

By including only certain subdirectories in a distribution, you are minimizing the time and effort required to download and patch each node. For example, each node in a heterogeneous network might download a platform-specific subdirectory and another subdirectory containing files common to all platforms.

## Distributing Applications and Servers

A [distribution descriptor](#) can be used in two contexts: within an application, and within a server. When the descriptor appears at the application level, it means every node in the application downloads that distribution. This is useful for distributing files required by all of the nodes on which servers are deployed, especially in a grid of homogeneous computers where it would be tedious to repeat the same distribution information in each server descriptor. Here is a simple XML example:

**XML**

```
<icegrid>
 <application name="PatchDemo">
 <distrib>
 <directory>Common</directory>
 </distrib>
 ...
 </application>
</icegrid>
```

At the server level, a distribution descriptor downloads the specified directories for the private use of the server:

## XML

```

<icegrid>
 <application name="PatchDemo">
 <distrib>
 <directory>Common</directory>
 </distrib>
 <node name="Node">
 <server id="SimpleServer" ...>
 <distrib>
 <directory>ServerFiles</directory>
 </distrib>
 </server>
 </node>
 </application>
</icegrid>

```

When a distribution descriptor is defined at both the application and server levels, as shown in the previous example, IceGrid assumes that a dependency relationship exists between the two unless the server is configured otherwise. IceGrid checks this dependency before patching a server; if the server is dependent on the application's distribution, IceGrid patches the application's distribution first, and then proceeds to patch the server's. You can disable this dependency by modifying the server's descriptor:

## XML

```

<icegrid>
 <application name="PatchDemo">
 <distrib>
 <directory>Common</directory>
 </distrib>
 <node name="Node">
 <server id="SimpleServer" application-distrib="false" ...>
 <distrib>
 <directory>ServerFiles</directory>
 </distrib>
 </server>
 </node>
 </application>
</icegrid>

```

Setting the `application-distrib` attribute to `false` informs IceGrid to consider the two distributions independent of one another.

## Server Integrity during Distribution

Before an IceGrid node begins patching a distribution, it ensures that all relevant servers are shut down and prevents them from reactivating until patching completes. For example, the node disables all of the servers whose descriptors declare a dependency on the [application distribution](#).

## Distribution Descriptor Variables

The node stores application and server distributions in its data directory. The path names of the distributions are represented by [reserved variables](#) that you can use in your descriptors:

- `application.distrib`  
This variable can be used within server descriptors to refer to the top-level directory of the application distribution.
- `server.distrib`  
The value of this variable is the top-level directory of a server distribution. It can be used only within a server descriptor that has a distribution.

The XML example shown below illustrates the use of these variables:

**XML**

```

<icegrid>
 <application name="PatchDemo">
 <distrib>
 <directory>Common</directory>
 </distrib>
 <node name="Node">
 <server id="Server1"
exe="${application.distrib}/Common/Bin/Server1" ...>
 </server>
 <server id="Server2"
exe="${server.distrib}/Server2Files/Bin/Server2" ...>
 <option>-d</option>
 <option>${server.distrib}/Server2Files</option>
 <distrib>
 <directory>Server2Files</directory>
 </distrib>
 </server>
 </node>
</application>
</icegrid>

```

Notice that the descriptor for `Server2` supplies the server's distribution directory as command-line options.

## Using Distribution in the Ripper Application

Adding an application distribution to our [ripper example](#) requires two minor changes to our descriptors:

## XML

```

<icegrid>
 <application name="Ripper">
 <replica-group id="EncoderAdapters">
 <load-balancing type="adaptive"/>
 <object identity="EncoderFactory"
type="::Ripper::MP3EncoderFactory"/>
 </replica-group>
 <server-template id="EncoderServerTemplate">
 <parameter name="index"/>
 <parameter name="exepath" default="/opt/ripper/bin/server"/>
 <server id="EncoderServer${index}" exe="${exepath}"
activation="on-demand">
 <adapter name="EncoderAdapter"
replica-group="EncoderAdapters"
 endpoints="tcp"/>
 </server>
 </server-template>
 <distrib/>
 <node name="Node1">
 <server-instance template="EncoderServerTemplate"
index="1"/>
 <server-instance template="IcePatch2"
directory="/opt/ripper/icepatch"/>
 </node>
 <node name="Node2">
 <server-instance template="EncoderServerTemplate"
index="2"/>
 </node>
 </application>
</icegrid>

```

An application distribution is sufficient for this example because we are deploying the same server on each node. We have also deployed an `IcePatch2` server on `Node1` using the template.

## IceGrid Administrative Sessions

To access IceGrid's administrative facilities from a program, you must first establish an administrative session. Once done, a wide range of services are at your disposal, including the manipulation of IceGrid registries, nodes, and servers; deployment of new components such as well-known objects; and dynamic monitoring of IceGrid events.

Note that, for [replicated registries](#), an administrative session can be established with either the master or a slave registry replica, but a session with a slave replica is restricted to read-only operations.

On this page:

- [Creating an Administrative Session](#)
- [Accessing Log Files Remotely](#)
- [Dynamic Monitoring in IceGrid](#)
  - [Observer Interfaces](#)
  - [Registering Observers](#)

### Creating an Administrative Session

The `Registry` interface provides two operations for creating an administrative session:

**Slice**

```

module IceGrid {
 exception PermissionDeniedException {
 string reason;
 };

 interface Registry {
 AdminSession* createAdminSession(string userId, string password)
 throws PermissionDeniedException;

 AdminSession* createAdminSessionFromSecureConnection()
 throws PermissionDeniedException;

 idempotent int getSessionTimeout();

 idempotent int getACMTimeout();
 // ...
 };
};

```

The `createAdminSession` operation expects a username and password and returns a session proxy if the client is allowed to create a session. By default, IceGrid does not allow the creation of administrative sessions. You must define the property `IceGrid.Registry.AdminInPermissionsVerifier` with the proxy of a permissions verifier object to enable session creation with `createAdminSession`. The verifier object must implement the interface `Glacier2::PermissionsVerifier`.

The `createAdminSessionFromSecureConnection` operation does not require a username and password because it uses the credentials supplied by an SSL connection to authenticate the client. As with `createAdminSession`, you must configure the proxy of a permissions verifier object before clients can use `createAdminSessionFromSecureConnection` to create a session. In this case, the `IceGrid.Registry.AdminSSLPermissionsVerifier` property specifies the proxy of a verifier object that implements the interface `Glacier2::SSLPermissionsVerifier`.

As an example, the following code demonstrates how to obtain a proxy for the registry and invoke `createAdminSession`:

**C++**

```

Ice::ObjectPrx base = communicator->stringToProxy("IceGrid/Registry");
IceGrid::RegistryPrx registry =
IceGrid::RegistryPrx::checkedCast(base);
string username = ...;
string password = ...;
IceGrid::AdminSessionPrx session;
try {
 session = registry->createAdminSession(username, password);
} catch (const IceGrid::PermissionDeniedException & ex) {
 cout << "permission denied:\n" << ex.reason << endl;
}

```

The `AdminSession` interface provides operations for [accessing log files](#) and [establishing observers](#). Furthermore, two additional operations are worthy of your attention:

**Slice**

```

module IceGrid {
 interface AdminSession extends Glacier2::Session {
 idempotent void keepAlive();
 idempotent Admin* getAdmin();
 // ...
 };
};

```

If your program uses an administrative session indefinitely, you must prevent the session from expiring. You have two options for keeping a session alive:

1. Call `Registry::getSessionTimeout` and periodically invoke `AdminSession::keepAlive` every *timeout* (or less) seconds
2. Call `Registry::getACMTimeout` and configure [ACM settings](#) on the connection

We recommend using the second approach, which you can implement as follows:

**C++**

```

int acmTimeout = registry->getACMTimeout();
if (acmTimeout > 0) {
 Ice::ConnectionPtr conn = session->ice_getCachedConnection();
 conn->setACM(acmTimeout, IceUtil::None, Ice::HeartbeatAlways);
}

```

Enabling heartbeats on the connection causes Ice to automatically send a heartbeat message at regular intervals determined by the given timeout value. The server ignores these messages, but they serve the purpose of keeping the session alive.

The ACM features shown here were introduced in Ice 3.6.

The `getAdmin` operation returns a proxy for the `IceGrid::Admin` interface, which provides complete access to the registry's settings. For this reason, you must use extreme caution when enabling administrative sessions.

## Accessing Log Files Remotely

IceGrid's `AdminSession` interface provides operations for remotely accessing the log files of a registry, node, or server:

### Slice

```
module IceGrid {
interface AdminSession extends Glacier2::Session {
 // ...

 FileIterator* openServerLog(string id, string path, int count)
 throws FileNotAvailableException, ServerNotExistException,
 NodeUnreachableException, DeploymentException;
 FileIterator* openServerStdErr(string id, int count)
 throws FileNotAvailableException, ServerNotExistException,
 NodeUnreachableException, DeploymentException;
 FileIterator* openServerStdOut(string id, int count)
 throws FileNotAvailableException, ServerNotExistException,
 NodeUnreachableException, DeploymentException;

 FileIterator* openNodeStdErr(string name, int count)
 throws FileNotAvailableException, NodeNotExistException,
 NodeUnreachableException;
 FileIterator* openNodeStdOut(string name, int count)
 throws FileNotAvailableException, NodeNotExistException,
 NodeUnreachableException;

 FileIterator* openRegistryStdErr(string name, int count)
 throws FileNotAvailableException,
 RegistryNotExistException,
 RegistryUnreachableException;
 FileIterator * openRegistryStdOut(string name, int count)
 throws FileNotAvailableException,
 RegistryNotExistException,
 RegistryUnreachableException;
};
};
```

In order to access the text of a program's standard output or standard error log, you must configure it using the `Ice.Stdout` and `Ice.StdErr` properties, respectively. For registries and nodes, you must define these properties explicitly but, for servers, the node defines these properties automatically if the property `IceGrid.Node.Output` is defined, causing the server's output to be logged in individual files.

If `IceGrid.Node.Output` is *not* defined, the following rules apply:

- If the node is started from a console or shell, servers share the node's `stdout` and `stderr`. If `Ice.Stdout` and/or `Ice.StdErr` properties are defined for the node, the servers' output is redirected to the specified files as well.
- If the node is started as a Unix daemon and `--noclose` is not used, the servers' output is lost, except if `Ice.Stdout` and/or `Ice.`

`StdErr` properties are set for the node, in which case the servers' output is redirected to the specified files.

- If the node is started as a Windows service, the servers' output is lost even if `Ice.Stdout` and/or `Ice.StdErr` are set.

Log messages from the node itself are sent to `stderr` unless you set `Ice.UseSyslog` (for Unix). If the node is started as a Windows service, its log messages always are sent to the Windows event log.

In the case of `openServerLog`, the value of the `path` argument must resolve to the same file as one of the server's [log descriptors](#). This security measure prevents a client from opening an arbitrary file on the server's host.

All of the operations accept a `count` argument and return a proxy to a `FileIterator` object. The `count` argument determines where to start reading the log file: if the value is negative, the iterator is positioned at the beginning of the file, otherwise the iterator is positioned to return the last `count` lines of text.

The `FileIterator` interface is quite simple:

**Slice**

```

module IceGrid {
interface FileIterator {
 bool read(int size, out Ice::StringSeq lines)
 throws FileNotAvailableException;
 void destroy();
};
};

```

A client may invoke the `read` operation as many times as necessary. The `size` argument specifies the maximum number of bytes that `read` can return; the client must not use a size that would cause the reply to exceed the client's configured [maximum message size](#).

If this is the client's first call to `read`, the `lines` argument holds whatever text was available from the iterator's initial position, and the iterator is repositioned in preparation for the next call to `read`. The operation returns false to indicate that more text is available and true if all available text has been read.

Line termination characters are removed from the contents of `lines`. When displaying the text, you must be aware that the first and last elements of the sequence can be partial lines. For example, the last line of the sequence might be incomplete if the limit specified by `size` is reached. The next call to `read` returns the remainder of that line as the first element in the sequence.

As an example, the C++ code below displays the contents of a log file and waits for new text to become available:

**C++**

```

IceGrid::FileIteratorPrx iter = ...;
while(true) {
 Ice::StringSeq lines;
 bool end = iter->read(10000, lines);
 if (!lines.empty()) {
 // The first line might be a continuation from
 // the previous call to read.
 cout << lines[0];
 for (Ice::StringSeq::const_iterator p =
++lines.begin(); p != lines.end(); ++p)
 cout << endl << *p << flush;
 }
 if (end)
 sleep(1);
}

```

Notice that the loop includes a delay in case `read` returns true, which prevents the client from entering a busy loop when no data is currently available.

The client should call `destroy` when the iterator object is no longer required. At the time the client's session terminates, IceGrid reclaims any iterators that were not explicitly destroyed.

If the client waits for new data, it must take steps to prevent the [administrative session](#) from expiring.

With these operations, an administrative client can retrieve any text file on a system where an IceGrid node is running. While it's common for this text file to contain the output of an Ice [logger](#), it could contain other unrelated outputs. This text file is presented as a sequence of strings, with no particular structure for these strings.

The [Logger admin facet](#) provides another, and often better, way to retrieve the log messages sent to the logger of a server, node or registry. With the [Logger](#) facet, you retrieve log messages—and only log messages—as typed structures, whether or not the logger's output is stored in a text file or stored at all. With the [AdminSession](#) file operations presented above, you can retrieve the log files of a server even when this server is not running; conversely, with the [Logger](#) admin facet, the target server must be running since this [Logger](#) facet is hosted in that server. Finally, the programming style espoused by the [AdminSession](#) file operations is a pull model: the administrative client calls `read` from time to time on the [FileIterator](#) object provided by IceGrid. With the [Logger](#) admin facet, the administrative client uses a push model: it registers a remote logger object with the target server, node and registry, and this remote logger receives new log messages as soon as they are generated.

## Dynamic Monitoring in IceGrid

IceGrid allows an application to monitor relevant state changes by registering callback objects. (The [IceGrid GUI tool](#) uses these callback interfaces for its implementation.) The callback interfaces are useful to, for example, automatically generate an email notification when a node goes down or some other state change of interest occurs.

### Observer Interfaces

IceGrid offers a callback interface for each major component of the IceGrid architecture:

## Slice

```

module IceGrid {
interface NodeObserver {
 void nodeInit(NodeDynamicInfoSeq nodes);
 void nodeUp(NodeDynamicInfo node);
 void nodeDown(string name);
 void updateServer(string node, ServerDynamicInfo updatedInfo);
 void updateAdapter(string node, AdapterDynamicInfo updatedInfo);
};

interface ApplicationObserver {
 void applicationInit(int serial, ApplicationInfoSeq applications);
 void applicationAdded(int serial, ApplicationInfo desc);
 void applicationRemoved(int serial, string name);
 void applicationUpdated(int serial, ApplicationUpdateInfo desc);
};

interface AdapterObserver {
 void adapterInit(AdapterInfoSeq adpts);
 void adapterAdded(AdapterInfo info);
 void adapterUpdated(AdapterInfo info);
 void adapterRemoved(string id);
};

interface ObjectObserver {
 void objectInit(ObjectInfoSeq objects);
 void objectAdded(ObjectInfo info);
 void objectUpdated(ObjectInfo info);
 void objectRemoved(Ice::Identity id);
};

interface RegistryObserver {
 void registryInit(RegistryInfoSeq registries);
 void registryUp(RegistryInfo node);
 void registryDown(string name);
};
};
};

```

The next section describes how to install an observer.

### Registering Observers

The `AdminSession` interface provides two operations for registering your observers:

## Slice

```

module IceGrid {
 interface AdminSession extends Glacier2::Session {
 idempotent void keepAlive();

 idempotent void setObservers(
 RegistryObserver* registryObs,
 NodeObserver* nodeObs,
 ApplicationObserver* appObs,
 AdapterObserver* adptObs,
 ObjectObserver* objObs)
 throws ObserverAlreadyRegisteredException;

 idempotent void setObserversByIdentity(
 Ice::Identity registryObs,
 Ice::Identity nodeObs,
 Ice::Identity appObs,
 Ice::Identity adptObs,
 Ice::Identity objObs)
 throws ObserverAlreadyRegisteredException;

 // ...
 };
};

```

You should invoke `setObservers` and supply proxies when it is possible for the registry to establish a separate connection to the client to deliver its callbacks. If network restrictions such as firewalls prevent such a connection, you should use the `setObserversByIdentity` operation, which creates a [bidirectional connection](#) instead.

You can pass a null proxy for any parameter to `setObservers`, or an empty identity for any parameter to `setObserversByIdentity`, if you want to use only some of the observers. In addition, passing a null proxy or an empty identity for an observer cancels a previous registration of that observer. The operations raise `ObserverAlreadyRegisteredException` if you pass a proxy or identity that was registered in a previous call.

Once the observers are registered, operations corresponding to state changes will be invoked on the observers. (See the [Slice API Reference](#) for details on the data passed to the observers. You can also look at the source code for the IceGrid GUI implementation in the Ice for Java distribution to see how observers are used by the GUI.)

Finally, remember to take the steps necessary to prevent the [administrative session](#) from expiring.

## Glacier2 Integration with IceGrid

This section provides information on integrating a [Glacier2 router](#) into your IceGrid environment.

On this page:

- [Configuration Changes for using Glacier2 with IceGrid](#)
- [Remote IceGrid Administration via Glacier2](#)
- [Resource Allocation using Glacier2 and IceGrid](#)
- [Session Considerations for Glacier2 and IceGrid](#)
- [Deploying Glacier2 with IceGrid](#)

### Configuration Changes for using Glacier2 with IceGrid

A typical IceGrid client must be configured with a [locator proxy](#), but the configuration requirements change when the client accesses the location service indirectly via a Glacier2 router as shown below:

*Using IceGrid via a Glacier2 router.*

In this situation, it is the router that must be configured with a locator proxy.

Assuming the registry's client endpoint in the illustration uses port 8000, the router requires the following setting for the `Ice.Default.Locator` property:

```
Ice.Default.Locator=IceGrid/Locator:tcp -h 10.0.0.2 -p 8000
```

Fortunately, the node supplies this property when it starts the router, so there is no need to configure it explicitly. Note that all of the router's clients use the same locator.

### Remote IceGrid Administration via Glacier2

If you intend to administer IceGrid remotely via a Glacier2 router, you must define one of the following properties (or both), depending on whether you use user name and password authentication or a secure connection:

```
Glacier2.SessionManager=IceGrid/AdminSessionManager
Glacier2.SSLSessionManager=IceGrid/AdminSSLSessionManager
```

These session managers are accessible via the registry's administrative session manager endpoints, so the Glacier2 router must be authorized to establish a connection to these endpoints. Note that you must secure these endpoints, otherwise arbitrary clients can manipulate the session managers. An administrative session is allowed to access any object by default. To restrict access to the `IceGrid::AdminSession` object and the `IceGrid::Admin` object that is returned by the session's `getAdmin` operation, you must set the property `IceGrid.Registry.AdminSessionFilters` to one.

## Resource Allocation using Glacier2 and IceGrid

To allocate servers and objects, a program can establish a client session via Glacier2. Depending on the authentication method, one or both of the following properties must be set in the Glacier2 configuration:

```
Glacier2.SessionManager=IceGrid/SessionManager
Glacier2.SSLSessionManager=IceGrid/SSLSessionManager
```

These session managers are accessible via the registry's session manager endpoints, so the Glacier2 router must be authorized to establish a connection to these endpoints.

A client session is allowed to access any object by default. To restrict access to the `IceGrid::Session` and `IceGrid::Query` objects, you must set the property `IceGrid.Registry.SessionFilters` to one. However, you can use the allocation mechanism to access additional objects and adapters. IceGrid adds an identity filter when a client allocates an object and removes that filter again when the object is released. When a client allocates a server, IceGrid adds an adapter identity filter for the server's indirect adapters and removes that filter again when the server is released.

## Session Considerations for Glacier2 and IceGrid

Providing access to [administrative sessions](#) and [client sessions](#) both require that you define at least one of the properties `Glacier2.SessionManager` and `Glacier2.SSLSessionManager`, which presents a potential problem if you intend to access both types of sessions via the same Glacier2 router.

The simplest solution is to dedicate a router instance to each type of session. However, if you need to access both types of sessions from a single router, you can accomplish it only if you use a different authentication mechanism for each type of session. For example, you can configure the router as follows:

```
Glacier2.SessionManager=IceGrid/SessionManager
Glacier2.SSLSessionManager=IceGrid/AdminSSLSessionManager
```

This configuration uses user name and password authentication for client sessions, and SSL authentication for administrative sessions. If this restriction is too limiting, you must use two router instances.

## Deploying Glacier2 with IceGrid

The Ice distribution includes [default server templates](#) for Ice services such as IcePatch2 and Glacier2 that simplify the task of deploying these servers in an IceGrid domain.

The relevant portion from the file `config/template.xml` is shown below:

## XML

```

<server-template id="Glacier2">
 <parameter name="instance-name" default="{application}.Glacier2"/>
 <parameter name="client-endpoints"/>
 <parameter name="server-endpoints"/>
 <parameter name="session-timeout" default="0"/>

 <server id="{instance-name}" exe="glacier2router">
 <properties>
 <property name="Glacier2.Client.Endpoints"
value="{client-endpoints}"/>
 <property name="Glacier2.Server.Endpoints"
value="{server-endpoints}"/>
 <property name="Glacier2.InstanceName"
value="{instance-name}"/>
 <property name="Glacier2.SessionTimeout"
value="{session-timeout}"/>
 </properties>
 </server-template>

```

Notice that the server's pathname is `glacier2router`, meaning the program must be present in the node's executable search path. Another important point is the server's activation mode: it uses manual activation (the default), meaning the router must be started manually. This requirement becomes clear when you consider that the router is the point of contact for remote clients; if the router is not running, there is no way for a client to contact the locator and cause the router to be started on-demand.

The template defines only a few properties; if you want to set additional properties, you can define them in the server instance property set.

Of interest is the `instance-name` parameter, which allows you to configure the `Glacier2.InstanceName` property. The parameter's default value includes the name of the application in which the template is used. This parameter also affects the [identities](#) of the objects implemented by the router.

Consider the following sample application:

```

<icegrid>
 <application name="Glacier2Demo">
 <node name="Node">
 <server-instance template="Glacier2"
client-endpoints="tcp -h 5.6.7.8 -p 8000"
session-timeout="300"
server-endpoints="tcp -h 10.0.0.1"/>
 ...
 </node>
 </application>
</icegrid>

```

Instantiating the `Glacier2` template creates a server identified as `Glacier2Demo.Glacier2` (as determined by the default value for the `instance-name` parameter). The router's objects use this value as the category in their identities, such as `Glacier2Demo.Glacier2/router`. The router proxy used by clients must contain a matching identity.

In order to refer to the `Glacier2` template in your application, you must have already configured the registry to use the `config/templates.xml` file as your [default templates](#), or copied the template into the XML file describing your application.

Note that IceGrid cannot start a Glacier2 router if the router's security configuration requires that a passphrase be entered. In this situation, you have no choice but to start the router yourself so that you can provide the passphrase when prompted.

## Adapter Descriptor Element

An `adapter` element defines an indirect `object adapter`.

This element may only appear as a child of a `server` or `service` element.

The following attributes are supported:

Attribute	Description	Required
<code>endpoints</code>	Specifies one or more <code>endpoints</code> for this object adapter. These endpoints typically do not specify a port. This attribute is translated into a definition of the adapter's <code>Endpoints</code> configuration property.	No
<code>id</code>	Specifies an object adapter identifier. The identifier must be unique among all adapters and replica groups in the registry. This attribute is translated into a definition of the adapter's <code>AdapterId</code> configuration property. If not defined, a default value is constructed from the adapter name and server ID (and service name for an IceBox <code>service</code> ).	Yes
<code>name</code>	The name of the object adapter as used in the server that <code>creates</code> it.	Yes
<code>priority</code>	Specifies the priority of the object adapter as an integer value. The object adapter priority is used by the <code>Ordered</code> replica group <code>load balancing</code> policy to determine the order of the endpoints returned by a <code>locate</code> request. Endpoints are ordered from the smallest priority value to the highest. If not defined, the value is 0.	No
<code>proxy-options</code>	The proxy options to use when generating the adapter well-known or allocatable object proxies. This attribute is also translated into a definition of the adapter's <code>ProxyOptions</code> configuration property.	No
<code>register-process</code>	This attribute is only valid if the enclosing server uses an Ice version prior to 3.3. In Ice 3.3 or later, this functionality is replaced by the <code>administrative facility</code> . If the value is <code>true</code> , this object adapter registers an object in the IceGrid registry that facilitates graceful shutdown of the server. Only one object adapter in a server should set this attribute to <code>true</code> . If not defined, the default value is <code>false</code> .	No
<code>replica-group</code>	Specifies a <code>replica group identifier</code> . A non-empty value signals that this object adapter is a member of the indicated replica group. This attribute is translated into a definition of the adapter's <code>ReplicaGroupId</code> configuration property. If not defined, the default value is an empty string.	No
<code>server-lifetime</code>	A value of <code>true</code> indicates that the lifetime of this object adapter is the same as the lifetime of its server. This information is used by the IceGrid node to determine the state of the server. Specifically, the server is considered <code>activated</code> when all the object adapters with the <code>server-lifetime</code> attribute set to <code>true</code> are registered with the registry (the object adapter registers itself during activation). Furthermore, server deactivation is considered to begin as soon as one object adapter with the <code>server-lifetime</code> attribute set to <code>true</code> is unregistered with the registry (the object adapter unregisters itself during deactivation).	No

An optional nested `description` element provides free-form descriptive text.

Here is an example to demonstrate the use of this element.

**XML**

```

<adapter name="MyAdapter"
 endpoints="default"
 id="MyAdapterId"
 proxy-options="-t -e 1.0"
 replica-group="MyReplicaGroup">
 <description>A description of the adapter.</description>
 ...
</adapter>

```

## Allocatable Descriptor Element

An allocatable element defines an [allocatable object](#) in the IceGrid registry. Clients can allocate this object using only its identity, or they can allocate objects of a specific type.

This element may only appear as a child of an [adapter](#) element.

The following attributes are supported:

Attribute	Description	Required
<code>identity</code>	Specifies the identity by which this allocatable object is known.	Yes
<code>property</code>	Specifies the name of a property to generate that contains the stringified identity of this allocatable.	No
<code>type</code>	An arbitrary string used to group allocatable objects. By convention, the string represents the most-derived Slice <a href="#">type ID</a> of the object, but an application is free to use another convention.	No
<code>proxy-options</code>	The proxy options to use for the proxy of the allocatable object returned by IceGrid.	No

See Also

- [Resource Allocation using IceGrid Sessions](#)

## Application Descriptor Element

An `application` element defines an IceGrid application. An application typically contains at least one `node` element, but it may also be used for other purposes such as defining `server` and `service` templates, `default templates`, `replica groups` and `property sets`.

This element must be a child of an `icegrid` element. Only one `application` element is permitted per file.

The following attributes are supported.

Attribute	Description	Required
<code>import-default-templates</code>	If <code>true</code> , the <code>default templates</code> configured for the IceGrid registry are imported and available for use within this application. If not specified, the default value is <code>false</code> .	No
<code>name</code>	The name of the application. This name must be unique among all applications in the registry. Within the application, child elements can refer to its name using the <code>reserved variable</code> <code>\${application}</code> .	Yes

An optional nested `description` element provides free-form descriptive text.

Here is an example to demonstrate the use of this element:

**XML**

```

<icegrid>
 <application name="MyApplication" import-default-templates="true">
 <description>A description of the application.</description>
 ...
 </application>
</icegrid>

```

## DbEnv Descriptor Element

A `dbenv` element causes an IceGrid node to generate [Freeze](#) configuration properties for the server or service in which it is defined. The IceGrid node also creates a directory for the Berkeley DB database environment if needed.

This element may contain [dbproperty](#) elements. This element may only appear as a child of a [server](#) or [service](#) element.

The following attributes are supported:

Attribute	Description	Required
home	Specifies the directory to use as the database environment. If not defined, a sub-directory in the node's data directory is used.	No
name	The name of the Berkeley DB database environment.	Yes

The values of the `name` and `home` attributes are used to define the `Freeze.DbEnv.env-name.DbHome` property as shown below:

```
Freeze.DbEnv.name.DbHome=home
```

An optional nested [description](#) element provides free-form descriptive text.

Here is an example to demonstrate the use of this element:

XML
<pre>&lt;dbenv name="MyEnv" home="/opt/data/db"&gt;   &lt;description&gt;A description of the Freeze/BDB database environment.&lt;/description&gt;   ... &lt;/dbenv&gt;</pre>

See Also

- [Freeze](#)
- [DbProperty Descriptor Element](#)
- [Server Descriptor Element](#)
- [Service Descriptor Element](#)
- [Description Descriptor Element](#)
- [Freeze.\\*](#)

## DbProperty Descriptor Element

A `dbproperty` element defines a Berkeley DB configuration property for a [Freeze](#) database environment.

This element may only appear as a child of a `dbenv` element.

The following attributes are supported:

Attribute	Description	Required
<code>name</code>	The name of the configuration property.	Yes
<code>value</code>	The value of the configuration property. If not defined, the value is an empty string.	No

Here is an example to demonstrate the use of this element:

**XML**

```
<dbenv name="MyEnv" home="/opt/data/db">
 <description>A description of the
database environment.</description>
 <dbproperty name="set_cachesize" value="0 52428800 1"/>
</dbenv>
```

See Also

- [Freeze](#)
- [DbEnv Descriptor Element](#)

## Description Descriptor Element

A `description` element specifies a description of its parent element.

This element may only appear as a child of the `application`, `replica-group`, `node`, `server`, `service`, `icebox`, `adapter`, and `dbenv` elements.

Here is an example to demonstrate the use of this element:

**XML**

```
<node name="localnode">
 <description>Free form descriptive text for localnode</description>
</node>
```

- [Node Descriptor Element](#)
- [Server Descriptor Element](#)
- [Service Descriptor Element](#)
- [IceBox Descriptor Element](#)
- [Adapter Descriptor Element](#)
- [DbEnv Descriptor Element](#)

## Directory Descriptor Element

A `directory` element specifies a directory in a `distribution`.

This element may only appear as a child of the `distrib` element.

This element supports no attributes.

See Also

- [Application Distribution](#)
- [Distrib Descriptor Element](#)

## Distrib Descriptor Element

A `distrib` element specifies the `distribution` files to download from an `IcePatch2` server as well as the server's proxy.

This element may only appear as a child of an `application` element or a `server` element.

The following attributes are supported:

Attribute	Description	Required
<code>icepatch</code>	Proxy for the <code>IcePatch2</code> server. If not defined, the default value is <code>\${application}.IcePatch2/server</code> .	No

Here is an example to demonstrate the use of this element:

**XML**

```
<distrib icepatch="DemoIcePatch2/server:tcp -p 12345">
 <directory>dir1</directory>
 <directory>dir2/subdir</directory>
</distrib>
```

See Also

- [Application Distribution](#)
- [IcePatch2](#)
- [Application Descriptor Element](#)
- [Server Descriptor Element](#)

## IceBox Descriptor Element

An `icebox` element defines an `IceBox` server to be deployed on a node. It typically contains at least one `service` element, and may supply additional information such as `command-line options`, `environment variables`, `configuration properties` and a `server distribution`.

This element may only appear as a child of a `node` element or a `server-template` element.

This element supports the same attributes as the `server` element.

An optional nested `description` element provides free-form descriptive text.

Here is an example to demonstrate the use of this element:

XML
<pre> &lt;icebox id="MyIceBox"   activation="on-demand"   activation-timeout="60"   application-distrib="false"   deactivation-timeout="60"   exe="/opt/Ice/bin/icebox"   pwd="/"&gt;   &lt;option&gt;--Ice.Trace.Network=1&lt;/option&gt;   &lt;env&gt;PATH=/opt/Ice/bin:\$PATH&lt;/env&gt;   &lt;property name="IceBox.UseSharedCommunicator.Service1" value="1"/&gt;   &lt;service name="Service1" .../&gt;   &lt;service-instance template="ServiceTemplate" name="Service2"/&gt; &lt;/icebox&gt; </pre>

## IceGrid Descriptor Element

The `icegrid` element is the top-level element for IceGrid descriptors in XML files. This element supports no attributes.  
See Also

- [Using IceGrid Deployment](#)

## Load-Balancing Descriptor Element

A load-balancing element determines the load balancing policy used by a replica group.

This element may only appear as a child of a `replica-group` element.

The following attributes are supported:

Attribute	Description	Required
load-sample	Specifies the load sample to use for the adaptive load balancing policy. It can only be defined if <code>type</code> is set to <code>adaptive</code> . Legal values are 1, 5 and 15. If not specified, the load sample default value is 1.	No
n-replicas	Specifies the maximum number of replicas used to compute the endpoints of the replica group. If not specified, the default value is 1.	No
type	Specifies the type of load balancing. Legal values are <code>adaptive</code> , <code>ordered</code> , <code>round-robin</code> and <code>random</code> .	Yes

Here is an example to demonstrate the use of this element:

**XML**

```

<application name="MyApp">
 <replica-group id="ReplicatedAdapter">
 <load-balancing type="adaptive" load-sample="15"
n-replicas="3"/>
 <description>A description of this replica group.</description>
 <object identity="WellKnownObject" .../>
 </replica-group>
 ...
</application>

```

See Also

- [Load Balancing](#)
- [Object Adapter Replication](#)
- [Replica-Group Descriptor Element](#)

## Log Descriptor Element

A `log` element specifies the name of a log file for a server or service. A `log` element must be defined for each log file that can be [accessed remotely](#) by an administrative tool. Note that it is not necessary to define a `log` element for the values of the `Ice.StdErr` and `Ice.Stdout` properties.

This element may only appear as a child of a `server` element or a `service` element.

The following attributes are supported:

Attribute	Description	Required
<code>path</code>	The path name of the log file. If a relative path is specified, it is relative to the current working directory of the node. The node must have sufficient access privileges to read the file.	Yes
<code>property</code>	Specifies the name of a property in which to store the path name of the log file as given in the <code>path</code> attribute.	No

Here is an example to demonstrate the use of this element:

**XML**

```
<server id="MyServer" ...>
 <log path="${server}.log" property="LogFile"/>
</server>
```

See Also

- [IceGrid Administrative Sessions](#)
- [Server Descriptor Element](#)
- [Service Descriptor Element](#)

## Node Descriptor Element

A `node` element defines an IceGrid node. The servers that the node is responsible for managing are described in child elements.

This element may only appear as a child of an `application` element. Multiple `node` elements having the same name may appear in an application. Their contents are merged and the last definition of `load-factor` has precedence.

The following attributes are supported:

Attribute	Description	Required
<code>load-factor</code>	A floating point value defining the factor that is multiplied with the node's load average. The load average is used by the adaptive <a href="#">load balancing</a> policy to figure out which node is the least loaded. The default is 1.0 on Unix platforms and 1/NCPUS on Windows (where NCPUS is the number of CPUs in the node's computer). Note that, if Unix and Windows machines are part of a <a href="#">replica group</a> , the Unix and Windows figures are not directly comparable, but the registry still makes an attempt to pick the least-loaded node.	No
<code>name</code>	The name must be unique among all nodes in the registry. Within the node, child elements can refer to its name using the <a href="#">reserved variable</a> <code>\${node}</code> . An <code>icegridnode</code> process representing this node must be started on the desired computer and its configuration property <code>IceGrid.Node.Name</code> must match this attribute.	Yes

Here is an example to demonstrate the use of this element:

**XML**

```

<node name="Node1" load-factor="2.0">
 <description>A description of this node.</description>
 <server id="Server1" ...>
 <property name="NodeName" value="${node}"/>
 ...
 </server>
</node>

```

See Also

- [Application Descriptor Element](#)
- [Load Balancing](#)
- [Object Adapter Replication](#)
- [icegridnode](#)

## Object Descriptor Element

An `object` element defines a [well-known object](#) in the IceGrid registry. Clients can refer to this object using only its identity, or they can search for well-known objects of a specific type.

This element may only appear as a child of an [adapter](#) element or a [replica-group](#) element.

The following attributes are supported:

Attribute	Description	Required
<code>identity</code>	Specifies the identity by which this object is known.	Yes
<code>property</code>	Specifies the name of a property to generate that contains the stringified identity of the object. This attribute is only allowed if this <code>object</code> element is a child of an <a href="#">adapter</a> element.	No
<code>type</code>	An arbitrary string used to group objects. By convention, the string represents the most-derived Slice <a href="#">type ID</a> of the object, but an application is free to use another convention.	No
<code>proxy-options</code>	The proxy options to use for the proxy of the well-known object return by IceGrid.	No

Here is an example to demonstrate the use of this element:

**XML**

```
<adapter name="MyAdapter" id="WellKnownAdapter" ...>
 <object identity="WellKnownObject"
type="::Module::WellKnownInterface" proxy-options="-o"/>
</adapter>
```

In the configuration above, the object can be located via the equivalent proxies `WellKnownObject` and `WellKnownObject@WellKnownAdapter`.

See Also

- [Well-Known Objects](#)
- [Adapter Descriptor Element](#)
- [Replica-Group Descriptor Element](#)
- [Type IDs](#)

## Parameter Descriptor Element

A `parameter` element defines a [template](#) parameter. Template parameters must be declared with this element to be used in template instantiation.

This element may only appear as a child of a `server-template` element or a `service-template` element.

The following attributes are supported:

Attribute	Description	Required
<code>name</code>	The name of the parameter. For example, if <code>index</code> is used as the name of a parameter, it can be referenced using <code>\${index}</code> in the server or service template.	Yes
<code>default</code>	An optional default value for the parameter. This value is used if the parameter is not defined when a server or service is instantiated.	No

Here is an example to demonstrate the use of this element:

**XML**

```

<server-template id="MyServerTemplate">
 <parameter name="index"/>
 <parameter name="exepath" default="/opt/myapp/bin/server"/>
 ...
</server-template>

```

See Also

## Properties Descriptor Element

The `properties` element is used in three situations:

- as a named property set if the `id` attribute is specified
- as a reference to a named property set if the `refid` attribute is specified
- as an unnamed property set if the `id` or `refid` attributes are not specified.

A property set is useful for defining a set of [properties](#) (a named property set) in application or node descriptors. Named property sets can be included in named or unnamed property sets with property set references.

A named property set element may only be a child of an [application](#) element or a [node](#) element. An unnamed property set element may only be a child of a [server](#), [icebox](#), [service](#), [server-instance](#) or [service-instance](#) element. An unnamed property set element with the `service` attribute defined may only be a child of a [server-instance](#) element. A reference to a named property set can only be a child of a named or unnamed property set element.

The following attributes are supported:

Attribute	Description	Required
<code>id</code>	Defines a new named property set with the given identifier. The identifier must be unique among all named property sets defined in the same scope. If not specified, the <code>properties</code> element refers to an unnamed property set or a property set reference.	No
<code>refid</code>	Defines a reference to the named property set with the given identifier. If not specified, the element refers to an unnamed or named property set.	No
<code>service</code>	Specifies the name of an IceBox service that is defined in the enclosing <code>server-instance</code> descriptor. The server instance must be an IceBox server that includes a service with the given name. An unnamed property set with this attribute defined extends the properties of the service. If not specified, the unnamed property set extends the properties of the server instance.	No

Here is an example to demonstrate the use of this element:

**XML**

```

<application name="Simple">
 <properties id="Debug">
 <property name="Ice.Trace.Network" value="1"/>
 </properties>

 <server id="MyServer" exe="./server">
 <properties>
 <properties refid="Debug"/>
 <property name="AppProperty" value="1"/>
 </properties>
 </server>
</application>

```

## Property Descriptor Element

An IceGrid node generates a [configuration file](#) for each of its servers and services. This file generally should not be edited manually because any changes are lost the next time the node generates the file. The `property` element is the correct way to define additional properties in a configuration file.

Note that IceGrid [administrative utilities](#) can retrieve the configuration properties of a server or service via the [administrative facility](#).

This element may only appear as a child of a `server` element, a `service` element, an `icebox` element or a `properties` element.

The following attributes are supported:

Attribute	Description	Required
name	Specifies the property name.	Yes
value	Specifies the property value. If not defined, the value is an empty string.	No

Here is an example to demonstrate the use of this element:

**XML**

```
<server id="MyServer" ...>
 <property name="Ice.ThreadPool.Server.SizeMax" value="10"/>
 ...
</server>
```

This `property` element adds the following definition to the server's configuration file:

```
Ice.ThreadPool.Server.SizeMax=10
```

## Replica-Group Descriptor Element

A `replica-group` element creates a virtual object adapter in order to provide [replication](#) and [load balancing](#) for a collection of object adapters. An `adapter` element declares its membership in a group by identifying the desired replica group. The element may declare [well-known objects](#) that are available in all of the participating object adapters. A `replica-group` element may contain a `load-balancing` child element that specifies the load-balancing algorithm the registry should use when resolving locate requests. If not specified, the registry uses a random load balancing policy with the number of replicas set to 0.

This element may only appear as a child of an `application` element.

The following attributes are supported:

Attribute	Description	Required
<code>id</code>	Specifies the identifier of the replica group, which must be unique among all adapters and replica groups in the registry. This identifier can be used in indirect proxies in place of an adapter identifier.	Yes
<code>filter</code>	Specifies the identifier of a replica group filter that performs <a href="#">custom load balancing</a> .	No
<code>proxy-options</code>	The proxy options to use for well-known object proxies declared with this replica group.	No

An optional nested `description` element provides free-form descriptive text.

Here is an example to demonstrate the use of this element:

**XML**

```

<application name="MyApp">
 <replica-group id="ReplicatedAdapter" filter="myCustomFilter"
proxy-options="-e 1.0">
 <load-balancing type="adaptive" load-sample="15"
n-replicas="3"/>
 <description>A description of this replica group.</description>
 <object identity="WellKnownObject" .../>
 </replica-group>
 ...
</application>

```

In this example, the proxy `WellKnownObject` is equivalent to the proxy `WellKnownObject@ReplicatedAdapter`.

## Server Descriptor Element

A `server` element defines a server to be deployed on a node. It typically contains at least one `adapter` element, and may supply additional information such as `command-line options`, `environment variables`, `configuration properties`, and a `server distribution`.

This element may only appear as a child of a `node` element or a `server-template` element.

The following attributes are supported:

Attribute	Description	Required
<code>activation</code>	Specifies whether the server's <code>activation</code> mode. Legal values are <code>manual</code> , <code>on-demand</code> , <code>always</code> and <code>session</code> . If not specified, <code>manual</code> activation is used by default.	No
<code>activation-timeout</code>	Defines the number of seconds a node will wait for the server to <code>activate</code> . If the timeout expires, a client waiting to receive the endpoints of an object adapter in this server will receive an empty set of endpoints. If not defined, the default timeout is the value of the <code>IceGrid.Node.WaitTime</code> property configured for the server's node.	No
<code>allocatable</code>	Specifies whether the server can be <code>allocated</code> . A server is allocated implicitly when one of its allocatable objects is allocated. The value of this attribute is ignored if the server activation mode is <code>session</code> ; a server with this activation mode is always allocatable. Otherwise, if not specified and the server activation mode is not <code>session</code> , the server is not allocatable.	No
<code>application-distrib</code>	Specifies whether this server's <code>distribution</code> is dependent on the application's distribution. If the value is <code>true</code> , the server cannot be patched until the application has been patched. If not defined, the default value is <code>true</code> .	No
<code>deactivation-timeout</code>	Defines the number of seconds a node will wait for the server to <code>deactivate</code> . If the timeout expires, the node terminates the server process. If not defined, the default timeout is the value of the node's configuration property <code>IceGrid.Node.WaitTime</code> .	No
<code>exe</code>	The pathname of the server executable. On Windows, if a relative path is specified, the executable is searched in the system path. On Linux, it's searched in the user path specified by the <code>PATH</code> environment variable from the environment where the <code>icengridnode</code> is started.	Yes
<code>ice-version</code>	Specifies the Ice version in use by this server. If not defined, IceGrid assumes the server uses the same version that IceGrid itself uses. A server that uses an Ice version prior to 3.3 must define this attribute if its adapters use the <code>register-process</code> attribute. For example, a server using Ice 3.2.x should use <code>3.2</code> as the value of this attribute.	No
<code>id</code>	Specifies the identifier for this server. The identifier must be unique among all servers in the registry. Within the server, child elements can refer to its identifier using the <code>reserved variable</code> <code>#{server}</code> .	Yes
<code>pwd</code>	The default working directory for the server. If not defined, the server is started in the node's current working directory.	No
<code>user</code>	Specifies the name of the user account under which the server is activated and run. If a user account mapper is configured for the node, the value of this attribute is used to find the corresponding account in the map. On Unix, the node must be running as root to be able to run servers under a different user account. On Windows, or if the node is not running as root on Unix, the only permissible value for this attribute is an empty string or the name of the user account under which the node is running. On Unix, if the node is running as root and this attribute is not specified, the server is run under the user <code>#{session.id}</code> if the server activation mode is <code>session</code> or under the user <code>nobody</code> if the activation mode is <code>manual</code> , <code>on-demand</code> or <code>always</code> .	No

An optional nested `description` element provides free-form descriptive text.

Here is an example to demonstrate the use of this element:

## XML

```
<server id="MyServer"
 activation="on-demand"
 activation-timeout="60"
 application-distrib="false"
 deactivation-timeout="60"
 exe="/opt/app/bin/myserver"
 pwd="/" >
 <option>--Ice.Trace.Network=1</option>
 <env>PATH=/opt/Ice/bin:$PATH</env>
 <property name="ServerId" value="{server}" />
 <adapter name="Adapter1" .../>
</server>
```

## Server-Instance Descriptor Element

A `server-instance` element deploys an instance of a `server-template` element on a node. It may supply additional information such as [configuration properties](#).

This element may only appear as a child of a `node` element.

The following attributes are supported:

Attribute	Description	Required
template	Identifies the server template.	Yes

All other attributes of the element must correspond to [parameters](#) declared by the template. The `server-instance` element must provide a value for each parameter that does not have a default value supplied by the template.

Here is an example to demonstrate the use of this element:

**XML**

```

<icegrid>
 <application name="SampleApp">
 <server-template id="ServerTemplate">
 <parameter name="id"/>
 <server id="${id}" activation="manual" .../>
 </server-template>
 <node name="Node1">
 <server-instance template="ServerTemplate" id="TheServer">
 <properties>
 <property name="Debug" value="1"/>
 </properties>
 </server-instance>
 </node>
 </application>
</icegrid>

```

## Server-Template Descriptor Element

A `server-template` element defines a `template` for a `server` element, simplifying the task of deploying multiple instances of the same server definition. The template should contain a parameterized `server` element that is instantiated using a `server-instance` element.

This element may only appear as a child of an `application` element.

The following attributes are supported:

Attribute	Description	Required
id	Specifies the identifier for the server template. This identifier must be unique among all server templates in the application.	Yes

A template may declare `parameters` that are used to instantiate the `server` element. You can define a default value for each parameter. Parameters without a default value are considered mandatory and values for them must be supplied by the `server-instance` element.

Here is an example to demonstrate the use of this element:

**XML**

```

<icegrid>
 <application name="SampleApp">
 <server-template id="ServerTemplate">
 <parameter name="id"/>
 <server id="${id}" activation="manual" .../>
 </server-template>
 <node name="Node1">
 <server-instance template="ServerTemplate" id="TheServer"/>
 </node>
 </application>
</icegrid>

```

## Service Descriptor Element

A `service` element defines an `IceBox` service. It typically contains at least one `adapter` element, and may supply additional information such as [configuration properties](#).

This element may only appear as a child of an `icebox` element or a `service-template` element.

The following attributes are supported:

Attribute	Description	Required
<code>entry</code>	Specifies the entry point of this service.	Yes
<code>name</code>	Specifies the name of this service. Within the service, child elements can refer to its name using the <a href="#">reserved variable</a> <code>\${service}</code> .	Yes

An optional nested `description` element provides free-form descriptive text.

Here is an example to demonstrate the use of this element:

**XML**

```

<icebox id="MyIceBox" ...>
 <service name="Service1" entry="service1:Create">
 <description>A description of this service.</description>
 <property name="ServiceName" value="${service}"/>
 <adapter name="MyAdapter" id="${service}Adapter" .../>
 </service>
 <service name="Service2" entry="service2:Create"/>
</icebox>

```

## Service-Instance Descriptor Element

A `service-instance` element creates an instance of a `service-template` element in an `IceBox` server. It may supply additional information such as [configuration properties](#).

This element may only appear as a child of an `icebox` element.

The following attributes are supported:

Attribute	Description	Required
<code>template</code>	Identifies the service <a href="#">template</a> .	Yes

All other attributes of the element must correspond to [parameters](#) declared by the template. The `service-instance` element must provide a value for each parameter that does not have a default value supplied by the template.

Here is an example to demonstrate the use of this element:

**XML**

```
<icebox id="IceBoxServer" ...>
 <service-instance template="ServiceTemplate" name="Service1">
 <properties>
 <property name="Debug" value="1"/>
 </properties>
 </service-instance>
</icebox>
```

See Also

## Service-Template Descriptor Element

A `service-template` element defines a `template` for a `service` element, simplifying the task of deploying multiple instances of the same service definition. The template should contain a parameterized `service` element that is instantiated using a `service-instance` element.

This element may only appear as a child of an `application` element.

The following attributes are supported:

Attribute	Description	Required
id	Specifies the identifier for the service template. This identifier must be unique among all service templates in the application.	Yes

A template may declare `parameters` that are used to instantiate the `service` element. You can define a default value for each parameter. Parameters without a default value are considered mandatory and values for them must be supplied by the `service-instance` element.

Here is an example to demonstrate the use of this element:

**XML**

```

<icegrid>
 <application name="IceBoxApp">
 <service-template id="ServiceTemplate">
 <parameter name="name"/>
 <service name="{name}" entry="DemoService:create">
 <adapter name="{service}" .../>
 </service>
 </service-template>
 <node name="Node1">
 <icebox id="IceBoxServer" ...>
 <service-instance template="ServiceTemplate"
name="Service1"/>
 </icebox>
 </node>
 </application>
</icegrid>

```

See Also

- [IceGrid Templates](#)

## Variable Descriptor Element

A `variable` element defines a `variable`.

This element may only appear as a child of an `application` element or `node` element.

The following attributes are supported:

Attribute	Description	Required
<code>name</code>	Specifies the variable name. The value of this variable is substituted whenever its name is used in variable syntax, as in <code>\${name}</code> .	Yes
<code>value</code>	Specifies the variable value. If not defined, the default value is an empty string.	No

Here is an example to demonstrate the use of this element:

**XML**

```

<icegrid>
 <application name="SampleApp">
 <variable name="Var1" value="foo"/>
 <variable name="Var2" value="${Var1}bar"/>
 ...
 </application>
</icegrid>

```

See Also

- [Using Descriptor Variables and Parameters](#)
- [Application Descriptor Element](#)
- [Node Descriptor Element](#)

## Using Command Line Options in Descriptors

Server descriptors and IceBox descriptors may specify command-line options that the node will pass to the program at startup. As the node prepares to execute the server, it assembles the command by appending options to the server executable's pathname.

In XML, you define a command-line option using the `option` element:

XML
<pre>&lt;server id="Server1" ...&gt;   &lt;option&gt;--Ice.Trace.Protocol&lt;/option&gt;   ... &lt;/server&gt;</pre>

The node preserves the order of options, which is especially important for Java servers. For example, JVM options must appear before the class name, as shown below:

XML
<pre>&lt;server id="JavaServer" exe="java" ...&gt;   &lt;option&gt;-Xnoclassgc&lt;/option&gt;   &lt;option&gt;ServerClassName&lt;/option&gt;   &lt;option&gt;--Ice.Trace.Protocol&lt;/option&gt;   ... &lt;/server&gt;</pre>

The node translates these options into the following command:

<pre>java -Xnoclassgc ServerClassName --Ice.Trace.Protocol</pre>
------------------------------------------------------------------

See Also

- [Server Descriptor Element](#)
- [IceBox Descriptor Element](#)

## Setting Environment Variables in Descriptors

Server descriptors and IceBox descriptors may specify environment variables that the node will define when starting a server. An environment variable definition uses the familiar *name=value* syntax, and you can also refer to other environment variables within the value. The exact syntax for variable references depends on the platform on which the server's descriptor is deployed.

On a Unix platform, the Bourne shell syntax is required:

```
LD_LIBRARY_PATH=/opt/Ice/lib:$LD_LIBRARY_PATH
```

On a Windows platform, the syntax uses the conventional style:

```
PATH=C:\Ice\lib;%PATH%
```

In XML, the `env` element supplies a definition for an environment variable:

### XML

```
<node name="UnixBox">
 <server id="UnixServer" exe="/opt/app/bin/server" ...>
 <env>LD_LIBRARY_PATH=/opt/Ice/lib:$LD_LIBRARY_PATH</env>
 ...
 </server>
</node>
<node name="WindowsBox">
 <server id="WindowsServer" exe="C:/app/bin/server.exe" ...>
 <env>PATH=C:\Ice\lib;%PATH%</env>
 ...
 </server>
</node>
```

If a value refers to an environment variable that is not defined, the reference is substituted with an empty string.

Environment variable definitions may also refer to [descriptor variables](#) and [template parameters](#):

### XML

```
<node name="UnixBox">
 <server id="UnixServer" exe="/opt/app/bin/server" ...>
 <env>PATH=${server.distrib}/bin:$PATH</env>
 ...
 </server>
</node>
```

On Unix, an environment variable `VAR` can be referenced as `$VAR` or `${VAR}`. You must be careful when using the latter syntax because

IceGrid assumes `${VAR}` refers to a descriptor variable or parameter and will report an error if no match is found. If you prefer to use this style to refer to environment variables, you must escape these occurrences as shown in the example below:

```
<node name="UnixBox">
 <server id="UnixServer" exe="/opt/app/bin/server" ...>
 <env>PATH=${server.distrib}/bin:${PATH}</env>
 ...
 </server>
</node>
```

IceGrid does not attempt to perform substitution on ``${PATH}`, but rather removes the leading `$` character and then performs environment variable substitution on ``${PATH}`.

## Using Descriptor Variables and Parameters

Variable descriptors allow you to define commonly-used information once and refer to them symbolically throughout your application descriptors.

On this page:

- [Descriptor Substitution Syntax](#)
  - [Limitations](#)
  - [Escaping a Variable](#)
- [Special Descriptor Variables](#)
- [Descriptor Variable Scoping Rules](#)
  - [Resolving a Reference](#)
  - [Template Parameters](#)
  - [Modifying a Variable](#)

### Descriptor Substitution Syntax

Substitution for a variable or parameter  $VP$  is attempted whenever the symbol  $\${VP}$  is encountered, subject to the limitations and rules described below. Substitution is case-sensitive, and a fatal error occurs if  $VP$  is not defined.

#### Limitations

Substitution is only performed in string values, and excludes the following cases:

- Identifier of a template descriptor definition

```
<server-template id="\${invalid}" ...>
```

- Name of a variable definition

```
<variable name="\${invalid}" ...>
```

- Name of a template parameter definition

```
<parameter name="\${invalid}" ...>
```

- Name of a template parameter assignment

```
<server-instance template="T" \${invalid}="val" ...>
```

- Name of a node definition

```
<node name="\${invalid}" ...>
```

- Name of an application definition

```
<application name="\${invalid}" ...>
```

Substitution is not supported for values of other types. The example below demonstrates an invalid use of substitution:

```
<variable name="register" value="true"/>
<node name="Node">
 <server id="Server1" ...>
 <adapter name="Adapter1" register-process=${register} .../>
```

In this case, a variable cannot supply the value of `register-process` because that attribute expects a boolean value, not a string.

Most values are strings, however, so this limitation is rarely a problem.

### Escaping a Variable

You can prevent substitution by escaping a variable reference with an additional leading `$` character. For example, in order to assign the literal string `${abc}` to a variable, you must escape it as shown below:

```
<variable name="x" value="$$${abc}"/>
```

The extra `$` symbol is only meaningful when immediately preceding a variable reference, therefore text such as `US$$55` is not modified. Each occurrence of the characters `$$` preceding a variable reference is replaced with a single `$` character, and that character does not initiate a variable reference. Consider these examples:

```
<variable name="a" value="hi"/>
<variable name="b" value="$$${a}"/>
<variable name="c" value="$$$${a}"/>
<variable name="d" value="$$$$${a}"/>
```

After substitution, `b` has the value `${a}`, `c` has the value `$hi`, and `d` has the value `$$${a}`.

### Special Descriptor Variables

IceGrid defines a set of read-only variables to hold information that may be of use to descriptors. The names of these variables are reserved and cannot be used as variable or parameter names. The table describes the purpose of each variable and defines the context in which it is valid.

Reserved Name	Description
<code>application</code>	The name of the enclosing application.
<code>application.distrib</code>	The pathname of the enclosing application's <a href="#">distribution</a> directory, and an alias for <code>\${node.datadir}/distribution/\${application}</code> .
<code>node</code>	The name of the enclosing node.
<code>node.os</code>	The name of the enclosing node's operating system. On Unix, this value is provided by <code>uname</code> . On Windows, the value is <code>Windows</code> .
<code>node.hostname</code>	The host name of the enclosing node.

<code>node.release</code>	The operating system release of the enclosing node. On Unix, this value is provided by <code>uname</code> . On Windows, the value is obtained from the <code>OSVERSIONINFO</code> data structure.
<code>node.version</code>	The operating system version of the enclosing node. On Unix, this value is provided by <code>uname</code> . On Windows, the value represents the current service pack level.
<code>node.machine</code>	The machine hardware name of the enclosing node. On Unix, this value is provided by <code>uname</code> . On Windows, the value can be <code>x86</code> , <code>x64</code> , or <code>IA64</code> , depending on the machine architecture.
<code>node.datadir</code>	The absolute pathname of the enclosing node's data directory.
<code>server</code>	The ID of the enclosing server.
<code>server.distrib</code>	The pathname of the enclosing server's <a href="#">distribution</a> directory, and an alias for <code>\${node.datadir}/servers/\${server}/distrib</code> .
<code>service</code>	The name of the enclosing service.
<code>session.id</code>	The client session identifier. For sessions created with a user name and password, the value is the user ID; for sessions created from a secure connection, the value is the distinguished name associated with the connection.

The availability of a variable is easily determined in some cases, but may not be readily apparent in others. For example, the following example represents a valid use of the `${node}` variable:

**XML**

```

<icegrid>
 <application name="App">
 <server-template id="T" ...>
 <parameter name="id"/>
 <server id="${id}" ...>
 <property name="NodeName" value="${node}"/>
 ...
 </server>
 </server-template>
 <node name="TheNode">
 <server-instance template="T" id="TheServer"/>
 </node>
 </application>
</icegrid>

```

Although the server template descriptor is defined as a child of an application descriptor, its variables are not evaluated until it is instantiated. Since a template *instance* is always enclosed within a node, it is able to use the `${node}` variable.

## Descriptor Variable Scoping Rules

Descriptors may only define variables at the application and node levels. Each node introduces a new scope, such that defining a variable at the node level overrides (but does not modify) the value of an application variable with the same name. Similarly, a template parameter overrides the value of a variable with the same name in an enclosing scope. A descriptor may refer to a variable defined in any enclosing scope, but its value is determined by the nearest scope. The following figure illustrates these concepts:

#### Variable scoping semantics.

In this diagram, the variable `x` is defined at the application level with the value 1. In `nodeA`, `x` is overridden with the value 2, whereas `x` remains unchanged in `nodeB`. Within the context of `nodeA`, `x` continues to have the value 2 in a server instance definition. However, when `x` is used as the name of a template parameter, the node's definition of `x` is overridden and `x` has the value 3 in the template's scope.

### Resolving a Reference

To resolve a variable reference `${var}`, IceGrid searches for a definition of `var` using the following order of precedence:

1. Pre-defined variables
2. Template parameters, if applicable
3. Node variables, if applicable
4. Application variables

After the initial substitution, any remaining references are resolved recursively using the following order of precedence:

1. Pre-defined variables
2. Node variables, if applicable
3. Application variables

### Template Parameters

Template parameters are not visible in nested template instances. This situation can only occur when an IceBox server template instantiates a service template, as shown in the following example:

## XML

```

<icegrid>
 <application name="IceBoxApp">
 <service-template id="ServiceTemplate">
 <parameter name="name"/>
 <service name="{name}" entry="DemoService:create">
 ...
 <property name="{name}.Identity"
value="{id}-{name}"/> <!-- WRONG! -->
 </service>
 </service-template>
 <server-template id="ServerTemplate">
 <parameter name="id"/>
 <icebox id="{id}" endpoints="default" ...>
 <service-instance template="ServiceTemplate"
name="Service1"/>
 </icebox>
 </server-template>
 <node name="Node1">
 <server-instance template="ServerTemplate"
id="IceBoxServer"/>
 </node>
 </application>
</icegrid>

```

The service template incorrectly refers to `id`, which is a parameter of the server template.

Template parameters can be referenced only in the body of a template; they cannot be used to define other parameters. For example, the following is illegal:

## XML

```

<server-template id="ServerTemplate">
 <parameter name="par1"/>
 <parameter name="par2" default="{par1}"/>
 ...
</server-template>

```

### Modifying a Variable

A variable definition can be overridden in an inner scope, but the inner definition does not modify the outer variable. If a variable is defined multiple times in the same scope (which is only relevant in XML definitions), the most recent definition is used for all references to that variable. Consider the following example:

**XML**

```
<application name="MyApp">
 <variable name="x" value="1"/>
 <variable name="y" value="{x}"/>
 <variable name="x" value="2"/>
 ...
</application>
```

When descriptors such as these are created, IceGrid validates their variable references but does not perform substitution until the descriptor is acted upon (such as when a node is generating a configuration file for a server). As a result, the value of `y` in the above example is `2` because that is the most recent definition of `x`.

## IceGrid Property Set Semantics

Ice servers and clients are configured with [properties](#). For servers [deployed](#) with IceGrid, these properties are automatically generated into a configuration file from the information contained in the application descriptor. The settings in that configuration file are passed to server via the `--Ice.Config` command-line option.

[Property descriptors](#) allow you to define property sets to efficiently manage and specify properties. Here are some of the benefits of using property sets:

- You can define sets of properties at the [application](#) or [node](#) element level and reference these properties in other property sets.
- You can specify properties for a specific [server](#) or [service](#) instance.

There are two kinds of property sets:

- **Named property sets**  
Named property sets are defined at the application or node level. They are useful only as the target of references from other property sets. Specifically, a named property set has no effect unless you reference it from a [server](#) descriptor.
- **Unnamed property sets**  
Unnamed property sets can be defined in [server](#), [service](#), [icebox](#), [server-instance](#) or [service-instance](#) elements and define the properties for a server or service. Unnamed property sets can reference named property sets.

Named and unnamed property sets are defined with the same [properties](#) descriptor. The context and the attributes of a `properties` element distinguish named property sets from unnamed property sets. Here is an example that defines a named and an unnamed property set:

**XML**

```

<application name="App">
 <properties id="Debug">
 <property name="UseDebug" value="1"/>
 </properties>

 <node name="TheNode">
 <server id="TheServer" exe="./server">
 <properties>
 <property name="Identity" value="hello"/>
 </properties>
 </server>
 </node>
</application>

```

In this example, we define the named property set `Debug` and the unnamed property set of the server `TheServer`. The server configuration will contain only the `Identity` property because the server property set does not reference the `Debug` named property set.

The `properties` element is used to reference a named property set: if a `properties` element appears inside another `properties` element, it is a reference to another property set and it must specify the `refid` attribute. With the previous example, to reference the `Debug` property set, we would write the following:

## XML

```

<application name="App">
 <properties id="Debug">
 <property name="UseDebug" value="1"/>
 </properties>

 <node name="TheNode">
 <server id="TheServer" exe="./server">
 <properties>
 <properties refid="Debug"/>
 <property name="Identity" value="hello"/>
 </properties>
 </server>
 </node>
</application>

```

Property sets, whether named or unnamed, are evaluated as follows:

1. Within a `properties` element, IceGrid locates all references to named property sets and evaluates all property settings in the referenced property sets.
2. Explicit property definitions following any named references are then evaluated and added to the property set formed in the preceding step. This means that explicit property settings override corresponding settings in any referenced property sets.

It is illegal to define a reference to a property set after setting a property value, so references to property sets must precede property definitions. For example, the following is illegal:

## XML

```

<properties>
 <property name="Prop1" value="Value1"/>
 <properties refid="Ref1"/>
</properties>

```

Just as the order of the property definitions is important, the order of property set references is also important. For example, the following two property sets are not equivalent:

## XML

```

<properties>
 <properties refid="Ref1"/>
 <properties refid="Ref2"/>
</properties>

<properties>
 <properties refid="Ref2"/>
 <properties refid="Ref1"/>
</properties>

```

Named property sets are evaluated at the point of definition. If you reference other property sets or use variables in a named property set definition, you must make sure that the referenced property sets or variables are defined in the same scope. For example, the following is correct:

## XML

```

<application name="App">

 <variable name="level" value="1"/>

 <properties id="DebugApp">
 <property name="DebugLevel" value="{level}">
 </properties>

</application>

```

However, the following example is wrong because the `{level}` variable is not defined at the application scope:

## XML

```

<application name="App">

 <properties id="DebugApp">
 <property name="DebugLevel" value="{level}">
 </properties>

 <node name="TheNode">
 <variable name="level" value="1"/>
 </node>

</application>

```

If both the application and the node define the `{level}` variable, the value of the `{level}` variable in the DebugApp property set

will be the value of the variable defined in the application descriptor.

So far, we have seen the definition of an unnamed property set only in a server descriptor. However, it is also possible to define an unnamed property set for server or service instances. This is a good way to specify or override properties specific to a server or service instance. For example:

**XML**

```

<application name="TheApp">
 <server-template id="Template">

 <parameter name="instance-name"/>

 <server id="${instance-name}" exe="./server">
 <properties>
 <property name="Timeout" value="30"/>
 </properties>
 </server>
 </server-template>

 <node name="TheNode">
 <server-instance template="Template" instance-name="MyInst">
 <properties>
 <property name="Debug" value="1"/>
 <property name="Timeout" value="-1"/>
 </properties>
 </server-instance>
 </node>
</application>

```

Here, the server instance overrides the `Timeout` property and defines an additional `Debug` property.

The server or service instance properties are evaluated as follows:

1. The unnamed property set from the template server or service descriptor is evaluated.
2. The unnamed property set from the server or service instance descriptor is evaluated and the resulting properties are added to the property set formed in the preceding step. This means that property settings in a server or service instance descriptor override corresponding settings in a template server or service descriptor.

The server or service instance unnamed property set and its parameters provide two different ways to customize the properties of a server or service template instance. It might not always be obvious which method to use: is it better to use a parameter to parameterize a given property or is it better to just specify it in the server or service instance property set?

For example, in the previous descriptor, we could have used a parameter with a default value for the `Timeout` property:

## XML

```

<application name="TheApp">
 <server-template id="Template">

 <parameter name="instance-name"/>
 <parameter name="timeout" default="30"/>

 <server id="{instance-name}" exe="./server">
 <properties>
 <property name="Timeout" value="{timeout}"/>
 </properties>
 </server>
 </server-template>

 <node name="TheNode">
 <server-instance template="Template"
instance-name="MyInst" timeout="-1">
 <properties>
 <property name="Debug" value="1"/>
 </properties>
 </server-instance>
 </node>
</application>

```

Here are some guidelines to help you decide whether to use a parameter or a property:

- Use a parameter for a property that should always be set.
- Use a parameter if you want to make the property obvious to the reader and user of the template.
- Do not use a parameter for optional properties if you want to rely on a default value for the server.
- Do not use parameters for properties that are rarely used.

## IceGrid XML Features

IceGrid provides some convenient features to simplify the task of defining descriptors in XML.

On this page:

- [Adding Flexibility with Targets](#)
- [Including Descriptor Files](#)

### Adding Flexibility with Targets

An IceGrid XML file may contain optional definitions that are `deployed` only when specifically requested. These definitions are called targets and must be defined within a `target` element. The elements that may legally appear within a `target` element are determined by its enclosing element. For example, a `node` element is legal inside a `target` element of an `application` element, but not inside a `target` element of a `server` element. Each `target` element must define a value for the `name` attribute, but names are not required to be unique. Rather, targets should be considered as optional components or features of an application that are deployed in certain circumstances.

The example below defines targets named `debug` that, if requested during deployment, configure their servers with an additional property:

**XML**

```

<icegrid>
 <application name="MyApp">
 <node name="Node">
 <server id="Server1" ...>
 <target name="debug">
 <property name="Ice.Trace.Network" value="2"/>
 </target>
 ...
 </server>
 <server id="Server2" ...>
 <target name="debug">
 <property name="Ice.Trace.Network" value="2"/>
 </target>
 ...
 </server>
 </node>
 </application>
</icegrid>

```

Target names specified in an `icegridadmin` command can be unqualified names like `debug`, in which case every target with that name is deployed, regardless of the target's nesting level. If you want to deploy targets more selectively, you can specify a fully-qualified name instead. A fully-qualified target name consists of its unqualified name prefaced by the names or identifiers of each enclosing element. For instance, a fully-qualified target name from the example above is `MyApp.Node.Server1.debug`.

### Including Descriptor Files

You can include the contents of another XML file into the current file using the `include` element, which is replaced with the contents of the included file. The elements in the included file must be enclosed in an `icegrid` element, as shown in the following example:

## XML

```

<!-- File: A.xml -->
<icegrid>
 <server-template id="ServerTemplate">
 <parameter name="id"/>
 ...
 </server-template>
</icegrid>

<!-- File: B.xml -->
<icegrid>
 <application name="MyApp">
 <include file="A.xml"/>
 <node name="Node">
 <server-instance template="ServerTemplate" .../>
 </node>
 </application>
</icegrid>

```

In `B.xml`, the `include` element identifies the name of the file to include using the `file` attribute. The top-level `icegrid` element is discarded from `A.xml` and its contents are inserted at the position of the `include` element in `B.xml`.

Note that the file name of an included file is relative to the application descriptor, not relative to the working directory.

You can include [specific targets](#) from a file by specifying their names in the optional `targets` attribute. If multiple targets are included, their names must be separated by whitespace. The example below illustrates the use of a target:

## XML

```

<!-- File: A.xml -->
<icegrid>
 <server-template id="ServerTemplate">
 <parameter name="id"/>
 ...
 </server-template>
 <target name="targetA">
 <server-template id="AnotherTemplate">
 ...
 </server-template>
 </target>
</icegrid>

<!-- File: B.xml -->
<icegrid>
 <application name="MyApp">
 <include file="A.xml" targets="targetA"/>
 <node name="Node">
 <server-instance template="ServerTemplate" .../>
 <server-instance template="AnotherTemplate" .../>
 </node>
 </application>
</icegrid>

```

## IceGrid Server Reference

### *Topics*

- [icegridregistry](#)
- [icegridnode](#)
- [Well-Known Registry Objects](#)
- [IceGrid Persistent Data](#)
- [Promoting a Registry Slave](#)

## icegridregistry

The IceGrid registry is a centralized repository of information, including [deployed applications](#) and [well-known objects](#). A registry can optionally be collocated with an IceGrid node, which conserves resources and can be convenient during development and testing. The registry server is implemented by the `icegridregistry` executable.

On this page:

- [Command Line Options for icegridregistry](#)
- [Configuring Registry Endpoints](#)
- [Registry Security Considerations](#)
- [Configuring a Data Directory for the Registry](#)
- [Registry Configuration Example](#)

### Command Line Options for icegridregistry

The registry supports the following command-line options:

```
$ icegridregistry -h
Usage: icegridregistry [options]
Options:
-h, --help Show this message.
-v, --version Display the Ice version.
--nowarn Don't print any security warnings.
--readonly Start the master registry in read-only mode.
--initdb-from-replica=<replica>
 Initialize the database from the given replica.
```

The `--readonly` option prevents any updates to the registry's database; it also prevents slaves from synchronizing their databases with this master. This option is useful when you need to verify that the master registry's database is correct after [promoting a slave](#) to become the new master. The `--initdb-from-replica` option, added in Ice 3.5.1, allows you to initialize the database from another registry replica. This option is useful when you need to start a new master with the contents of a slave database.

Additional command line options are supported, including those that allow the registry to run as a [Windows service](#) or [Unix daemon](#), and Ice includes a [utility](#) to help you install an IceGrid registry as a Windows service.

### Configuring Registry Endpoints

The IceGrid registry creates up to five sets of endpoints, configured with the following properties:

- [IceGrid.Registry.Client.Endpoints](#)  
Client-side endpoints supporting the following interfaces:
  - `Ice::Locator`
  - `IceGrid::Query`
  - `IceGrid::Registry`
  - `IceGrid::Session`
  - `IceGrid::AdminSession`
  - `IceGrid::Admin`

There are security implications in allowing access to administrative sessions, as explained in the next section.

- [IceGrid.Registry.Server.Endpoints](#)  
Server-side endpoints for object adapter registration.
- [IceGrid.Registry.SessionManager.Endpoints](#)  
Optional endpoints for delegating [session authentication](#) to a [Glacier2](#) router.

- `IceGrid.Registry.AdminSessionManager.Endpoints`  
Optional endpoints for delegating administrative session authentication to a Glacier2 router.
- `IceGrid.Registry.Internal.Endpoints`  
Internal endpoints used by IceGrid nodes and registry replicas. This property must be defined even if no nodes or replicas are being used.

## Registry Security Considerations

A client that successfully establishes an administrative session with the registry has the ability to compromise the security of the registry host. As a result, it is imperative that you configure the registry carefully if you intend to allow the use of administrative sessions.

Administrative sessions are disabled unless you explicitly configure the registry to use an authentication mechanism. To allow authentication with a user name and password, you can specify a password file using the property `IceGrid.Registry.AdminCryptPasswords` or use your own permissions verifier object by supplying its proxy in the property `IceGrid.Registry.AdminPermissionsVerifier`. Your verifier object must implement the `Glacier2::PermissionsVerifier` interface.

To authenticate administrative clients using their SSL connections, define `IceGrid.Registry.AdminSSLPermissionsVerifier` with the proxy of a verifier object that implements the `Glacier2::SSLPermissionsVerifier` interface.

## Configuring a Data Directory for the Registry

You must provide an empty directory in which the registry can initialize its databases. The path name of this directory is supplied by the configuration property `IceGrid.Registry.Data`.

The files in this directory must not be edited manually, but rather indirectly using one of the administrative tools. To clear a registry's databases, first ensure the server is not currently running, then remove all of the files in its data directory and restart the server.

## Registry Configuration Example

The registry requires values for the three mandatory endpoint properties, as well as the data directory property, as shown in the following example:

```
IceGrid.Registry.Client.Endpoints=tcp -p 4061
IceGrid.Registry.Server.Endpoints=tcp
IceGrid.Registry.Internal.Endpoints=tcp
IceGrid.Registry.Data=/opt/ripper/registry
```

In addition, we also recommend defining `IceGrid.InstanceName`, whose value affects the identities of the registry's well-known objects.

The remaining configuration properties are discussed in `IceGrid.*`.

## icegridnode

An IceGrid node is a process that [activates](#), [monitors](#), and [deactivates](#) registered server processes. You can run any number of nodes in a domain, but typically there is one node per host. A node must be running on each host on which servers are activated automatically, and nodes cannot run without an IceGrid registry.

The IceGrid node server is implemented by the `icegridnode` executable. If you wish to run a registry and node in one process, `icegridnode` is the executable you must use.

On this page:

- [Command Line Options for icegridnode](#)
- [Configuring Node Endpoints](#)
- [Node Security Considerations](#)
- [Configuring a Data Directory for the Node](#)
- [Node Configuration Example](#)

### Command Line Options for icegridnode

The node supports the following command-line options:

```
Usage: icegridnode [options]
Options:
-h, --help Show this message.
-v, --version Display the Ice version.
--nowarn Don't print any security warnings.
--readonly Start the collocated master registry in
 read-only mode.
--initdb-from-replica=<replica>
 Initialize the collocated registry database from
the
 given replica.

--deploy DESCRIPTOR [TARGET1 [TARGET2 ...]]
 Add or update descriptor in file DESCRIPTOR,
 with optional targets.
```

If you are running the node with a collocated registry, the `--readonly` option prevents any updates to the registry's database; it also prevents slaves from synchronizing their databases with this master. This option is useful when you need to verify that the master registry's database is correct after [promoting a slave](#) to become the new master. The `--initdb-from-replica` option, added in Ice 3.5.1, allows you to initialize the database from another registry replica. This option is useful when you need to start a new master with the contents of a slave database.

The `--deploy` option allows an application to be [deployed](#) automatically as the node process starts, which can be especially useful during testing. The command expects the name of the XML deployment file, and optionally allows the names of the individual [targets](#) within the file to be specified.

Additional command line options are supported, including those that allow the node to run as a [Windows service or Unix daemon](#), and Ice includes a [utility](#) to help you install an IceGrid node as a Windows service.

### Configuring Node Endpoints

The IceGrid node's endpoints are defined by the `IceGrid.Node.Endpoints` property and must be accessible to the registry. It is not necessary to use a fixed port because each node contacts the registry at startup to provide its current endpoint information.

## Node Security Considerations

It is important that you give careful consideration to the permissions of the account under which the node runs. If the servers that the node will activate have no special [access requirements](#), and all of the servers can use the same account, it is recommended that you do not run the node under an account with system privileges, such as the root account on Unix or the Administrator account on Windows.

## Configuring a Data Directory for the Node

The node requires an empty directory that it can use to store server files. The pathname of this directory is supplied by the configuration property `IceGrid.Node.Data`. To clear a node's state, first ensure the server is not currently running, then remove all of the files in its data directory and restart the server.

The node's [data directory](#) may also contain files and subdirectories used by your application's servers, such as configuration files and Freeze database environments. Before destroying the contents of the node's data directory, make sure that all servers are stopped and any important files are backed up.

When running a collocated node and registry server, we recommend using separate directories for the registry and node data directories.

## Node Configuration Example

A minimal node configuration is shown in the following example:

```
IceGrid.Node.Endpoints=tcp
IceGrid.Node.Name=Node1
IceGrid.Node.Data=/opt/ripper/node

Ice.Default.Locator=IceGrid/Locator:tcp -p 4061
```

The value of the `IceGrid.Node.Name` property must match that of a deployed node known by the registry.

The `Ice.Default.Locator` property is used by the node to contact the registry. The value is a proxy that contains the [registry's client endpoints](#). (You can avoid the need to define `Ice.Default.Locator` by using [IceLocatorDiscovery](#).)

If you wish to run a collocated registry and node server, enable the property `IceGrid.Node.CollocateRegistry` and include the [registry's configuration properties](#).

The remaining configuration properties are discussed in [IceGrid.\\*](#).

## Well-Known Registry Objects

On this page:

- [Default Identities of Registry Objects](#)
- [Using the LocatorFinder Interface](#)

### Default Identities of Registry Objects

The IceGrid registry hosts several [well-known objects](#). The following table shows the default identities of these objects and their corresponding Slice interfaces:

Default Identity	Interface
IceGrid/AdminSessionManager	Glacier2::SessionManager
IceGrid/AdminSessionManager- <i>replica</i>	Glacier2::SessionManager
IceGrid/AdminSSLSessionManager	Glacier2::SSLSessionManager
IceGrid/AdminSSLSessionManager- <i>replica</i>	Glacier2::SSLSessionManager
IceGrid/Locator	Ice::Locator
IceGrid/Query	IceGrid::Query
IceGrid/Registry	IceGrid::Registry
IceGrid/Registry- <i>replica</i>	IceGrid::Registry
IceGrid/RegistryUserAccountMapper	IceGrid::UserAccountMapper
IceGrid/RegistryUserAccountMapper- <i>replica</i>	IceGrid::UserAccountMapper
IceGrid/SessionManager	Glacier2::SessionManager
IceGrid/SSLSessionManager	Glacier2::SSLSessionManager
Ice/LocatorFinder	Ice::LocatorFinder

You can assign unique identities to these objects by configuring the `IceGrid.InstanceName` property, as shown in the following example:

```
IceGrid.InstanceName=MP3Grid
```

This property changes the identities of the well-known objects to use MP3Grid instead of IceGrid as the identity category. For example, the identity of the locator becomes MP3Grid/Locator.

Changes to `IceGrid.InstanceName` do not affect the identity of the `Ice/LocatorFinder` object. See the [next section](#) for more information.

The client's configuration must also be changed to reflect the new identity:

```
Ice.Default.Locator=MP3Grid/Locator:tcp -h registryhost -p 4061
```

Furthermore, any uses of these identities in application code must be updated as well.

## Using the `LocatorFinder` Interface

As of Ice 3.6, Ice requires all locator implementations to support the `Ice::LocatorFinder` interface:

### Slice

```
module Ice {
 interface LocatorFinder {
 Locator* getLocator();
 };
};
```

An object supporting this interface must be available with the identity `Ice/LocatorFinder`. By knowing the host and port of a locator's client endpoints, a client can discover the locator's proxy at run time with a call to `getLocator`:

### C++

```
Ice::ObjectPrx prx = communicator->stringToProxy("Ice/LocatorFinder:tcp
-p 4061 -h gridhost");
Ice::LocatorFinderPrx finder = Ice::LocatorFinderPrx::checkedCast(prx);
Ice::LocatorPrx locator = finder->getLocator();
communicator->setDefaultLocator(locator);
```

- [Well-Known Objects](#)

## IceGrid Persistent Data

The IceGrid registry and node both store information in the data directories specified by the `IceGrid.Registry.Data` and `IceGrid.Node.Data` properties, respectively. This section describes what the registry and node are storing and discusses backup and recovery techniques.

On this page:

- [Registry Persistent Data](#)
- [Node Persistent Data](#)

### Registry Persistent Data

The registry's data directory is a [Freeze](#) database environment that stores the following information:

- Applications [deployed](#) using the `addApplication` operation on the `IceGrid::Admin` interface (which includes the IceGrid GUI and command-line [administrative clients](#)). Applications specify servers, well-known objects, object adapters, replica groups, and allocatable objects. Applications can be removed with the `removeApplication` operation.
- [Well-known objects](#) registered using the `addObject` and `addObjectWithType` operations on the `IceGrid::Admin` interface. Well-known objects added by these operations can be removed using the `removeObject` operation.
- [Adapter endpoints](#) registered dynamically by servers using the `Ice::LocatorRegistry` interface. The property `IceGrid.Registry.DynamicRegistration` must be set to a value larger than zero to allow the dynamic registration of object adapters. These adapters can be removed using the `removeAdapter` operation.
- Some internal proxies used by the registry to contact nodes and other registry replicas during startup. The proxies enable the registry to notify these entities about the registry's availability.

[Client session](#) and [administrative sessions](#) established with the IceGrid registry are not persistent. If the registry is restarted, these sessions must be recreated. For client sessions in particular, this implies that objects allocated using the allocation mechanism will no longer be allocated once the IceGrid registry restarts.

If the registry's database is corrupted or lost, you must recover the deployed applications, the well-known objects, and the adapter endpoints. You do not need to worry about the internal proxies stored by the registry, as the nodes and registry replicas will eventually contact the registry again.

Depending on your deployed applications and your use of the registry, you should consider backing up the registry's database, especially if you cannot easily recover the persistent information.

For example, if you rely on dynamically-registered adapters, or on well-known objects registered programmatically via the `IceGrid::Admin` interface, you should back up the registry database because recovering this information may be difficult. On the other hand, if you only deploy a few applications from XML files, you can easily recover the applications by redeploying their XML files, and therefore backing up the database may be unnecessary.

Be aware that restarting the registry with an empty database may cause the server information stored by the nodes to be deleted. This can be an issue if the deployed servers have databases stored in the node data directory. The next section provides more information on this subject.

### Node Persistent Data

The IceGrid node stores information for servers deployed by IceGrid applications. This information is stored in the `servers` subdirectory of the node's data directory. There is one subdirectory per server; the name of the subdirectory is the server's ID. Each server directory contains configuration files, and may also contain [database environments](#) and the [distribution data](#) of the server. The node's data directory also contains a `distrib` directory to store per-application distribution data. This directory contains a subdirectory for each application that specifies a distribution and has a server deployed on the node.

If a server directory is deleted, the node recreates it at startup. The node will also recreate the server configuration files and the database environment directories. However, the node cannot restore the prior contents of a server's database environment. It is your responsibility to back up these database environments and restore them when necessary. If the server or application distribution data is deleted from the node's data directory, you can easily recover the deleted information by patching these distributions again using the IceGrid administrative tools.

If you store your server database environments outside the node's data directory (such as in a directory that is regularly backed up), or if you do not have any database environments inside the node's data directory, you do not need to back up the contents of the node's data directory.

## Promoting a Registry Slave

In a [replicated IceGrid deployment](#), you may need to promote a slave to be the new master if the current master becomes unavailable. For example, this situation can occur when the original master cannot be restarted immediately due to a hardware problem, or when your application requires a feature that is only accessible via the master, such as the [resource allocation](#) facility or the ability to modify the [deployment data](#).

To promote a slave to become the new master, you must shut down the slave and change its `IceGrid.Registry.ReplicaName` property to `Master` (or remove the property altogether). On restart, the new master notifies the nodes and registries that were active before it was shut down. An inactive registry or node will eventually connect to the new master if its default locator proxy contains the endpoint of the new master registry or the endpoint of a slave that is connected to the new master. If you cannot afford any down-time of the registry and want to minimize the down-time of the master, you should run at least two slaves. That way, if the master becomes unavailable, there will always be one registry available while you promote one of the slaves.

With Ice versions 3.5.0 and prior, a slave synchronizes its database upon connecting to the new master, therefore it is imperative that you promote a slave whose database is valid and up-to-date. To verify that the promoted master database is up-to-date, you can start the new master with the `--readonly` command-line option. While this option is in force, the new master does not update its database, and slaves do not synchronize their databases. You can review the master database with the IceGrid [administrative tools](#) and, if the deployment looks correct, you can restart the master without the `--readonly` option to permit updates and slave synchronization.

Starting with Ice 3.5.1, a check has been added to ensure that an out-of-date master database cannot overwrite a newer slave database. In such a scenario, an error message is printed out on the consoles of the IceGrid master and slave, and the slave connection to the master is aborted. You can still connect to the slave and master with the IceGrid [administrative tools](#) to verify their databases. Once you determine which database to keep, you can restart either the slave or the master with the `--initdb-from-replica=<name>` option to initialize the out-of-date database with the correct version. This check only works when both the master and slave use Ice 3.5.1 or later.

Note that there is nothing to prevent you from running two masters. If you start two masters and they contain different versions of the deployment information, some slaves and nodes might get updated with out-of-date deployment information (causing some of your servers to be deactivated). You can correct the problem by shutting down the faulty master, but it is important to keep this issue in mind when you restart a master since it might disrupt your applications.

- [icegridadmin Command Line Tool](#)

## IceGrid and the Administrative Facility

The Ice [administrative facility](#) provides a general purpose solution for administering individual Ice programs. IceGrid extends this functionality in several convenient ways:

- IceGrid automatically enables the facility in deployed servers, in its nodes and in its registry replicas.
- IceGrid uses the [Process facet](#) to terminate an active server, giving it an opportunity to perform an orderly shutdown.
- IceGrid provides a secure mechanism for invoking administrative operations on deployed servers, IceGrid nodes and IceGrid registry replicas.

The IceGrid administrative tools in turn use IceGrid's extended administrative facility to:

- display the [properties](#) of servers and services.
- attach remote loggers to the [Logger](#) of servers, services, nodes and registry replicas.
- manipulate and monitor [IceBox](#) services.

We discuss each of these items in separate sections below.

On this page:

- [Enabling the Administrative Facility for a Deployed Server, Node or Registry Replica](#)
  - [Ice.Admin.Endpoints for Servers](#)
  - [admin Objects in Nodes and Registry Replicas](#)
- [Deactivating a Deployed Server](#)

  - [Obtaining a Proxy](#)
  - [Callbacks without Glacier2](#)
  - [Callbacks with Glacier2](#)
- [Using the Administrative Facility in IceGrid Utilities](#)
  - [Properties](#)
  - [Administering IceBox Services](#)

## Enabling the Administrative Facility for a Deployed Server, Node or Registry Replica

As we saw in our [deployment example](#), the configuration properties for a deployed server include definitions for the following properties:

- `Ice.Admin.Endpoints`
- `Ice.Admin.ServerId`

The definition of `Ice.Admin.Endpoints` enables the [Administrative Facility](#).

### Ice.Admin.Endpoints for Servers

If a server's descriptor does not set `Ice.Admin.Enabled` and does not supply a value for `Ice.Admin.Endpoints`, IceGrid supplies a default value for `Ice.Admin.Endpoints` as shown below:

```
Ice.Admin.Endpoints=tcp -h 127.0.0.1
```

For [security reasons](#), IceGrid specifies the local host interface (127.0.0.1) so that administrative access is limited to clients running on the same host. This configuration permits the IceGrid node to invoke operations on the server's [admin object](#), but prevents remote access unless the client establishes an [IceGrid administrative session](#).

Specifying a fixed port is unnecessary because the server registers its endpoints with IceGrid upon each new activation.

### admin Objects in Nodes and Registry Replicas

Each IceGrid node and IceGrid registry replica provides by default an [admin object](#) hosted in the `IceGrid.Node` object adapter (for nodes) or in the `IceGrid.Registry.Internal` object adapter (for registry replicas). If you don't want an admin object in a node or registry replica, set `Ice.Admin.Enabled` to 0 or a negative value in this node or registry's configuration.

Each of these admin objects carries all the built-in facets, currently `Logger`, `Metrics`, `Process` and `Properties`. Proxies to these admin objects can be retrieved through the `getNodeAdmin` and `getRegistryAdmin` operations described below.

## Deactivating a Deployed Server

An IceGrid node uses the `Ice::Process` interface to gracefully deactivate a server. In programs using Ice 3.3 or later, this interface is implemented by the administrative facet named `Process`. In earlier versions of Ice, an object adapter implemented this interface in a special servant if the adapter's `RegisterProcess` property was enabled.

Regardless of version, the Ice run time registers an `Ice::Process` proxy with the IceGrid registry when properly configured. Registration normally occurs during communicator initialization, but it can be delayed when a server needs to install its own administrative facets.

When the node is ready to deactivate a server, it invokes the `shutdown` operation on the server's `Ice::Process` proxy. If the server does not terminate in a timely manner, the node asks the operating system to terminate the process. Each server can be configured with its own `deactivation timeout`. If no timeout is configured, the node uses the value of the property `IceGrid.Node.WaitTime`, which defaults to 60 seconds.

If a server does not register an `Ice::Process` proxy, the IceGrid node cannot request a graceful termination and must resort instead to a more drastic, and potentially harmful, alternative by asking the operating system to terminate the server's process. On Unix, the node sends the `SIGTERM` signal to the process and, if the server does not terminate within the deactivation timeout period, sends the `SIGKILL` signal.

On Windows, the node first sends a `Ctrl+Break` event to the server and, if the server does not stop within the deactivation timeout period, terminates the process immediately.

Servers that disable the `Process` facet can install a signal handler in order to intercept the node's notification about pending deactivation. For example, portable C++ programs could use the `IceUtil::CtrlCHandler` class for this purpose. However, we recommend that servers be allowed to use the `Process` facet when possible.

## Routing Administrative Requests

IceGrid defaults to using the local host interface when defining the endpoints of a deployed server's administrative object adapter. This configuration allows local clients such as the IceGrid node to access the server's `admin object` while preventing direct invocations from remote clients. A server's `admin object` may still be accessed remotely, but only by clients that establish an `IceGrid administrative session`. To facilitate these requests, IceGrid uses an intermediary object that relays requests to the server via its node. For example, the following figure illustrates the path of a `getProperty` invocation:

*Routing for administrative requests on a server.*

## Obtaining a Proxy

During an `administrative session`, a client has two ways of obtaining the intermediary proxy for a server's `admin object`:

### Slice

```

module IceGrid {
 interface Admin {
 idempotent string getServerAdminCategory();
 idempotent Object* getServerAdmin(string id)
 throws ServerNotExistException, NodeUnreachableException,
 DeploymentException;
 // ...
 };
};

```

If the client wishes to construct the proxy itself and already knows the server's ID, the client need only modify the proxy of the `IceGrid::Admin` object with a new identity. The identity's category must be the return value of `getServerAdminCategory`, while its name is the ID of the desired server. The example below demonstrates how to create the proxy and access the `Properties` facet of a server:

### C++

```

IceGrid::AdminSessionPrx session = ...;
IceGrid::AdminPrx admin = session->getAdmin();
Ice::Identity serverAdminId;
serverAdminId.category = admin->getServerAdminCategory();
serverAdminId.name = "MyServerId";
Ice::PropertiesAdminPrx props =
 Ice::PropertiesAdminPrx::checkedCast(
 admin->ice_identity(serverAdminId), "Properties");

```

Alternatively, the `getServerAdmin` operation returns a proxy that refers to the `admin` object of the given server. This operation performs additional validation and therefore may raise one of the exceptions shown in its signature above.

A client can also obtain an intermediary proxy to the `admin` object of an `IceGrid` node or `IceGrid` registry replica by calling `getNodeAdmin` or `getRegistryAdmin`:

### Slice

```

module IceGrid {
 interface Admin {
 idempotent Object* getNodeAdmin(string name)
 throws NodeNotExistException, NodeUnreachableException;

 idempotent Object* getRegistryAdmin(string name)
 throws RegistryNotExistException;
 // ...
 };
};

```

The name parameter corresponds to the node name or registry replica name. There is no operation comparable to `getServerAdminCategory` for IceGrid nodes and IceGrid registry replicas.

## Callbacks without Glacier2

IceGrid also supports the relaying of callback requests from a back-end server to an administrative client over the client's existing connection to the registry, which is especially important for a client using a network port that is forwarded by a firewall or protected by a secure tunnel.

For this mechanism to work properly, a client that established its [administrative session](#) directly with IceGrid and not via a [Glacier2 router](#) must take additional steps to ensure that the proxies for its callback objects contain the proper identities and endpoints. The `IceGrid::AdminSession` interface provides an operation to help with the client's preparations:

**Slice**

```

module IceGrid {
 interface AdminSession ... {
 idempotent Object* getAdminCallbackTemplate();
 // ...
 };
};

```

As its name implies, the `getAdminCallbackTemplate` operation returns a *template proxy* that supplies the identity and endpoints a client needs to configure its callback objects. The information contained in the template proxy is valid for the lifetime of the administrative session. This operation returns a null proxy if the client's administrative session was established via a Glacier2 router, in which case the client should use the callback strategy described in the next section instead.

The endpoints contained in the template proxy are those of an object adapter in the IceGrid registry. The client must transfer these endpoints to the proxies for its callback objects so that callback requests from a server are sent first to IceGrid and then relayed over a [bidirectional connection](#) to the client, as shown below:

*Routing for callback requests from a server.*

Here is the complete list of steps:

1. Invoke `getAdminCallbackTemplate` to obtain the template proxy.
2. Extract the category from the template proxy's identity and use it in all callback objects.
3. Extract the endpoints from the template proxy and use them to establish the published endpoints of the callback object adapter.
4. Create the callback object adapter and associate it with the administrative session's connection, thereby establishing a bidirectional connection with IceGrid.
5. Add servants to the callback object adapter.

As an example, let us assume that we have deployed an IceBox server with the server id `icebox1` and our objective is to register a `ServiceObserver` callback that monitors the state of the IceBox services. The first step is to obtain a proxy for the administrative facet named `IceBox.ServiceManager`:

**C++**

```
IceGrid::AdminSessionPrx session = ...;
IceGrid::AdminPrx admin = session->getAdmin();
Ice::ObjectPrx obj = admin->getServerAdmin("icebox1");
IceBox::ServiceManagerPrx svcmgr =
 IceBox::ServiceManagerPrx::checkedCast(
 obj, "IceBox.ServiceManager");
```

Next, we retrieve the template proxy and compose the published endpoints for our callback object adapter:

**C++**

```
Ice::ObjectPrx tmpl = admin->getAdminCallbackTemplate();
Ice::EndpointSeq endpts = tmpl->ice_getEndpoints();
string publishedEndpoints;
for (Ice::EndpointSeq::const_iterator p = endpts.begin();
 p != endpts.end(); ++p) {
 if (p == endpts.begin())
 publishedEndpoints = (*p)->toString();
 else
 publishedEndpoints += ":" + (*p)->toString();
}
communicator->getProperties()->setProperty(
 "CallbackAdapter.PublishedEndpoints", publishedEndpoints);
```

The final steps involve creating the callback object adapter, adding a servant, establishing the bidirectional connection and registering our callback with the service manager:

**C++**

```
Ice::ObjectAdapterPtr callbackAdapter =
 communicator->createObjectAdapter("CallbackAdapter");
Ice::Identity cbid;
cbid.category = tmpl->ice_getIdentity().category;
cbid.name = "observer";
IceBox::ServiceObserverPtr obs = new ObserverI;
Ice::ObjectPrx cbobj = callbackAdapter->add(obs, cbid);
IceBox::ServiceObserverPrx cb =
 IceBox::ServiceObserverPrx::uncheckedCast(cbobj);
callbackAdapter->activate();
session->ice_getConnection()->setAdapter(callbackAdapter);
svcmgr->addObserver(cb);
```

At this point the client is ready to receive callbacks from the IceBox server whenever one of its services changes state.

## Callbacks with Glacier2

A client that creates an [administrative session](#) via a [Glacier2 router](#) already has a bidirectional connection over which callbacks from administrative facets are relayed. The flow of requests is shown in the illustration below, which presents a simplified view with the router and IceGrid services all running on the same host.

*Routing for callback requests from a server.*

To prepare for [receiving callbacks](#), the client must perform the same steps as for any router client:

1. Obtain a proxy for the router.
2. Retrieve the category to be used in callback objects.
3. Create the callback object adapter and associate it with the router, thereby establishing a bidirectional connection.
4. Add servants to the callback object adapter.

Repeating the example from the previous section, we assume that we have deployed an IceBox server with the server ID `icebox1` and our objective is to register a [ServiceObserver](#) callback that monitors the state of the IceBox services. The first step is to obtain a proxy for the administrative facet named `IceBox.ServiceManager`:

```

C++

IceGrid::AdminSessionPrx session = ...;
IceGrid::AdminPrx admin = session->getAdmin();
Ice::ObjectPrx obj = admin->getServerAdmin("icebox1");
IceBox::ServiceManagerPrx svcmgr =
 IceBox::ServiceManagerPrx::checkedCast(obj, "IceBox.ServiceManager"
);

```

Now we are ready to create the object adapter and register the observer:

**C++**

```

Ice::RouterPrx router = communicator->getDefaultRouter();
Ice::ObjectAdapterPtr callbackAdapter =
 communicator->createObjectAdapterWithRouter("CallbackAdapter", router);
Ice::Identity cbid;
cbid.category = router->getCategoryForClient();
cbid.name = "observer";
IceBox::ServiceObserverPtr obs = new ObserverI;
Ice::ObjectPrx cbobj = callbackAdapter->add(obs, cbid);
IceBox::ServiceObserverPrx cb =
IceBox::ServiceObserverPrx::uncheckedCast(cbobj);
callbackAdapter->activate();
svcmgr->addObserver(cb);

```

At this point the client is ready to receive callbacks from the IceBox server whenever one of its services changes state.

## Using the Administrative Facility in IceGrid Utilities

This section discusses the ways in which the [IceGrid utilities](#) make use of the administrative facility.

### Properties

The command line and graphical utilities allow you to explore the configuration properties of a server or service.

One property in particular, `BuildId`, is given special consideration by the graphical utility. Although it is not used by the Ice run time, the `BuildId` property gives you the ability to describe the build configuration of your application. The property's value is shown by the graphical utility in its own field in the attributes of a server or service, as well as in the list of properties. You can also retrieve the value of this property using the command-line utility with the following statement:

```
> server property MyServerId BuildId
```

Or, for an IceBox service, with this command:

```
> service property MyServerId MyService BuildId
```

The utilities use the [Properties facet](#) to access these properties, via a proxy obtained as described [above](#).

### Administering IceBox Services

`IceBox` provides an administrative facet that implements the `IceBox::ServiceManager` interface, which supports operations for stopping an active service, and for starting a service that is currently inactive. These operations are available in both the command line and graphical utilities.

IceBox also defines a [ServiceObserver](#) interface for receiving callbacks when services are stopped or started. The graphical utility implements this interface so that it can present an updated view of the state of an IceBox server. We presented [examples](#) that demonstrate how to register an observer with the IceBox administrative facet.

## Securing IceGrid

IceGrid's registry and node services expose multiple network endpoints that a malicious client could use to gain access to IceGrid functionality and interfere with deployed applications. This presents a significant security risk in network environments that are exposed to untrusted clients. For example, a malicious client could connect to a node and use IceGrid's internal interfaces to deploy and run its own server executable.

This page describes the steps you can take to secure your IceGrid application.

### IceGrid Security Overview

Using a firewall is one way to prevent unauthorized use of IceGrid's facilities. Another solution is to use [IceSSL](#): you can generate SSL certificates for each component and configure them to trust and accept connections only from other authorized components. The remainder of this section discusses the IceSSL solution but also provides useful information for those interested in securing IceGrid with a firewall.

To restrict access using IceSSL, we need to establish trust relationships between IceGrid registry replicas, nodes, and deployed servers. IceSSL allows us to do this using [configuration properties](#). The trust relationships are based on the information contained in SSL certificates.

There are several possible strategies for generating certificates. At a minimum you will need the following:

- one certificate for all of the registries
- one certificate for all of the nodes
- one certificate for all of the servers managed by IceGrid

The certificates that you generate for registries and nodes should be protected with a password to ensure that only privileged users can start these services. However, we do not recommend using a password to protect the certificate for deployed servers because it would need to be specified in clear text in each server's configuration (servers that are activated by IceGrid must not prompt for a password). Furthermore, this password might appear in multiple places, such as an XML descriptor file, the IceGrid registry database, and property files generated by IceGrid nodes. The complexity involved in protecting access to every file that contains a clear text password could be overwhelming. Instead, we recommend that you protect access to the server certificate using file system permissions.

Depending on your organization and the roles of each person that uses IceGrid, you may decide to create additional certificates. For example, you might create a unique certificate for each IceGrid node instance if you deploy nodes on end-user machines and wish to configure the IceGrid registry to authorize connections only from the nodes of trusted users.

You can use the `iceca` script to establish a [certificate authority](#) and generate certificates. The sections that follow describe the interactions between the registry, node, and servers, and show how to configure IceSSL to restrict access to trusted peers. For the purposes of this discussion, we assume that the SSL certificates use the common names shown below:

- IceGrid Registry
- IceGrid Node
- Server

The Ice distribution includes a C++ example that demonstrates how to configure a secure IceGrid deployment in the `demo/IceGrid/secure` subdirectory. This example includes a script to generate certificates for a registry, a node, a Glacier2 router, and a server. For more information, see the `README` file provided with the example.

### Understanding the Registry Endpoints

The IceGrid registry has three mandatory endpoints representing the client, server, and internal endpoints. The registry also has two optional endpoints (the session manager and administrative session manager endpoints) that are only useful when [accessing IceGrid via Glacier2](#).

## Client Endpoint

The registry client endpoint is used by Ice applications that create client sessions in order to use the [resource allocation](#) facility. It is also used by [administrative clients](#) that create sessions for managing the registry. Finally, the client endpoint is used by Ice applications that use the `IceGrid::Query` interface or resolve indirect proxies via the IceGrid locator.

Two distinct permission verifiers authorize the creation of [client sessions](#) and [administrative sessions](#). The remaining functionality available via the client endpoint, such as resolving objects and object adapters using the `IceGrid::Query` interface or the Ice locator mechanism, is accessible to any client that is able to connect to the client endpoint.

It is safe to use an insecure transport for the client endpoint if it is only being used for locator queries. However, you should use a secure transport if you have enabled client and administrative sessions (by configuring the appropriate permission verifiers). Creating a session over an insecure transport poses a security risk because the user name and password are sent in clear text over the network.

If you include secure and insecure transports in the registry's client endpoints, you should ensure that applications that need to authenticate with IceGrid permission verifiers use a [secure transport](#).

It is not necessary to restrict SSL access to the client endpoints (using the property `IceSSL.TrustOnly.Server.IceGrid.Registry.Client`) as long as you use client and administrative permission verifiers for authentication. This property is only useful for restricting access to client and administrative sessions when using null permission verifiers. Note however that if both client and administrative sessions are enabled, you will only be able to restrict access to one set of clients since you cannot distinguish clients that create client sessions from clients that create administrative sessions.

## Server Endpoint

Ice servers use the registry's server endpoint to register their object adapter endpoints and send information to [administrative clients](#) connected via the registry.

Securing this endpoint with IceSSL is necessary to prevent a malicious program from potentially hijacking a server by registering its endpoints first. The property definition shown below demonstrates how to limit access to this endpoint to trusted Ice servers:

```
IceSSL.TrustOnly.Server.IceGrid.Registry.Server=CN="Server"
```

## Internal Endpoint

IceGrid nodes and registry replicas use the internal endpoint to communicate with the registry. For example, nodes connect to the internal endpoint of each active registry, and [registry slaves](#) establish a session with their master via this endpoint.

The internal endpoint must be secured with IceSSL to prevent malicious Ice applications from gaining access to sensitive functionality that is intended to be used only by nodes and registry replicas. You can restrict access to this endpoint with the following property:

```
IceSSL.TrustOnly.Server.IceGrid.Registry.Internal=CN="IceGrid
Node";CN="IceGrid Registry"
```

## Session Manager Endpoint

The session manager endpoint is used by Glacier2 to create IceGrid [client sessions](#). The functionality exposed by this endpoint is unrestricted so you must either secure it or disable it (this endpoint is disabled by default). The property shown below demonstrates how to configure IceSSL so that only Glacier2 routers are accepted by this endpoint:

```
IceSSL.TrustOnly.Server.IceGrid.Registry.SessionManager=CN="Glacier2
Router Client"
```

In this example, `Glacier2 Router Client` is the common name of the Glacier2 router used by clients to create IceGrid client sessions.

### Administrative Session Manager Endpoint

Glacier2 routers use the registry's administrative session manager endpoint to create IceGrid [administrative sessions](#). The functionality exposed by this endpoint is unrestricted, so you must either secure it or disable it (this endpoint is disabled by default). The property shown below demonstrates how to configure IceSSL so that only Glacier2 routers are accepted by this endpoint:

```
IceSSL.TrustOnly.Server.IceGrid.Registry.AdminSessionManager=CN="Glacie
r2 Router Admin"
```

In this example, `Glacier2 Router Admin` is the common name of the Glacier2 router used by clients to create IceGrid administrative sessions. Note that if you use a single Glacier2 router instance for [both client and administrative sessions](#), you will need to use the same common name to restrict access to both session manager endpoints:

```
IceSSL.TrustOnly.Server.IceGrid.Registry.SessionManager=CN="Glacier2
Router Client"
IceSSL.TrustOnly.Server.IceGrid.Registry.AdminSessionManager=CN="Glacie
r2 Router Client"
```

### IceLocatorDiscovery Endpoint

The registry (including all replicas) listens by default for UDP multicast requests from [IceLocatorDiscovery](#) clients. Each client request includes a proxy to which the registry sends its response; by default, the client's "response callback" proxy uses a UDP unicast endpoint but it can be configured to use a different transport. The registry invokes on the client's response callback proxy and provides a proxy of its own containing the registry's [client](#) endpoint.

Ice does not support a secure multicast transport therefore these discovery requests cannot be encrypted or restricted via trust relationships. You can prevent registries from listening for discovery requests by setting [IceGrid.Registry.Discovery.Enabled](#):

```
IceGrid.Registry.Discovery.Enabled=0
```

### Outgoing Connections

The registry establishes outgoing connections to other registries and nodes. You should configure the `IceSSL.TrustOnly.Client` property to restrict connections to these trusted peers:

```
IceSSL.TrustOnly.Client=CN="IceGrid Registry";CN="IceGrid Node"
```

The registry can also connect to Glacier2 routers and permission verifier objects. To allow connections to these services, you must include in this property the common names of Glacier2 routers that create client or administrative sessions, as well as the common names of servers that host the permission verifier objects.

## Understanding the Node Endpoints

An IceGrid node has only one endpoint, which is used for internal communications with the registry. As a result, it should be configured to accept connections only from IceGrid registries:

```
IceSSL.TrustOnly.Server=CN="IceGrid Registry"
```

A node also establishes outgoing connections to the registry's internal endpoint, as well as the `Ice.Admin` endpoint of deployed servers. You should configure the `IceSSL.TrustOnly.Client` property as shown below to verify the identity of these peers:

```
IceSSL.TrustOnly.Client=CN="Server";CN="IceGrid Registry"
```

## Understanding the Administrative Endpoints with IceGrid

By default, IceGrid sets the endpoints of a deployed server's `Ice.Admin` adapter to `tcp -h 127.0.0.1`. This setting is already quite secure because it only accepts connections from processes running on the same host. However, since you already need to configure IceSSL so that a server can authenticate with the IceGrid registry (servers connect to the registry to register their endpoints), you might as well use a secure endpoint for the `Ice.Admin` adapter and configure it to accept connections only from IceGrid nodes:

```
IceSSL.TrustOnly.Server.Ice.Admin=CN="IceGrid Node"
```

This is only necessary if the `Ice.Admin` endpoint is enabled (which it is by default).

You can also set the `IceSSL.TrustOnly.Client` property so that the server is only permitted to connect to the IceGrid registry:

```
IceSSL.TrustOnly.Client=CN="IceGrid Registry"
```

If your server invokes on other servers, you will need to modify this setting to allow secure connections to them.

## icegridadmin Command Line Tool

The `icegridadmin` utility is a command-line tool for administering an IceGrid domain. Deploying an application with this utility requires an XML file that defines the descriptors.

On this page:

- [Usage](#)
- [Application Commands](#)
- [Node Commands](#)
- [Registry Commands](#)
- [Server Commands](#)
- [Service Commands](#)
- [Adapter Commands](#)
- [Object Commands](#)
- [Server Template](#)
- [Service Template](#)

### Usage

The IceGrid administration tool supports the following command-line options:

```
Usage: icegridadmin [options]
Options:
-h, --help Show this message.
-v, --version Display the Ice version.
-e COMMANDS Execute COMMANDS.
-d, --debug Print debug messages.
-s, --server Start icegridadmin as a server (to parse XML
files).
-i, --instanceName Connect to the registry with the given instance
name.
-H, --host Connect to the registry at the given host.
-P, --port Connect to the registry running on the given port.
-u, --username Login with the given username.
-p, --password Login with the given password.
-S, --ssl Authenticate through SSL.
-r, --replica NAME Connect to the replica NAME.
```

The `-e` option causes the tool to execute the given commands and then exit without entering an interactive mode. The `-s` option starts `icegridadmin` in a server mode that supports the `IceGrid::FileParser` interface; a proxy for the object is printed to standard output. If neither `-e` nor `-s` is specified, the tool enters an interactive mode in which you issue commands at a prompt.

To communicate with the IceGrid registry, `icegridadmin` establishes an [administrative session](#). The tool uses SSL authentication if you specify the `-s` option or define its equivalent property `IceGridAdmin.AuthenticateUsingSSL`. Otherwise, `icegridadmin` uses password authentication and prompts you for the username and password if you do not specify them via command-line options or properties. If you want `icegridadmin` to establish its session using a [Glacier2 router](#), define `Ice.Default.Router` appropriately.

If specified, the following command-line options override their property equivalents:

Option	Property
<code>-i, --instanceName</code>	<code>IceGridAdmin.InstanceName</code>
<code>-H, --host</code>	<code>IceGridAdmin.Host</code>

<code>-P, --port</code>	<code>IceGridAdmin.Port</code>
<code>-u, --username</code>	<code>IceGridAdmin.Username</code>
<code>-p, --password</code>	<code>IceGridAdmin.Password</code>
<code>-S, --ssl</code>	<code>IceGridAdmin.AuthenticateUsingSSL</code>
<code>-r, --replica</code>	<code>IceGridAdmin.Replica</code>

`icegridadmin` determines its target registry as follows:

1. Connect via a Glacier2 router if `Ice.Default.Router` is defined.
2. Otherwise, if `Ice.Default.Locator` is defined, connect to the specified registry.
3. Otherwise, if a host is defined via the `-H` or `--host` options or the equivalent property, connect to the registry at the specified host. If no port is defined via the `-P` or `--port` options or the equivalent property, `icegridadmin` uses the standard IceGrid TCP (4061) or SSL (4062) port.
4. Otherwise, `icegridadmin` attempts to locate a registry by issuing a UDP multicast [discovery request](#). (`icegridadmin` does not use the `IceGridDiscovery` plug-in.) If the tool discovers more than one registry, it presents a list and asks you to select one.

See `IceGridAdmin.*` for more information on the configuration properties supported by `icegridadmin`.

Once it has connected to the registry and successfully established a session, `icegridadmin` displays its command prompt. The `help` command displays the following usage information:

- `help`  
Print this message.
- `exit, quit`  
Exit this program.
- `CATEGORY help`  
Print the help section of the given `CATEGORY`
- `COMMAND help`  
Print the help of the given `COMMAND`.

The tool's commands are organized by category. The supported command categories are shown below:

- `application`
- `node`
- `registry`
- `server`
- `service`
- `adapter`
- `object`
- `server template`
- `service template`

You can obtain more information about each category using the `help` command:

```
>>> application help
```

## Application Commands

- `application add [-n | --no-patch] DESC [TARGET ... ] [NAME=VALUE ... ]`  
Add applications described in the XML descriptor file `DESC`. If specified the optional `targets` are deployed. `Variables` are defined using the `NAME=VALUE` syntax. The application is automatically `patched` unless the `-n` or `--no-patch` option is used to disable it.
- `application remove NAME`  
Remove the application named `NAME`.

- `application describe NAME`  
Describe the application named `NAME`.
- `application diff [-s | --servers] DESC [TARGET ...] [NAME=VALUE ...]`  
Print the differences between the application in the XML descriptor file `DESC` and the current deployment. If `-s` or `--servers` is specified, print the the list of servers affected by the differences. [Variables](#) are defined using the `NAME=VALUE` syntax.
- `application update [-n | --no-restart] DESC [TARGET ...] [NAME=VALUE ...]`  
Update the application in the XML descriptor file `DESC`. If `-n` or `--no-restart` is specified, the update will fail if it would require restarting one or more servers. [Variables](#) are defined using the `NAME=VALUE` syntax. Use the `diff --servers` command to discover which servers would be affected by an update, including those that would require a restart.
- `application patch [-f | --force] NAME`  
[Patch](#) the application named `NAME`. If `-f` or `--force` is specified, IceGrid will first shut down any servers that depend on the data to be patched.
- `application list`  
List all deployed applications.

## Node Commands

- `node list`  
List all registered nodes.
- `node describe NAME`  
Show information about node `NAME`.
- `node ping NAME`  
Ping node `NAME`.
- `node load NAME`  
Print the load of the node `NAME`.
- `node sockets [NAME]`  
Print the number of processor sockets for node `NAME`. If `NAME` is omitted, print the number of processor sockets for each node. (The [IceGrid.Node.ProcessorSocketCount](#) property allows you to explicitly set this value for systems where the number of sockets cannot be obtained programmatically.)
- `node show [OPTIONS] NAME [log | stderr | stdout]`  
Print the Ice log messages of the node (with `log`), or print the text from the node's standard error or standard output (with `stderr` or `stdout`). The supported options are shown below:
  - `-f, --follow`  
With `log`, create a [remote logger](#) that prints each new log message.  
With `stderr` or `stdout`, wait for new text to be available in the file where `stderr` or `stdout` is redirected.
  - `-t, --tail N`  
Print the last `N` log messages (for `log`) or `N` lines of text (for `stderr` or `stdout`)
  - `-h, --head N`  
Print the first `N` lines of text (invalid option with `log`).
- `node shutdown NAME`  
Shutdown node `NAME`.

## Registry Commands

- `registry list`  
List all registered registries.
- `registry describe NAME`  
Show information about registry `NAME`.
- `registry ping NAME`  
Ping registry `NAME`.
- `registry show [OPTIONS] NAME [log | stderr | stdout]`  
Print the Ice log messages of the registry (with `log`), or print the text from the registry's standard error or standard output (with `stderr` or `stdout`).

rr or stdout). The supported options are shown below:

- -f, --follow  
With log, create a [remote logger](#) that prints each new log message.  
With stderr or stdout, wait for new text to be available in the file where stderr or stdout is redirected.
  - -t, --tail N  
Print the last N log messages (for log) or N lines of text (for stderr or stdout)
  - -h, --head N  
Print the first N lines of text (invalid option with log).
- registry shutdown NAME  
Shutdown registry NAME.

## Server Commands

- server list  
List all registered servers.
- server remove ID  
Remove server ID.
- server describe ID  
Describe server ID.
- server properties ID  
Get the run-time properties of server ID.
- server property ID NAME  
Get the run-time property NAME of server ID.
- server state ID  
Get the state of server ID.
- server pid ID  
Get the process ID of server ID.
- server start ID  
Start server ID.
- server stop ID  
Stop server ID.
- server patch ID  
[Patch](#) server ID.
- server signal ID SIGNAL  
Send SIGNAL (such as SIGTERM or 15) to server ID.
- server stdout ID MESSAGE  
Write MESSAGE on server ID's standard output.
- server stderr ID MESSAGE  
Write MESSAGE on server ID's standard error.
- server show [OPTIONS] ID [log | stderr | stdout | LOGFILE]  
Print the Ice log messages of the server (with log), or print the text from the server's standard error, standard output or the log file LOGFILE (with stderr, stdout or LOGFILE). The supported options are shown below:
  - -f, --follow  
With log, create a [remote logger](#) that prints each new log message.  
With stderr, stdout and LOGFILE, wait for new text to be available in the file.
  - -t, --tail N  
Print the last N log messages (for log) or N lines of text (for stderr, stdout or LOGFILE)
  - -h, --head N  
Print the first N lines of text (invalid option with log).
- server enable ID  
Enable server ID.

- `server disable ID`  
Disable server ID. A [disabled server](#) cannot be started on demand.

## Service Commands

- `service start ID NAME`  
Starts service NAME in IceBox server ID.
- `service stop ID NAME`  
Stops service NAME in IceBox server ID.
- `service describe ID NAME`  
Describes service NAME in IceBox server ID.
- `service properties ID NAME`  
Get the run-time properties of service NAME from IceBox server ID.
- `service property ID NAME PROPERTY`  
Get the run-time property PROPERTY of service NAME from IceBox server ID.
- `service list ID`  
List the services in IceBox server ID.

## Adapter Commands

- `adapter list`  
List all registered adapters.
- `adapter endpoints ID`  
Show the endpoints of adapter or replica group ID.
- `adapter remove ID`  
Remove adapter or replica group ID.

## Object Commands

The `object` command operates on [well-known objects](#).

- `object add PROXY [TYPE]`  
Add a well-known object to the registry, optionally specifying its type.
- `object remove IDENTITY`  
Remove a well-known object from the registry.
- `object find TYPE`  
Find all well-known objects with the type TYPE.
- `object describe EXPR`  
Describe all well-known objects whose stringified identities match the expression EXPR. A trailing wildcard is supported in EXPR, for example `"object describe Ice*"`.
- `object list EXPR`  
List all well-known objects whose stringified identities match the expression EXPR. A trailing wildcard is supported in EXPR, for example `"object list Ice*"`.

## Server Template

- `server template instantiate APPLICATION NODE TEMPLATE [NAME=VALUE ...]`  
Instantiate the requested [server template](#) defined in the given application on a node. [Variables](#) are defined using the NAME=VALUE syntax.
- `server template describe APPLICATION TEMPLATE`  
Describe a [server template](#)TEMPLATE from the given application.

## Service Template

- `service template describe APPLICATION TEMPLATE`  
Describe a `service template`TEMPLATE from the given application.

## Getting Started with IceGrid Admin

This page describes how to launch the IceGrid Admin tool.

On this page:

- [System Requirements](#)
- [Starting IceGrid Admin](#)
- [Command Line Arguments](#)
- [Main IceGrid Admin Window](#)
  - [Tabs](#)
  - [Status Bar](#)

### System Requirements

IceGrid Admin is a Java™ application supported on a wide range of platforms, including Windows, Linux and OS X.

The minimum requirements for running IceGrid Admin are listed below:

- `icegridgui.jar`, usually installed in the `bin` or `lib` directory of your Ice installation
- Java SE Runtime Environment 7 or later

In order to use IceGrid Admin's [metrics graphs](#) feature, you will need the JavaFX Runtime Environment, bundled with recent updates of the Oracle Java SE Runtime Environment 7 on Windows, Linux and OS X.

You can download Oracle Java SE for most platforms from [Oracle](#).

If you want to read IceGrid XML files from IceGrid Admin, you also need to have the `icegridadmin` command-line utility (version 3.6) in your `PATH`.

### Starting IceGrid Admin

On Windows IceGrid Admin can be started by clicking the IceGrid Admin icon in the Start menu:

On OS X IceGrid Admin can be started by clicking the IceGrid Admin icon in Finder Applications folder:

On Linux with a RPM installation, you can use the `icegridgui` script installed in `/usr/bin`:

```
$ icegridgui
```

On all platforms, you can also start IceGrid Admin from a terminal by typing:

```
java -jar path-to-icegridgui.jar
```

### Command Line Arguments

IceGrid Admin can be configured using Ice properties, and like with most Ice applications, these properties can be set using command-line arguments or a configuration file (or both).

Since IceGrid Admin is an Ice application (a client to the IceGrid registry), setting regular Ice properties can be useful as well. For example, you can set the `Ice.Trace.Network` property to get detailed information about network communications sent to `stderr`.

```
$ icegridgui --Ice.Trace.Network=2
```

There are also a number of properties specific to IceGrid Admin itself, describe in [IceGridAdmin.\\*](#).

If you need to set many properties, it is a good idea to write a configuration file and use the `--Ice.Config` command-line argument to specify the location of this file. For example:

```
> java -jar "C:\Program Files (x86)\ZeroC\Ice-3.6b\bin\icegridgui.jar"
--Ice.Config=icegridadmin.conf
```

### Main IceGrid Admin Window

The main IceGrid Admin window allows to navigate between your live deployment and the definitions of several applications.

#### **Tabs**

The main IceGrid Admin window shows one or more tabs:

- The Live Deployment tab (  ) displays information about an IceGrid deployment you have logged into. There is always one and only one Live Deployment tab. When you are not connected to an IceGrid deployment, the corresponding pane is empty.
- A Live Application tab (  ) displays application definitions retrieved from the IceGrid registry you are connected to. As long as you do not change anything in the associated pane, IceGrid Admin will keep the information up-to-date. For example if another administrator adds a new server definition in this application definition, it will appear automatically and immediately in this pane.
- A File-Based Application tab (  ) displays application definitions retrieved from an IceGrid XML file.
- An icon-less tab displays the definitions of an application that is not bound to an IceGrid registry or to a file, such as a brand new application. A live application with unsaved modifications also becomes icon-less if the connection to its IceGrid registry is lost.

IceGrid Admin may show any number of application tabs, including none at all.

### Status Bar

The status bar at the bottom of the main window shows information about operations performed by IceGrid Admin, or messages received from the IceGrid registry.

See Also

- [IceGridAdmin.\\*](#)
- [icegridadmin Command Line Tool](#)

## Live Deployment Tab

The Live Deployment tab shows the run-time status and configuration of an existing IceGrid deployment, and allows you to perform various administrative tasks on this deployment, such as:

- start or stop a server
- retrieve metrics associated with a server
- display metrics from one or more servers on a graph
- enable or disable a server
- send signal to a server
- retrieve the log files of a server
- patch an entire application
- register a new "well-known" object with the IceGrid registry
- undeploy a deployed application

## Connection to an IceGrid Registry

In order to administer or monitor an IceGrid deployment, you need to connect to the IceGrid registry of this deployment. If your IceGrid registry is replicated, you can connect to any replica for monitoring purposes; if you intend to change definitions, for example to describe a new server, you need to connect to the master IceGrid registry. This page describes how to connect to an IceGrid registry.

On this page:

- [Connecting using a Saved Connection](#)
- [Creating a new Connection](#)
  - [TCP Connection to a local IceGrid registry](#)
  - [SSL Connection to local IceGrid using X.509 Credentials](#)
  - [SSL Connection through Glacier2 router](#)
- [SSL Connections and Certificates](#)
- [Editing a Saved Connection](#)
- [Closing a Connection](#)

### Connecting using a Saved Connection

Use `File > Login...` or press the

button to open the `Saved Connections` dialog:

Double-click on the IceGrid registry you want to connect to, or select the IceGrid registry and click on the `Connect` button.

If the connection contains saved credentials, IceGrid Admin will immediately attempt to connect to the selected IceGrid registry with these credentials. Otherwise, it will open a new dialog to request the missing password (two passwords in some cases), such as:

### Creating a new Connection

In the `Saved Connections` dialog, click on `New Connection` to open the `New Connection` wizard.

We describe three typical connection scenarios in the sections below.

#### TCP Connection to a local IceGrid registry

Let's create a TCP connection to the IceGrid registry running on localhost.

Step 1: Select Direct Connection:

Step 2: Check the box to connect to the master registry:

If you have several replicas this ensures you will always connect to the master registry.

Step 3: Select Manual Endpoint to manually enter address information:

As of Ice 3.6, IceGrid Admin can also [discover registries](#) using UDP multicast. Any registries it finds will be shown in the list, or click the Refresh button to search again.

Step 4: Select the first option to enter the addressing information as a hostname and port number:

Step 5: Enter localhost for the hostname, leave the port number blank and keep TCP as the protocol:

**New Connection - IceGrid Admin**

**Hostname:** localhost  
The hostname or IP address of the IceGrid registry.

**Port number:**   
The port number the IceGrid registry listens on; leave empty to use the default IceGrid registry port number.

**Protocol:**  TCP  SSL

< Back    Next >    Finish    Cancel

Step 6: Enter a username and password for this connection:

**New Connection - IceGrid Admin**

**Username:** tom

**Password:** ●●●●●●●

Enter your password above to save it with this connection; otherwise you will need to enter your password each time you connect.

< Back    Next >    Finish    Cancel

Step 7: Click `Finish` to save the connection; IceGrid Admin then attempts to connect to the IceGrid registry.

#### *SSL Connection to local IceGrid using X.509 Credentials*

Now let's create a direct SSL connection to an IceGrid registry and authenticate using our X.509 key (also used for SSL authentication). The target IceGrid registry must be configured to accept SSL connections and authentication using SSL credentials; see [IceGrid.Registry.AdminSSLPermissionsVerifier](#).

Steps 1 to 4 are identical to the simple TCP connection described above.

Step 5: Enter the hostname of the IceGrid registry, leave the port number empty to use the default IceGrid port number (4061 for TCP and 4062 for SSL), and select SSL for the protocol:

**New Connection - IceGrid Admin**

**Hostname:**

The hostname or IP address of the IceGrid registry.

**Port number:**

The port number the IceGrid registry listens on; leave empty to use the default IceGrid registry port number.

**Protocol:**  TCP  **SSL**

Step 6: Select Yes to provide an X.509 certificate for SSL authentication:

**New Connection - IceGrid Admin**

**Do you want to provide a X.509 certificate for SSL authentication?**

No

**Yes**

Step 7: Select the X.509 key used for SSL authentication from the Alias drop-down list; this list corresponds to the My Certificates set in the Certificate Manager described in the next section. Click on the `Import...` button to open the Certificate Manager dialog.

Step 8: Choose to use this X.509 certificate (carried through the SSL connection) to authenticate ourselves with the IceGrid registry:

Step 9: Click `Finish` to save the connection and connect to the IceGrid registry. Unless we entered (and therefore saved) the X.509 key password with the connection, we are prompted for this password:

#### SSL Connection through Glacier2 router

Here we'll connect to an IceGrid registry "behind" a Glacier2 router. In this case, we need to connect to the Glacier2 router and authenticate ourselves with the router. We do not provide any information about the IceGrid registry itself: we will connect to the IceGrid registry identified by the target Glacier2 router configuration. See [Glacier2 Integration with IceGrid](#).

Step 1: Select Routed Connection:

Step 2: Enter the addressing information for the target Glacier2 router as a hostname and port number:

Step 3: Enter the hostname of the Glacier2 router, leave the port number empty to use the default Glacier2 port number (4063 for TCP and 4064 for SSL), and select SSL for the protocol:

Step 4: Choose not to authenticate ourselves for SSL, so we do not provide a X.509 certificate:

Step 5: Provide a username and password for the connection to the Glacier2 router:

Step 6: Click `Finish` to save the connection; IceGrid Admin then attempts to connect to the IceGrid registry through the Glacier2 router.

### **SSL Connections and Certificates**

IceGrid Admin maintains a persistent store of X.509 certificates for SSL connections with IceGrid registries. You can import, view and remove these certificates with the Certificate Manager. Use `File > Certificate Manager...` or click on the `Import...` button in the Connection wizard to open the Certificate Manager:

The Certificate Manager maintains three sets of certificates:

- **My Certificates**  
These certificates are used to authenticate IceGrid Admin when establishing an SSL connection with an IceGrid registry or Glacier2 router (this first authentication is at the SSL level); once the SSL connection is established, this certificate can also be used to authenticate with the target IceGrid registry or Glacier router (at the application level).
- **Server Certificates**  
The certificates of IceGrid registries and Glacier2 routers that IceGrid Admin trusts when establishing an SSL connection. All certificates signed by a Trusted CA (see below) are automatically trusted and usually do not need to be imported in this set.
- **Trusted CAs**  
The certificates of Certificate Authorities.

You do not need to import server certificates or CA certificates prior to establishing an SSL connection with an IceGrid registry or Glacier2 router. IceGrid Admin performs the following checks when establishing an SSL connection:

- If the X.509 certificate presented by the IceGrid registry or Glacier2 router matches a Server Certificate, proceed
- Otherwise, if this certificate is signed by a trusted CA, is valid (*now* is within the certificate's validity period) and its alternate name is a match for the SSL connection remote address, proceed
- Otherwise, display a Connection Security Warning dialog similar to the dialog below to let you decide whether or not to proceed with this certificate:

If you select `Yes, Always Trust`, the certificate is added in the persistent Server Certificates set.

A "client" X.509 certificate (saved in My Certificates) is only necessary when the target IceGrid registry or Glacier2 router requires one. This depends on the setting of the `IceSSL.VerifyPeer` property in those servers: when `IceSSL.VerifyPeer` is 2, IceGrid Admin must provide a valid certificate. If you forget to provide a certificate, or provide an invalid certificate, the connection establishment will fail with an IceSSL error comparable to the following:

### ***Editing a Saved Connection***

In the `Saved Connections` dialog, click on `Edit Connection` to edit a connection. This opens the `Connection wizard` for your saved connection. With this wizard, IceGrid Admin does not attempt to connect to the target IceGrid registry when you click on the `Finish` button.

### ***Closing a Connection***

Use `File > Logout` or press the

button to disconnect from an IceGrid registry. This clears all information in the `Live Deployment` pane.

## Run Time Components

IceGrid Admin shows the following run time components:

- Registry (  )  
Represents the IceGrid registry process with which IceGrid Admin communicates
- Slave Registry (  )  
Represents a slave registry process, when you have several replicated IceGrid registries
- Node (  )  
Represents an IceGrid node process
- Regular Server (  )  
Represents a regular server process, started and monitored by an IceGrid node
- IceBox Server (  )  
Represents an IceBox server process, started and monitored by an IceGrid node
- Adapter (  )  
Represents an Ice indirect object adapter, deployed within a server or a service
- Database Environment (  )  
Represents a Freeze/Berkeley DB Database Environment, deployed within a server or a service
- IceBox Service (  )  
Represents an IceBox service, deployed on an IceBox server
- Metrics View (  )  
Represents a Metrics view associated with an Ice server or service.

All actions on these components (through menus, buttons and keyboard short-cuts) affect directly and immediately the running IceGrid deployment.

## Registry Run Time Component

The registry is the root node of the Run Time Components tree, and represents the IceGrid registry process administered by IceGrid Admin.

On this page:

- [Actions](#)
- [Properties](#)
- [Children](#)

### Actions

A registry provides the following actions, from its contextual menu and from the `Tools > Registry` menu:

- **Add Well-Known Object**  
Create a new dynamic well-known object in the IceGrid registry.
- **Retrieve Ice log**  
Retrieve the log messages sent to the IceGrid registry's `logger` into an `Ice Log Dialog`. The Ice Log Dialog attaches a `remote logger` to the registry's logger.
- **Retrieve stdout**  
Retrieve the IceGrid registry's stdout into a `Log File Dialog`. This retrieval succeeds only when the registry's stdout output has been redirected to a file using the `Ice.Stdout` property.
- **Retrieve stderr**  
Retrieve the IceGrid registry's stderr into a `Log File Dialog`. This retrieval succeeds only when the registry's stderr output has been redirected to a file using the `Ice.Stderr` property.
- **Shutdown**  
Shutdown the registry process.

You cannot restart an IceGrid registry from IceGrid Admin.

### Properties

The Registry Properties panel shows:

- **Hostname**  
The name of the host on which the IceGrid registry process is running.
- **Deployed Applications**

Deployed Applications	
Name	Last Update
OnFile	Dec 31, 2012 4:11:59 PM
Simple	Dec 31, 2012 4:12:53 PM

This table shows all the applications deployed on this IceGrid registry, along with the date and time of the last update of each application. A contextual menu allows you to:

- open the corresponding application descriptor
  - patch the application, that is, instruct the IceGrid nodes to download the latest version of this application's files
  - show additional details on this application in this registry
  - remove (undeploy) the application from the registry
- **Dynamic Well-Known Objects**

Dynamic Well-Known Objects	
Proxy	Type
DemoIceGrid/InternalRegistry-Master -t -e 1.1:tcp -h localhost -p 5...	::IceGrid::InternalRegistry
DemoIceGrid/InternalRegistry-Replica1 -t -e 1.1:tcp -h localhost -p ...	::IceGrid::InternalRegistry
DemoIceGrid/InternalRegistry-Replica2 -t -e 1.1:tcp -h localhost -p ...	::IceGrid::InternalRegistry
DemoIceGrid/Locator -t -e 1.1:tcp -h localhost -p 12000 -t 10000:tc...	::Ice::Locator
DemoIceGrid/Query -t -e 1.1:tcp -h localhost -p 12000 -t 10000:tcp ...	::IceGrid::Query
DemoIceGrid/Registry -t -e 1.1:tcp -h localhost -p 12000 -t 10000	::IceGrid::Registry
DemoIceGrid/Registry-Replica1 -t -e 1.1:tcp -h localhost -p 12001 -...	::IceGrid::Registry
DemoIceGrid/Registry-Replica2 -t -e 1.1:tcp -h localhost -p 12002 -...	::IceGrid::Registry

This table shows the well-known objects registry dynamically with the IceGrid registry: well-known objects defined using adapter and replica-group definitions are not included. A contextual menu allows you to add or remove entries from this table, and to show a given entry in its own dialog.

- **Dynamic Object Adapters**

This table shows the object adapters registered dynamically with the registry. It is typically empty. A registry allows dynamically registered adapters only when its `IceGrid.Registry.DynamicRegistration` property is set to a value greater than 0. A contextual menu allows you to remove entries from this table.

Note that application filtering does not affect this panel: all applications, well-known objects and dynamic object adapters are always displayed.

### Children

A registry node can have two types of children:

- [Slave Registry](#)
- [Node](#)

### ***Slave Registry Run Time Component***

An IceGrid deployment may use several IceGrid registry replicas, with one Master registry and a number of read-only Slave registries.

#### **Actions**

A slave registry provides the following actions, from its contextual menu and from the `Tools > Registry` menu

- **Retrieve Ice log**  
Retrieve the log messages sent to the IceGrid registry's `logger` into an [Ice Log Dialog](#). The Ice Log Dialog attaches a `remote logger` to the registry's logger.
- **Retrieve stdout**  
Retrieve the IceGrid registry's `stdout` into a [Log File Dialog](#). This retrieval succeeds only when the registry's `stdout` output has been redirected to a file using the `Ice.Stdout` property.
- **Retrieve stderr**  
Retrieve the IceGrid registry's `stderr` into a [Log File Dialog](#). This retrieval succeeds only when the registry's `stderr` output has been redirected to a file using the `Ice.Stderr` property.
- **Shutdown**  
Shutdown the registry process.

You cannot restart an IceGrid registry from IceGrid Admin.

#### **Properties**

The Registry Properties panel shows:

- **Hostname**  
The name of the host on which the IceGrid registry process is running.

## Node Run Time Component

A node represents an IceGrid node process registered with the IceGrid registry.

On this page:

- [States](#)
- [Actions](#)
- [Properties](#)
- [Children](#)

### States

A node can be either up (

) or down (

). A "down" node is shown only when it is described by an application deployed on this IceGrid registry.

### Actions

A node provides the following actions, from its contextual menu and from the `Tools > Node` menu:

- **Retrieve Ice log**  
Retrieve the log messages sent to the IceGrid node's `logger` into an [Ice Log Dialog](#). The Ice Log Dialog attaches a [remote logger](#) to the node's logger.
- **Retrieve stdout**  
Retrieve the IceGrid node's stdout into a [Log File Dialog](#). This retrieval succeeds only when the node's stdout output has been redirected to a file using the `Ice.Stdout` property.
- **Retrieve stderr**  
Retrieve the IceGrid node's stderr into a [Log File Dialog](#). This retrieval succeeds only when the node's stderr output has been redirected to a file using the `Ice.Stderr` property.
- **Shutdown**  
Shutdown the IceGrid node process.

You cannot restart an IceGrid node from IceGrid Admin.

### Properties

The screenshot shows a 'Node Properties' window with two main sections: 'System Information' and 'Configuration'.

**System Information:**

- Hostname: BDESKTOP
- Operating System: Windows 6.1 Service Pack 1
- Machine Type: x64 with 4 CPU threads
- CPU Usage: 2.8% 3.4% 3.0% (with a Refresh button)

**Configuration:**

Load Factor	Application	Value
	Simple	Default

The Node Properties panel shows:

- **Hostname**  
The name of the host on which the IceGrid node process is running.
- **Operating System**  
The operating system name and version of the host on which the IceGrid node process is running.
- **Machine Type**  
The type of CPUs and the number of CPU threads of the host on which the IceGrid node process is running. For example, a computer with a dual-core CPU and 2 "hyper threads" per core will show 4 CPU threads.
- **CPU Usage (Windows) or Load Average (Linux/Unix)**  
On Windows, shows the percentage of CPU utilization in the past 1, 5, and 15 minutes. On Linux/Unix, shows the load-average in the past 1, 5 and 15 minutes. These values are retrieved when the Node Properties panel is displayed. Click on the Refresh button to retrieve the latest values.
- **Load Factor**  
Shows the load factor defined by each application using this node.

#### Children

A registry node can only have two types of children:

- Regular Server
- IceBox Server

## Server Run Time Component

A server represents an Ice server process. It can be either regular server (with typically a single Ice communicator) or an IceBox server hosting a number of IceBox services.

On this page:

- [States](#)
- [Actions](#)
- [Properties](#)
- [Children](#)

### States

A server is always in one of the following states (the first icon is for regular servers, the second for IceBox servers):

- **Unknown** (
  - 
  - 
 ): this state is shown when the parent IceGrid node is down.
- **Inactive** (
  - 
  - 
 ): the server is not running.
- **Activating** (
  - 
  - 
 ): the server is starting up. The IceGrid registry is waiting for the server to register all its object adapters with server lifetime.
- **Active** (
  - 
  - 
 ): the server is running, and has registered all its object adapters with server lifetime with the IceGrid registry.
- **Deactivating** (
  - 
  - 
 ): the server is shutting down. The IceGrid registry is waiting for the server process to exit.
- **Destroyed** (
  - 
  - 
 ): the server being removed of the IceGrid registry. This is a very transient state.

A server can also be either enabled or disabled; when disabled, the icons above are grayed-out. A disabled server cannot be started until it is re-enabled.

### Actions

A server provides the following actions, from its contextual menu, from the `Tools > Server` menu, and from buttons on the Server Properties panel:

- **Start**  
Instruct the IceGrid node to start the server.
- **Stop**  
Instruct the IceGrid node to shutdown the server.
- **Enable**  
Mark the server as "enabled".
- **Disable**  
Mark the server as "disabled". A [disabled server](#) cannot be started; however an already running server can be marked "disabled".
- **Patch Distribution**  
Patch the server's distribution, that is, instruct the IceGrid node to download the latest files from the server's distribution.

- **Write Message**  
Open a dialog that allows you to write a message to the server's stdout or stderr.
- **Retrieve Ice log**  
Retrieve the log messages sent to the server's [logger](#) into an [Ice Log Dialog](#). The Ice Log Dialog attaches a [remote logger](#) to the server's logger.
- **Retrieve stdout**  
Retrieve the stdout log file of this server into a [Log File Dialog](#). This retrieval succeeds only when the server's stdout output has been redirected to a file using the [Ice.StdOut](#) property. This is usually achieved by setting the `IceGrid.Node.Output` property in the IceGrid node configuration file.
- **Retrieve stderr**  
Retrieve the stderr log file of this server into a [Log File Dialog](#). This retrieval succeeds only when the server's stderr output has been redirected to a file using the [Ice.StdErr](#) property. This is usually achieved by setting the `IceGrid.Node.Output` property in the IceGrid node configuration file.
- **Retrieve log file**  
Retrieve a log file of this server into a [Log File Dialog](#).
- **Send Signal**  
Send a signal to a server, for example SIGQUIT. Available only for non-Windows servers.

### Properties

The Server Properties panel shows first the Runtime Status of the server, i.e. "live" values retrieved from the server:

- **State**  
The state of the server (Active, Deactivating, Inactive etc., see above)
- **Enabled**  
A checkbox that is checked when the server is enabled.
- **Process Id**  
The process ID of the server.
- **Build Id**  
The build Id of this server: this corresponds to the Ice property [BuildId](#).
- **Properties**  
A table showing all the Ice properties currently set in this server. These properties are retrieved each time you select a new server in IceGrid Admin, and each time you click on the Refresh button next to the Build Id field.

The remaining Server Properties under Configuration come from the IceGrid descriptors associated with this server:

- **Application**

The name of the application containing this server's definition. The button on the right shows the server definition in an Application tab.

- **Description**  
A free-text description of this server.
- **Properties**  
A table showing all the Ice properties of this server. These properties may come from template definitions, property sets, server-instance properties etc. They are all combined in this table.
- **Path to Executable**  
The path to the server's executable, used by the IceGrid node to start the server.
- **Ice Version**

The Ice version of this server.

- **Working Directory**  
The path to the server's working directory used by the IceGrid node when starting the server.
- **Command Arguments**  
The command-line arguments given to the server when started by IceGrid.
- **Run as**  
On Linux/Unix, a server may be started as a specific user when IceGrid node runs as root. Run as shows this username. When blank, the server runs as the IceGrid node user except if IceGrid node runs as root (on Linux/Unix); in this case, the server runs as nobody.
- **Environment Variables**  
A server started by IceGrid node gets these environment variables in addition to the environment variables inherited from the IceGrid node.
- **Activation Mode**  
The server's activation mode.
- **Activation Timeout**  
The server's activation timeout.
- **Deactivation Timeout**  
The server's deactivation timeout.
- **Allocatable**  
This checkbox Shows whether this server is allocatable or not.
- **Depends on the application distribution**  
If this checkbox is checked, this server depends on the enclosing application's distribution: each time this distribution is patched, the server is automatically shut down before the patch.
- **IcePatch2 Proxy**  
A stringified or well-known proxy for the IcePatch2 server than contains this server's distribution. When blank, this server does not have its own distribution.
- **Directories**  
List of directories included in the server distribution. When blank, the entire IcePatch2 server repository is used as the server distribution.

#### Children

A regular server node can have two types of children:

- [Adapter](#)
- [Database Environment](#)

An IceBox server node can have only one type of children:

- [Service](#)

## Adapter Run Time Component

An adapter represents an Ice object adapter described in the IceGrid registry that resides in a server or an IceBox service. Note that direct object adapters are not displayed since IceGrid knows nothing about them.

On this page:

- [States](#)
- [Properties](#)

### States

An adapter can be either active (

) or inactive (

).

### Properties

The Adapter Properties panel shows first the Runtime Status of the object adapter, i.e. "live" values retrieved from the enclosing server or service:

- **Status**  
The status of this object adapter: Active or Inactive.
- **Published Endpoints**  
The endpoints that this object adapter has registered with the IceGrid registry. Blank when the adapter's status is Inactive.

The remaining Server Properties under Configuration come from the IceGrid descriptor that defined this object adapter:

- **Description**  
A free-text description of this adapter.
- **Adapter ID**  
This object adapter's ID. Adapter IDs are unique within an IceGrid deployment.
- **Replica Group**  
When this adapter belongs to a replica group, shows the replica group ID. Blank otherwise.
- **Priority**  
The adapter's priority. Used only when the adapter belongs to a replica group with the "Ordered" load balancing policy.
- **Endpoints**  
The Endpoints configuration property of this object adapter.
- **Published Endpoints**  
The PublishedEndpoints configuration property of this object adapter.
- **Register Process**  
When the Register Process checkbox is checked, this object adapter will register an `Ice::Process` object with IceGrid upon activation. This setting is meaningful only for servers with an Ice version less than 3.3.
- **Server Lifetime**  
When the Server Lifetime checkbox is checked, IceGrid considers that this object adapter is activated when the server starts up and deactivated when the server shuts down. This allows IceGrid to detect when a server is fully activated (all its object adapters with a server-lifetime have registered) and when a server is shutting down (at least one object adapter with server-lifetime has unregistered).
- **Well-known Objects**  
The well-known objects defined by this object adapter.
- **Allocatable Objects**  
The allocatable objects defined by this object adapter.

### ***Database Environment Run Time Component***

A Database Environment (

) represents a Berkeley DB database environment, used by the Freeze persistence service.

#### **Properties**

The Database Environment Properties panel shows:

- **Description**  
A free-text description of this Berkeley DB database environment.
- **DB Home**  
The path to the home directory of this database environment, which corresponds to the Ice property `Freeze.DbEnv.env-name.DbHome`. It is often created by the IceGrid node in the server's private directory.
- **Properties**  
Berkeley DB configuration properties for this database environment. IceGrid generates a `DB_CONFIG` file in the DB Home directory with these properties.

## Service Run Time Component

A service represents an IceBox service loaded (or potentially loaded) within an IceBox server.

On this page:

- [States](#)
- [Actions](#)
- [Properties](#)
- [Children](#)

### States

A service can be either started (

) or stopped (

) within an IceBox server.

### Actions

An IceBox service provides the following actions, from its contextual menu, from the `Tools > Service` menu, and from buttons on the Service Properties panel:

- **Start**  
Instruct the IceBox server to start the service.
- **Stop**  
Instruct the IceBox server to stop this service.
- **Retrieve Ice log**  
Retrieve the log messages sent to the service's `logger` into an `Ice Log Dialog`. The Ice Log Dialog attaches a `remote logger` to the service's logger.
- **Retrieve log file**  
Retrieve the log file of this service into a `Log File Dialog`.

### Properties

The Service Properties panel shows first the Runtime Status of the service, i.e. "live" values retrieved directly from the service:

- **State**  
A checkbox that is checked when the service is started.
- **Build Id**  
The build Id of this service: this corresponds to the Ice property `BuildId`.
- **Properties**  
A table showing all the Ice properties currently set in this service. These properties are retrieved each time you select a new service in IceGrid Admin, and each time you click on the Refresh button next to the Build Id field.

The remaining Server Properties come from the IceGrid descriptors associated with this service:

- **Description**  
A free-text description of this service.
- **Properties**  
A table showing all the Ice properties of this service. These properties may come from template definitions, property sets, service-instance properties etc. They are all combined in this table.
- **Entry Point**  
The entry point for this service. This corresponds to the value of the `IceBox.Service.name` property.

### Children

An IceBox service can have two types of children:

- [Adapter](#)
- [Database Environment](#)

## Metrics View Run Time Component

A Metrics View displays the Metrics maps associated with a Server or Service.

On this page:

- [States](#)
- [Actions](#)
- [Metrics Report](#)

### States

A metrics view can be either enabled (

) or disabled(

). Once enabled, a Metrics View may degrade the performance of the instrumented server or service.

### Actions

An Metrics View provides the following actions, from its contextual menu and from the `Tools > Metrics View` menu:

- **Enable**  
Enable this Metrics View.
- **Disable**  
Disable this Metrics View.

### Metrics Report

The Metrics Report panel shows the maps included in the Metrics View. The columns of the maps include the metrics themselves (for example, the total number of operations dispatched by the server since the Metrics view was enabled) and computed values (for example, the average lifetime of an operation dispatch, since the Metrics view was enabled).

Tool tips on each column describe the metrics or computed value displayed by the column.

IceGrid Admin retrieves the latest metrics every 5 seconds and automatically refreshes the current Metrics Report.

Note that IceGrid Admin displays only non-empty metrics maps; for example, if a server does not make any remote invocation, its Invocation map is empty and will not be displayed.

## Application Component

An application is primarily a way to group definitions and does not actually exist in a live deployment.

Nevertheless, IceGrid Admin offers a number of application-related actions in the live deployment view through the Filter live deployment button and the `Tools > Application` menu:

- **Patch Distribution**  
Instruct the IceGrid nodes to download the latest version of the files associated with the selected application.
- **Show details**  
Show various information about the selected application.
- **Filter live deployment**  
Shows only the selected application in the live deployment view; servers and other components associated with other applications are "filtered out".

When filtering is enabled, the name of the selected application appears to the right of the registry name. In the picture below, the live deployment view shows only the application named 'Simple'.

- **Remove from registry**  
Remove the selected application from the registry.

## Ice Log Dialog

The Ice Log dialog shows the Ice log messages of a server, service, node or registry retrieved through IceGrid. The monitored Ice application sends these log messages to a [remote logger](#) implemented by the Ice Log dialog.

On this page:

- [States](#)
- [Preferences](#)
- [Filter](#)

### States

An Ice log dialog is always in one of the following states:

- **Running**  
The dialog is attached to the monitored application's logger: it displays new log messages as soon as it receives them.
- **Paused**  
The dialog is attached to the monitored application's logger: it queues new log messages, but does not display them.
- **Stopped**  
The dialog is no longer attached to the monitored application's logger.

When an Ice log dialog is running or paused, and the target server, node or registry is stopped, the Ice log dialog automatically transitions to the Stopped state. However, when an Ice log dialog is attached to an IceBox service, the Ice log dialog's state does not change when only the service is stopped, because stopping a service does not shutdown or destroy the associated communicator.

### Preferences

Use the `Edit > Preferences...` menu to open the Preferences dialog. These preferences apply to the current dialog and to any Ice Log dialog opened later on.

This dialog allows you to view and update the following settings:

- **Max log messages in buffer**  
The maximum number of lines displayed in the Ice log dialog.
- **Number of log messages retrieved initially**  
When a new dialog is opened, or when restarting a stopped dialog, the dialog retrieves and displays up to this number of lines.

### *Filter*

Use the `Edit > Filter...` menu to open the Filter dialog. This filter applies only to the current Ice Log dialog.

This dialog allows you to filter the log messages sent by the monitored Ice applications. All the filtering is done in this remote Ice application.

- **Error, Warning, Print and Trace Check Boxes**  
Check the type of log messages you want to receive.
- **Trace Categories**  
Enter the list of trace categories you want to receive, or leave empty to receive trace messages with any trace category.

## Log File Dialog

The Log File dialog shows a log file (text file) retrieved through IceGrid. Often, a process will be writing to this log file and the dialog will periodically check for new lines to display.

On this page:

- [States](#)
- [Preferences](#)

### States

A log file dialog is always in one of the following states:

- **Running**  
The dialog is periodically checking for new lines.
- **Paused**  
The dialog is "connected" to a remote log file but does not currently retrieve new lines.
- **Stopped**  
The dialog is not retrieving new lines from the remote log file.

### Preferences

Use the `Edit > Preferences...` menu to open the Preferences dialog. These preferences apply to the current dialog and to any Log File dialog opened later on.

This dialog allows you to view and update the following settings:

- **Max lines in buffer**  
The maximum number of lines displayed in the log dialog.
- **Max characters in buffer**  
The maximum number of characters displayed in the log dialog.
- **Number of lines retrieved initially**  
When a new dialog is opened, or when restarting a stopped dialog, the dialog retrieves and displays up to this number of lines.
- **Max bytes read per request**  
The maximum number of bytes retrieve by each request. Pick a value that is low enough to make the dialog appear responsive and big enough to avoid many round-trips when lots of data are logged. IceGrid Admin requires a value between 100 and Ice.MessageSizeMax - 512.
- **Poll period**  
When in the running state, the dialog attempts to retrieve new lines from the log file (through IceGrid) every Poll period seconds.

## Metrics Graph

A Metrics Graph displays metrics retrieved from one or more Ice servers or IceBox services.

The horizontal axis corresponds to the time, while the vertical axis plots the corresponding metrics values.

The Metrics Graph feature requires [Java 7](#) and [JavaFX](#).

On this page:

- [Creating a New Metrics Graph](#)
- [Adding and Removing Metrics](#)
- [Adjusting Scale and Color](#)
- [Metrics Graph Preferences](#)

### Creating a New Metrics Graph

You can create a new Metrics Graph window with the `File > New > Metrics Graph` menu, or with a contextual menu over a metric in a [Metrics View](#), for example:

### Adding and Removing Metrics

A metric is added to a Metrics Graph with drag & drop, or through a contextual menu over this metric.

To remove a metric from a Metrics Graph, select this metric and press Delete or the

button.

### Adjusting Scale and Color

You can display metrics with different scales on the same graph by adjusting the scale factor of each metric. The values plotted are the metric's values times the scale factor; the default scale factor is 1.0.

Metrics Field	Scale	Last	Average	Minimum	Maximum	Color
Tx	0.00001	286475.000	285200.156	269900.000	286475.000	Red

You can also change the color used to display a metric's line by clicking on the Color cell of the metric.

### Metrics Graph Preferences

The File > Preferences menu of a Metrics Graph window opens a dialog that allows you to configure several properties of your Metrics Graph:

For each metric plotted in a Metrics Graph, IceGrid Admin retrieves the corresponding value every `Sample interval` seconds (by default every 5 seconds), and displays `n` values (`n = 120` by default). `Sample interval` times `Samples displayed` correspond to the time period represented on a graph; by default, it is  $5s * 120 = 10$  minutes.

## Application Tabs

IceGrid definitions are organized in "applications", with typically one or a few applications deployed on a given IceGrid instance.

An Application tab allows you to:

- create a new application: describe servers, IceBox services, the nodes you want to run them, specify load-balancing policies, etc.
- browse and edit the definition of an existing, live application deployed in an IceGrid instance
- browse and edit the definition of an application stored in an IceGrid XML file.

### Topics

- [Editing and Saving IceGrid Descriptors](#)
- [Navigation within an Application Tab](#)
- [IceGrid Descriptors](#)
  - [Variables in IceGrid Descriptors](#)
  - [Application Descriptor](#)
  - [Node Descriptor](#)
  - [Server Descriptor](#)
  - [Service Descriptor](#)
  - [Adapter Descriptor](#)
  - [Database Environment Descriptor](#)
  - [Property Set Descriptor](#)
  - [Replica Group Descriptor](#)
  - [Server Template Descriptor](#)
  - [Service Template Descriptor](#)

## Editing and Saving IceGrid Descriptors

On this page:

- [Editing](#)
- [Copy & Paste](#)
- [Error Checking](#)
- [Saving](#)
- [Discarding Updates](#)
- [Concurrent Updates to the same IceGrid Registry](#)

### Editing

As soon as you make any update in a form, IceGrid Admin enables two buttons at the bottom of this form: Apply and Discard.

If you navigate to another node without pressing Apply or Discard, the default is Apply: your changes are applied to the in-memory representation of the application definition. However these changes are not stored to the IceGrid registry or XML file until you save the application definition (see below).

Editing a live application (

) also disconnects this application from the IceGrid registry: updates made by other users are no longer propagated to the Application tab.

### Copy & Paste

Most descriptor sub-trees can be copied and later pasted. Copies are always deep-copies: for example if you copy a node, all the servers on this code are copied, including all the the sub-elements of these servers (object adapters, database environment, services, etc.).

After pasting a sub-tree, you typically need to check and edit the new elements to avoid any duplicate server IDs, adapter IDs etc.

## Error Checking

IceGrid Admin performs very little error checking while you are working on an application definition. For example, you may temporarily keep several servers with the same ID, leave some parameters of a template instance unset, or use an undefined variable. All such errors are only detected when you save your application to an IceGrid registry.

There are nonetheless two types of constraints enforced by IceGrid Admin at all times:

- two descriptor nodes in an application tab display cannot have the same name.
- some fields (such as Path to Executable for a server) cannot be empty.

If you violate such a constraint, IceGrid Admin prevents you from applying your change.

## Saving

You save an application definition to an IceGrid registry or an XML file with the menu item `File > Save`, `File > Save to File`, `File > Save to Registry (Servers may restart)`, `File > Save to Registry (No Server restart)` or with the corresponding toolbar buttons.

`Save` is equivalent to `Save to Registry (Servers may restart)` for a live application, and to `Save to File` for a file-bound application.

Saving an application to the IceGrid registry causes the registry to distribute any relevant changes to the affected nodes. In turn, each node applies those changes to its servers. If a server is running at the time of an update, the node may need to stop and restart it, depending on the changes that you make. Consequently, saving to the registry could cause a disruption in service to any clients that are actively using the affected servers.

The following application changes do *not* require a restart:

- Adding, modifying, or removing a server's configuration properties
- Adding new servers

All other changes will require a restart. IceGrid Admin provides two versions of the `Save to Registry` command, one that allows restarts and one that does not. To avoid accidentally causing any disruption in service, we recommend using the `No server restart` option first; this command will fail if any of your updates require a restart. At that point, you can decide whether to force the servers to restart using the other `Save` command.

If you change a server's configuration properties with `Save to Registry (No Server restart)`, IceGrid updates the stored properties of this server, and also the properties of your running server instance through its [Properties Facet](#). If these properties are only read by the server at start-up, this may not have the desired effect. If you want to trigger a server restart even when only properties have changed, use `Save to Registry (Servers may restart)`.

## Discarding Updates

You may discard all your updates by selecting `File > Discard Updates` or pressing the corresponding toolbar button. `Discard Updates` simply reloads the application from the IceGrid registry or its associated XML file.

## Concurrent Updates to the same IceGrid Registry

If several administrators update the same application definition concurrently, the last save will silently overwrite previous (concurrent) updates.

To avoid this situation, you can acquire an exclusive write access to the IceGrid registry with `File > Acquire Exclusive Write Access`. After this exclusive write access is granted, any attempt by another session to save to the IceGrid registry will result in an error:

### Navigation within an Application Tab

Each Application tab maintains a history of the nodes you have visited in this tab. You can navigate these nodes using the `View > Go Back to the Previous Node` and `View > Go to the Next Node` menu items, or with the equivalent toolbar buttons:

Also on some forms a green arrow button provides a link to another node (typically a template) in the same Application pane:

## IceGrid Descriptors

An application definition is described using one application descriptor with a number of nested sub-descriptors (and sub-sub descriptors). The descriptors correspond to Slice types in the IceGrid registry interfaces, and to XML element in an IceGrid XML representation.

IceGrid Admin maps these descriptors to nodes on a tree representation:

### Topics

- Variables in IceGrid Descriptors
- Application Descriptor
- Node Descriptor
- Server Descriptor
- Service Descriptor
- Adapter Descriptor
- Database Environment Descriptor
- Property Set Descriptor
- Replica Group Descriptor
- Server Template Descriptor
- Service Template Descriptor

## Variables in IceGrid Descriptors

Variables allow you to define commonly-used information once and refer to them symbolically throughout your application descriptors.

On this page:

- [Syntax](#)
- [Where are Variables Allowed?](#)
- [Escaping a Variable](#)
- [Pre-Defined Variables](#)
- [Variable Substitution in IceGrid Admin](#)
- [Scoping Rules](#)
- [Resolving a Reference](#)
- [Modifying a Variable](#)

### Syntax

Substitution for a variable or parameter VP is attempted whenever the symbol `${VP}` is encountered, subject to the limitations and rules described below. Substitution is case-sensitive, and a fatal error occurs if VP is not defined when the application is saved to an IceGrid registry.

### Where are Variables Allowed?

Substitution is performed in all string fields except the following:

- server and service template IDs (when defining a template or when referring to a template)
- variable names
- template parameter names
- node names
- application names

### Escaping a Variable

You can prevent substitution by escaping a variable reference with an additional leading `$` character. For example, in order to assign the literal string `$(abc)` to a variable, you would use `$$$(abc)` as this variable's value.

The extra `$` symbol is only meaningful when immediately preceding a variable reference, therefore text such as `US$$55` is not modified. Each occurrence of the characters `$$` preceding a variable reference is replaced with a single `$` character, and that character does not initiate a variable reference.

### Pre-Defined Variables

IceGrid defines a set of read-only variables to hold information that may be of use to descriptors. The names of these variables are reserved and cannot be used as variable or parameter names. The table below describes the purpose of each variable and defines the context in which it is valid.

Name	Description
application	The name of the enclosing application.
application.distrib	The pathname of the enclosing application distribution directory, and an alias for <code>\$(node.datadir)/distrib/\${application}</code> .
node	The name of the enclosing node.
node.os	The name of the enclosing node operating system. On Unix, this value is provided by <code>uname</code> . On Windows, the value is <code>Windows</code> .
node.hostname	The host name of the enclosing node.
node.release	The operation system release of the enclosing node. On Unix, this value is provided by <code>uname</code> . On Windows, the value is obtained from the <code>OSVERSIONINFO</code> data structure.
node.version	The operation system version of the enclosing node. On Unix, this value is provided by <code>uname</code> . On Windows, the value represents the current service pack level.
node.machine	The machine hardware name of the enclosing node. On Unix, this value is provided by <code>uname</code> . On Windows, the value is <code>x86</code> or <code>x64</code> .

node.datadir	The absolute pathname of the enclosing node data directory.
server	The ID of the enclosing server.
server.distrib	The pathname of the enclosing server distribution directory, and an alias for <code>\${node.datadir}/servers/\${server}/distrib</code> .
service	The name of the enclosing service.
session.id	The client session identifier. For sessions created with a user name and password, the value is the user ID; for sessions created from a secure connection, the value is the distinguished name associated with the connection.

The availability of a variable is easily determined in some cases, but may not be readily apparent in others. For example, you can use the `${node}` variable in a property value within a server template definition, because variables in the body of a server template are evaluated when the server template is instantiated on a specific node.

#### Variable Substitution in IceGrid Admin

In a number of panes, you can substitute variables and template parameters by their respective value. Use `View > Show Variables` and `View > Substitute Variables` or the corresponding toolbar toggle buttons:

When variable-substitution is enabled, the descriptors are displayed read-only.

#### Scoping Rules

Descriptors may only define variables at the application and node levels. Each node introduces a new scope, such that defining a variable at the node level overrides (but does not modify) the value of an application variable with the same name. Similarly, a template parameter overrides the value of a variable with the same name in an enclosing scope. A descriptor may refer to a variable defined in any enclosing scope, but its value is determined by the nearest scope. The diagram below illustrates these concepts:

In this diagram, the variable `x` is defined at the application level with the value 1. In node A, `x` is overridden with the value 2, whereas `x` remains unchanged in node B. Within the context of node A, `x` continues to have the value 2 in a server instance definition. However, when `x` is used as the name of a template parameter, the node's definition of `x` is overridden and `x` has the value 3 in the template's scope.

#### Resolving a Reference

To resolve a variable reference `${var}`, IceGrid searches for a definition of `var` using the following order of precedence:

- Pre-defined variables
- Template parameters, if applicable
- Node variables, if applicable
- Application variables

After the initial substitution, any remaining references are resolved recursively using the following order of precedence:

- Pre-defined variables
- Node variables, if applicable
- Application variables
- Template Parameters

Template parameters are not visible in nested template instances. This situation can only occur when an IceBox server template instantiates a service template.

#### Modifying a Variable

A variable definition can be overridden in an inner scope, but the inner definition does not modify the outer variable.

See Also

- [Using Descriptor Variables and Parameters](#)

## Application Descriptor

On this page:

- [Creating a new Application](#)
- [Properties](#)
- [Children](#)

### Creating a new Application

You can create a new application using `File > New Application`: this opens a new Application tab, with an empty application definition.

When you are connected to an IceGrid registry, you can also use `File > New Application with Default Templates from Registry`. This also opens new Application tab with a brand new application definition. This new application contains a copy of all the templates definitions contained in the IceGrid registry default template file. See [IceGrid.Registry.DefaultTemplates](#).

### Properties

The Application Properties panel offers the following fields:

- **Name**  
The name of the application. This field is not editable for live applications.
- **Description**  
A free-text description of this application.
- **Variables**  
This table shows application-level [IceGrid variables](#).
- **IcePatch2 Proxy**  
A stringified or well-known proxy for the IcePatch2 server than contains this application's distribution. Possible values:

Value	Description
"None selected" (default) or blank	no distribution defined
<code>\${application}.IcePatch2/server</code>	the well-known proxy of an IcePatch2 server deployed in this application using the IcePatch2 default server-template (with a default instance-name parameter value).
<i>stringified proxy</i>	your own stringified or well-known proxy

- **Directories**  
List of directories included in the application distribution. When blank, the entire IcePatch2 server repository is used as the distribution.

### Children

An application node can have five types of children:

- [Node](#)
- [Property Set](#)
- [Replica Group](#)
- [Server Template](#)
- [Service Template](#)

## ***Node Descriptor***

A node represents an IceGrid node that starts and monitors your servers. Several applications can be deployed on the same node; however a node descriptor describes only the servers defined by the enclosing application.

On this page:

- [Properties](#)
- [Children](#)

### **Properties**

The Node Properties panel offers the following fields:

- **Name**  
The name of the node. This name must match the IceGrid.Node.Name configuration property of the node process.
- **Description**  
A free-text description of this node.
- **Variables**  
This table shows node-level [IceGrid variables](#).
- **Load Factor**  
A floating point value used to compare different nodes when making a [load-balancing](#) decision based on load-average (for Linux and Unix) or CPU utilization (for Windows). Leaving this value blank is equivalent to the default: 1.0 on Linux and Unix, and 1.0 divided by the number of CPUs on Windows.

### **Children**

A node can have two types of children:

- [Server](#)
- [Property Set](#)

## Server Descriptor

A server represents an Ice server deployed on a node as part of an application. IceGrid supports three kinds of servers:

- **Plain Server**  
A normal Ice server, with typically a single Ice communicator. IceGrid generates a single Ice configuration file for this server.
- **IceBox Server**  
An IceBox server, with usually a number of IceBox services deployed in it. IceGrid generates an Ice configuration file for the IceBox server itself, and also a separate Ice configuration for each IceBox service.
- **Server Instance**  
A server (either plain server or IceBox server) defined using a server template.

On this page:

- [Plain Server](#)
  - [Properties](#)
  - [Children](#)

### Plain Server

#### Properties

The Server Properties panel offers the following fields:

- **Server ID**  
The ID of the server; corresponds to the `Ice.Admin.ServerId` property. Each server must have a unique ID within an IceGrid deployment.
- **Description**  
A free-text description of this server.
- **Property Sets**  
List of property-set IDs; you refer to a [property set](#) to "include" all its properties in the server.
- **Properties**  
Ice properties private to this server.
- **Log Files**  
This table can be used to declare a number of log files used by this server. Path is the path to the log file (a relative path is relative to the IceGrid node working directory); when Property is set, IceGrid generates a property with this name and the log file path as value.  
You declare log files to be able to conveniently retrieve them using IceGrid Admin (in the [Live Deployment](#) tab) or with the `icegrid admin` command-line utility.
- **Path to Executable**  
Path to the server's executable; cannot be blank. A relative path is relative to the IceGrid node working directory.
- **Ice Version**  
The Ice version of this server. If you don't provide a value, IceGrid assumes it's the same version as the IceGrid registry.
- **Working Directory**  
The working directory for the server when started by the IceGrid node.
- **Command Arguments**  
The command-line arguments given to the server when started by the IceGrid node.
- **Run as**  
On Linux and Unix, when IceGrid node is running as root, it is possible to run the server under any username. Enter the desired username in this field.

When not set (the default), the server runs as the same user as the IceGrid node, except when IceGrid node runs as root. In this case, the server runs as nobody.

- **Environment Variables**

The environment variables for the server when started by the IceGrid node. These variables are in addition to variables defined in the IceGrid node own environment.

- **Activation Mode**

The server's activation mode. Must be one of:

Activation Mode	Description
always	IceGrid keeps this server running all the time
manual	This server is started "manually", using IceGrid Admin or the <code>icegridadmin</code> command-line utility
on-demand	IceGrid starts this server when it resolves the object-adapter ID of an object adapter defined in this server
session	IceGrid starts a separate instance of this server for each IceGrid session that allocates this server

The Activation Mode can also be a variable or a combination of variables that resolves to one of the values above.

- **Activation Timeout**

When activating a server, IceGrid gives timeout seconds to object adapters with server lifetime to register their endpoints with the IceGrid registry. During this time, lookup for the corresponding adapter IDs are delayed.

If not set or set to 0, the IceGrid node uses the value of its `IceGrid.Node.WaitTime` property.

- **Deactivation Timeout**

When deactivating a server, IceGrid gives timeout seconds to the server to exit gracefully. After this timeout, the server process is killed.

If not set or set to 0, the IceGrid node uses the value of its `IceGrid.Node.WaitTime` property.

- **Allocatable**

Specifies whether the server can be allocated. A server is allocated implicitly when one of its allocatable objects is allocated. This checkbox is ignored if the server activation mode is session; a server with this activation mode is always allocatable. Default: false.

- **Depends on the application distribution**

A server that depends on the application distribution is stopped and disabled before any application distribution update, and re-enabled after such update. Default: true.

- **IcePatch2 Proxy**

A stringified (or well-known) proxy for the IcePatch2 server than contains this server's private distribution. Possible values:

Value	Description
"None selected" (default) or blank	no private distribution defined
<code>\${application}.IcePatch2/server</code>	the well-known proxy of an IcePatch2 server deployed in this application using the IcePatch2 default server-template (with a default instance-name parameter value).
<i>stringified proxy</i>	your own stringified or well-known proxy

- **Directories**

List of directories included in the application distribution. When blank, the entire IcePatch2 server repository is used as the distribution.

### Children

A plain server can have two types of children:

- [Adapter](#)
- [Database Environment](#)

### IceBox Server

### Properties

The Properties panel for an IceBox server is identical to the Properties panel for a [Plain Server](#).

When you create a new IceBox server, some properties are created automatically:

Property Name	Property Value
IceBox.InstanceName	\${server}
Ice.Admin.Endpoints	tcp -h 127.0.0.1

The `Ice.Admin.Endpoints` setting enables the Admin object in the main communicator of this IceBox server.

The Path to Executable is typically `icebox`, `iceboxd` (for a C++ IceBox), `java` (for a Java IceBox) or `iceboxcs` (for a .NET IceBox). In Java, the Command Arguments should include the IceBox container class name, `IceBox.Server`.

### Children

An IceBox server can have only one type of children, [Service](#).

### Server Instance

A server instance is a server created from a server template; it may be a plain server or an IceBox server.

### Properties

The Server Instance Properties panel offers the following fields:

- **Template**  
The name of the [Server Template](#).
- **Parameters**  
Use this table to assign values to the template parameters defined in the server template.
- **Property Sets**  
List of property-set IDs; you refer to a [property set](#) to "include" all its properties in this server-instance.
- **Properties**  
Ice properties private to this server. Overall, the properties of the server instance are a combination of properties defined in the server template (including its own property sets references) augmented and possibly overridden by properties defined in the server instance.

### Children

An instance of an IceBox server template can have one type of children, [Property Set](#).

An instance of a plain server template cannot have any child.

## Service Descriptor

A service represents an IceBox service deployed on an IceBox server. IceGrid supports two kinds of services:

- **Plain Service**  
A service defined directly with a service descriptor
- **Service Instance**  
A service defined using a service template

On this page:

- [Load Order](#)
- [Plain Service](#)
  - [Properties](#)
  - [Children](#)
- [Service Instance](#)
  - [Properties](#)

### Load Order

The load-order of services within an IceBox server is determined by their display order in IceGrid Admin. You can reorder services using `Edit > Move Up` or `Edit > Move Down` (also available from each service's contextual menu).

### Plain Service

#### Properties

The Service Properties panel offers the following fields:

- **Service Name**  
The name of the service. Must be unique within the enclosing IceBox server.
- **Description**  
A free-text description of this service.
- **Property Sets**  
List of property-set IDs; you refer to a [property set](#) to "include" all its properties in the service.
- **Properties**  
Ice properties private to this service.
- **Log Files**  
This table can be used to declare a number of log files used by this service. Path is the path to the log file (a relative path is relative to the IceGrid node working directory); when Property is set, IceGrid generates a property with this name and the log file path as value. You declare log files to be able to conveniently retrieve them using IceGrid Admin (in the [Live Deployment](#) pane) or with the `icegridadmin` command-line utility.
- **Entry Point**  
The service's [entry point](#), for example `IceStormService,35:createIceStorm`. IceGrid will append `--Ice.Config=path-to-service-config-file` to this entry point when it generates the `IceBox.Service.name` property in the enclosing IceBox server config file.

#### Children

A plain service can have two types of children:

- [Adapter](#)
- [Database Environment](#)

### Service Instance

#### Properties

The Service Instance Properties panel offers the following fields:

- **Template**  
The name of the [Service Template](#).
- **Parameters**  
Use this table to give values to the template parameters defined in the service template.
- **Property Sets**  
List of property-set IDs; you refer to a [property set](#) to "include" all its properties in the service.
- **Properties**  
Ice properties private to this service.

## Adapter Descriptor

Each indirect object adapter registered with IceGrid requires its own Adapter descriptor. If you need to specify a direct adapter, simply create a number of Ice properties in your server.

### Properties

The Adapter Properties panel offers the following fields:

- **Adapter Name**  
The name of the object adapter. This name must be unique within the enclosing Ice communicator, and is only used to lookup adapter properties.
- **Description**  
A free-text description of this object adapter.
- **Adapter ID**  
The ID of the object adapter. This ID must be unique within an IceGrid deployment. Default value: `$(server).adapter-name`.
- **Replica Group**  
The ID of this adapter's [Replica Group](#). By default, an adapter does not belong to any replica group.
- **Priority**  
The adapter priority in its [Replica Group](#). The default priority is 0.
- **Endpoints**  
The configured endpoints for this object adapter. Corresponds to the `adapter-name.Endpoints` property. Default: default, which means listen using the default protocol (tcp by default) on an OS assigned port, on all interfaces.
- **Published Endpoints**  
The configured published endpoints for this object adapter. Corresponds to the `adapter-name.PublishedEndpoints` property. Default: actual endpoints (computed at run time), derived by Ice from the Endpoints field above.
- **Proxy Options**  
The default Proxy Options for well-known objects defined within this object adapter, and the Proxy Options for proxies created by this object adapter. Corresponds to the `adapter-name.ProxyEndpoints` property. Default: empty string.
- **Register Process**  
This setting is ignored for servers running Ice version 3.3 or greater.  
When checked, this adapter will create and register an `Ice::Process` object with IceGrid during activation. Such object is used to cleanly shutdown the server from IceGrid. Each server should register one, and only one such `Ice::Process` object.
- **Server Lifetime**  
When checked, IceGrid expects this adapter to register its endpoints during server startup and unregister them during server shutdown. See also Activation Timeout in [Server Properties](#). Default: true (checked).
- **Well-known Objects**  
A table of well-known objects defined by this adapter. When Property is set, IceGrid generates a property with this name and with Identity as value.
- **Allocatable Objects**  
A table of allocatable objects defined by this adapter. When Property is set, IceGrid generates a property with this name and with Identity as value.

### ***Database Environment Descriptor***

You can describe the Freeze database environment(s) used by your server or service with Database Environment Descriptors. Each descriptor describes a single Freeze database environment.

#### **Properties**

The Database Environment Properties panel offers the following fields:

- **Name**  
The name of the Freeze Database Environment. This name must be unique within the enclosing Ice communicator.
- **Description**  
A free-text description of this database environment.
- **DB Home**  
The path of the home directory of the Berkeley DB environment. The default is "Created by the IceGrid Node": when selected, IceGrid node creates automatically a directory in its local server tree. Otherwise, if you enter your own value, the path must exist: IceGrid node will not create this directory if it does not exist.
- **Properties**  
This table shows a list of Berkeley DB properties for this database environment. These are *not* Ice properties. IceGrid generates a `DB_CONFIG` file in the DB Home directory with these settings.

### ***Property Set Descriptor***

A Property Set defines a set of Ice properties. IceGrid Admin supports two kinds of Property Sets:

- **Named Property Set**  
A property set defined within an [application](#) or within a [node](#). Server and service definitions refer to such property sets to "include" the corresponding properties.
- **Service-Instance Property Set**  
A property set defined as a child of an [IceBox server instance](#). Such a property set provides properties to a service instance within a concrete IceBox server.

### **Properties**

The Property Set Properties panel offers the following fields:

- **ID** (Named Property Set only)  
The ID of a named property set.
- **Service Name** (Service Instance property set)  
The service name.
- **Property Sets**  
List of Property Set IDs. The corresponding property sets are "included" in this property set.
- **Properties**  
Ice properties private to this Property Set

## Replica Group Descriptor

A replica group represents an abstract grouping of identical, or very similar, object adapters. An object adapter joins this group by setting this replica group ID in its Replica Group field.

### Properties

The Replica Properties panel offers the following fields:

- **Replica Group ID**  
The ID of this replica group. Must be unique within an IceGrid deployment.
- **Description**  
A free-text description of this replica group.
- **Proxy Options**  
The default Proxy Options for well-known objects defined within this replica group.
- **Well-known Objects**  
A table of well-known objects defined by this replica group.
- **Load Balancing Policy**  
The load-balancing policy used by IceGrid when resolving the Replica Group ID in proxies. Must be one of:

Policy	Description
Adaptive	Returns the endpoints of the object adapters whose nodes report the lowest load-average (on Linux/Unix) or CPU utilization (on Windows). The actual load-average or CPU utilization value of each node is multiplied by the node's load-factor for this comparison. See <a href="#">Load Sample</a> below, and <a href="#">Node</a> .
Ordered	Returns the endpoints of the object adapters with the highest priority. See <a href="#">Adapter</a> .
Random	Returns the endpoints of object adapters selected at random. This is the default policy.
Round-robin	IceGrid puts all the object adapters in a list, and for each new resolution, it returns the endpoints from the next <i>How many Adapters</i> items on this list.

- **How many Adapters**  
Specify the number of object adapters selected by IceGrid for each resolution. 1 is a common value. When set to 0 (the default), IceGrid returns the endpoints of all object adapters in this replica group.
- **Load Sample**  
Available only with the Adaptive load-balancing policy. Specify the load-average or CPU utilization sample to use when comparing nodes: it can be 1 (default), 5 or 15 minutes.

## ***Server Template Descriptor***

A server template is used to capture the common definitions of several similar or identical servers.

On this page:

- [Properties](#)
- [Children](#)

### **Properties**

The Server Template Properties panel offers the following fields:

- **Template ID**  
The ID the template. Must be unique within the application.
- **Parameters**  
The list of parameters for this template. Each parameter can have an optional default value.
- **Plain Server Properties**  
The remaining fields are the [Plain Server](#) fields.

### **Children**

A plain server template can have two types of children:

- [Adapter](#)
- [Database Environment](#)

An IceBox server template can have only one kind of children, [Service](#).

## ***Service Template Descriptor***

A service template is used to capture the common definitions of several similar or identical services.

On this page:

- [Properties](#)
- [Children](#)

### **Properties**

The Service Template Properties panel offers the following fields:

- **Template ID**  
The ID the template. Must be unique within the application.
- **Parameters**  
The list of parameters for this template. Each parameter can have an optional default value.
- **Plain Service Properties**  
The remaining fields are the [Plain Service](#) fields.

### **Children**

A service template can have two types of children:

- [Adapter](#)
- [Database Environment](#)

## IceGrid Server Activation

On this page:

- [Server Activation Modes](#)
- [Server Activation in Detail](#)
- [Requirements for Server Activation](#)
- [Efficiency Considerations for Server Activation](#)
- [Activating Servers with Specific User IDs](#)
- [Automating Endpoint Registration](#)

### Server Activation Modes

You can choose among four activation modes for servers deployed and managed by an IceGrid node:

- **Manual**  
You must start the server explicitly via the IceGrid GUI or `icegridadmin`, or programmatically via the `IceGrid::Admin` interface.
- **Always**  
IceGrid activates the server when its node starts. If the server stops, IceGrid automatically reactivates it.
- **On demand**  
IceGrid activates the server when a client invokes an operation on an object in the server.
- **Session**  
This mode also provides on-demand activation but requires the server to be allocated by a session.

### Server Activation in Detail

On-demand server activation is a valuable feature of distributed computing architectures for a number of reasons:

- It minimizes application startup times by avoiding the need to pre-start all servers.
- It allows administrators to use their computing resources more efficiently because only those servers that are actually needed are running.
- It provides more reliability in the case of some server failure scenarios, e.g., the server is reactivated after a failure and may still be capable of providing some services to clients until the failure is resolved.
- It allows remote activation and deactivation.

On-demand activation occurs when an Ice client [requests the endpoints](#) of one of the server's object adapters via a locate request. If the server is not active at the time the client issues the request, the node activates the server and waits for the target object adapter to register its endpoints. Once the object adapter endpoints are registered, the registry returns the endpoint information back to the client. This sequence ensures that the client receives the endpoint information *after* the server is ready to receive requests.

### Requirements for Server Activation

In order to use on-demand activation for an object adapter, the adapter must have an identifier and be entered in the IceGrid registry.

When using session activation mode, IceGrid requires that the server be [allocated](#); on-demand activation fails for servers that have not been allocated.

The session activation mode recognizes an additional [reserved variable](#) in the server descriptor, `${session.id}`. The value of this variable is the user ID or, for SSL sessions, the distinguished name associated with the session.

### Efficiency Considerations for Server Activation

Once a server is activated, it remains running indefinitely (unless it uses the session activation mode). A node [deactivates a server](#) only when explicitly requested to do so. As a result, server processes tend to accumulate on the node's host.

One of the advantages of on-demand activation is the ability to manage computing resources more efficiently. Of course there are many aspects to this, but Ice makes one technique particularly simple: servers can be configured to terminate gracefully after they have been idle for a certain amount of time.

A typical scenario involves a server that is activated on demand, used for a while by one or more clients, and then terminated automatically when no requests have been made for a configurable number of seconds. All that is necessary is setting the server's configuration property

`Ice.ServerIdleTime` to the desired idle time.

For a server activated in session activation mode, IceGrid deactivates the server when the session releases the server or when the session is destroyed.

## Activating Servers with Specific User IDs

On Unix platforms you can activate server processes with specific effective user IDs, provided that the IceGrid node is running as root. If the IceGrid node does not run as root, servers are always activated with the effective user ID of the IceGrid node process. (The same is true for Windows — servers always run with the same user ID as the IceGrid node process.)

For the remainder of this section, we assume that the node runs as root on a Unix machine.

The `user` attribute of the `server descriptor` specifies the user ID for a server. If this attribute is not specified and the activation mode is not `session`, the default value is `nobody`. Otherwise, the default value is `${session.id}` if the activation mode is `session`.

Since individual users often have different account names and user IDs on different machines, IceGrid provides a mechanism to map the value of the `user` attribute in the server descriptor to a user account. To do this, you must configure the node to use a user account mapper object. This object must implement the `IceGrid::UserAccountMapper` interface:

```

Slice

```
exception UserAccountNotFoundException {};

interface UserAccountMapper {
    string getUserAccount(string user)
        throws UserAccountNotFoundException;
};
```

```

The IceGrid node invokes `getUserAccount` and passes the value of the server descriptor's `user` attribute. The return value is the name of the user account.

IceGrid provides a built-in file-based user account mapper that you can configure for the node and the registry. The file contains any number of user-account-ID pairs. Each pair appears on a separate line, with white space separating the user account from the identifier. For example, the file shown below contains two entries that map two distinguished names to the user account `lisa`:

```

```
lisa O=ZeroC\\, Inc., OU=Ice, CN=Lisa
lisa O=ZeroC\\, Inc., OU=Ice, CN=Lisa S.
```

```

The distinguished names must be unique. If the same distinguished name appears several times in a file, the last entry is used.

You can specify the path of the user account file with the `IceGrid.Registry.UserAccounts` property for the registry and the `IceGrid.Node.UserAccounts` property for a node.

To configure an IceGrid node to use the IceGrid registry file-based user account mapper, you need to set the `IceGrid.Node.UserAccountMapper` property to the well-known proxy `IceGrid/RegistryUserAccountMapper`. Alternatively, you can set this property to the proxy of your own user account mapper object. Note that if this property is set, the node ignores the setting of `IceGrid.Node.UserAccounts`.

## Automating Endpoint Registration

Servers must be [properly configured](#) to enable automatic endpoint registration. It should be noted however that IceGrid simplifies the configuration process in two ways:

- The IceGrid [deployment facility](#) automates the creation of a [configuration file](#) for the server, including the definition of object adapter identifiers and endpoints.

- A server that is activated automatically by an IceGrid node does not need to explicitly configure a proxy for the locator because the IceGrid node defines it in the server's configuration file.

## IceGrid Troubleshooting

On this page:

- [Troubleshooting Activation Failures](#)
- [Troubleshooting Proxy Failures](#)
- [Troubleshooting Server Failures](#)
- [Disabling Faulty Servers](#)

### Troubleshooting Activation Failures

Server activation failure is usually indicated by the receipt of a `NoEndpointException`. This can happen for a number of reasons, but the most likely cause is an incorrect configuration. For example, an IceGrid node may fail to [activate a server](#) because the server's executable file, shared libraries, or classes could not be found. There are several steps you can take in this case:

1. Enable activation tracing in the node by setting the configuration property `IceGrid.Node.Trace.Activator=3`.
2. Examine the tracing output and verify the server's command line and working directory are correct.
3. Relative pathnames specified in a command line may not be correct relative to the node's current working directory. Either replace relative pathnames with absolute pathnames, or restart the node in the proper working directory.
4. Verify that the server is configured with the correct `PATH` or `LD_LIBRARY_PATH` settings for its shared libraries. For a Java server, its `CLASSPATH` may also require changes.

Another cause of activation failure is a server fault during startup. After you have confirmed that the node successfully spawns the server process using the steps above, you should then [check for signs of a server fault](#) (e.g., on Unix, look for a `core` file in the node's current working directory).

### Troubleshooting Proxy Failures

A client may receive `Ice::NotRegisteredException` if [binding fails](#) for an indirect proxy. This exception indicates that the proxy's object identity or object adapter is not known by the IceGrid registry. The following steps may help you discover the cause of the exception:

1. Use `icegridadmin` to verify that the object identity or object adapter identifier is actually registered, and that it matches what is used by the proxy:

```
>>> adapter list
...
>>> object find ::Hello
...
```

2. If the problem persists, review your configuration to ensure that the locator proxy used by the client matches the registry's client endpoints, and that those endpoints are accessible to the client (i.e., are not blocked by a firewall).
3. Finally, enable locator tracing in the client by setting the configuration property `Ice.Trace.Locator=2`, then run the client again to see if any log messages are emitted that may indicate the problem.

### Troubleshooting Server Failures

Diagnosing a server failure can be difficult, especially when servers are activated automatically on remote hosts. Here are a few suggestions:

1. If the server is running on a Unix host, check the current working directory of the IceGrid node process for signs of a server failure, such as a `core` file.
2. Judicious use of tracing can help to narrow the search. For example, if the failure occurs as a result of an operation invocation, enable protocol tracing in the Ice run time by setting the configuration property `Ice.Trace.Protocol=1` to discover the object identity and operation name of all requests. Of course, the default log output channels (standard out and standard error) will probably be lost if the server is activated automatically, so either start the server manually (see below) or [redirect the log output](#). You can also use the `Ice::Logger` interface to emit your own trace messages.
3. Run the server in a debugger; a server configured for automatic activation can also be started manually if necessary. However, since the IceGrid node did not activate the server, it cannot monitor the server process and therefore will not know when the server terminates. This will prevent subsequent activation unless you clean up the IceGrid state when you have finished debugging and

terminated the server. You can do this by starting the server using `icegridadmin`:

```
>>> server start TheServer
```

This will cause the node to activate (and therefore monitor) the server process. If you do not want to leave the server running, you can stop it with the `server stop` command.

4. After the server is activated and is in a quiescent state, attach your debugger to the running server process. This avoids the issues associated with starting the server manually (as described in the previous step), but does not provide as much flexibility in customizing the server's startup environment.

Another cause for a server to fail to activate correctly is if there is a mismatch in the adapter identifiers used by the server for its adapters, and the adapter identifiers specified in the server's deployment descriptor. After starting a server process, the node waits for the server to activate all of its object adapters and report them as ready; if the server does not do this, the node reports a failure once a timeout expires. The timeout is controlled by the setting of the property `IceGrid.Node.WaitTime`. (The default value is 60 seconds.)

You can check the status of each of a server's adapters using `icegridadmin` or the GUI tool. While the node waits for an adapter to be activated by the server, it reports the status of the adapter as "activating". If you experience timeouts before each adapter's status changes to "active", the most likely cause is that the deployment descriptor for the server either mentions more object adapters than are actually created by the server, or that the server uses an identifier for one or more adapters that does not match the corresponding identifier in the deployment descriptor.

## Disabling Faulty Servers

You may find it necessary to disable a server that terminates in an error condition. For example, on a Unix platform each server failure might result in the creation of a new (and potentially quite large) core file. This problem is exacerbated when the server is used frequently, in which case repeated cycles of activation and failure can consume a great deal of disk space and threaten the viability of the application as a whole.

As a defensive measure, you can configure an IceGrid node to disable these servers automatically using the `IceGrid.Node.DisableOnFailure` property. In the disabled state, a server cannot be activated on demand. The default value of the property is zero, meaning the node does not disable a server that terminates improperly. A positive value causes the node to temporarily disable a faulty server, with the value representing the number of seconds the server should remain disabled. If the property has a negative value, the server is disabled indefinitely, or until the server is explicitly enabled or started via an administrative action.

You can also manually disable a server at any time using an administrative tool. A manually disabled server remains disabled indefinitely until an administrator enables or starts it. Disabling an *active* server has no effect on the server process; the server is unaware of the change to its status and continues to service requests from connected clients as usual. However, as of Ice 3.5, disabling a server does prevent IceGrid from including the endpoints of the server's object adapters in any subsequent `locate` requests, and it excludes those object adapters from any `replica groups` in which they might participate.

Typically, the ultimate goal of disabling a server is to gracefully migrate clients from the faulty server to ones that are behaving correctly. For a client that starts after the server is disabled, migration occurs immediately: the Ice run time in the client issues a `locate` request on the first proxy invocation, and the result returned by IceGrid excludes any endpoints from the disabled server. For a client that is active at the time the server is disabled, it does not migrate to a different server until its Ice run time issues a new `locate` request and obtains a new set of endpoints for the target object. The timing of this new `locate` request depends on several factors:

- If the client has an existing connection to the server, that connection will remain open and active as determined by the configuration settings of the client and server. For example, `active connection management` could eventually cause the connection to be closed automatically from either end due to inactivity. A subsequent proxy invocation may result in a new `locate` request.
- The client's use of `connection caching` also plays an important role. If the client's proxy is configured to cache connections, the client may continue to use the disabled server indefinitely. Connection caching should be disabled to ensure that migration eventually takes place.
- The Ice run time in the client also `caches the results` of `locate` requests. Although by default these results do not expire, setting a `cache timeout` allows you to specify how frequently the Ice run time issues new `locate` requests. Consider this code:

**C++**

```
proxy =
proxy->ice_connectionCached(false)->ice_locatorCacheTimeout(20);
```

By disabling connection caching and setting a locator cache timeout, we can ensure that migration occurs within twenty seconds for

invocations on this proxy.

## IceGrid Database Utility

The `icegriddb` utility is a command-line tool for importing and exporting an IceGrid registry database. This tool is especially useful when migrating to Ice 3.7, where IceGrid uses a different database implementation and storage format. Using `icegriddb`, you can export your existing IceGrid 3.6 registry database and then import the data using the Ice 3.7 version of `icegriddb`.

On this page:

- [Usage](#)
- [Exporting an IceGrid Database](#)
- [Importing an IceGrid Database](#)

## Usage

The IceGrid Database utility supports the following command-line options:

```
Usage: icegriddb <options>
Options:
-h, --help Show this message.
-v, --version Display version.
--import FILE Import database from FILE.
--export FILE Export database to FILE.
--dbhome DIR The database directory.
-d, --debug Print debug messages.
```

## Exporting an IceGrid Database

To export an IceGrid registry database, use the `--export` option to specify the output file and the `--dbhome` option to specify the path name of the registry's database environment. To discover the location of your database environment, review the registry's configuration and look for the setting of `IceGrid.Registry.Data`. For example, the IceGrid sample programs typically use this setting:

```
IceGrid.Registry.Data=db/registry
```

Run the following command to export the database:

```
$ icegriddb --export registry.ixp --dbhome db/registry
```

The utility will fail with an error message if the given path does not contain a registry database.

## Importing an IceGrid Database

To import an IceGrid registry database, use the `--import` option to specify the input file and the `--dbhome` option to specify the path name of the registry's database environment. For example, use the following command to import a database into the `dbNew/registry` directory from a file named `registry.ixp`:

```
$ icegriddb --import registry.ixp --dbhome dbNew/registry
```

The target directory must be empty.

## IcePatch2

IcePatch2 is the Ice solution for secure replication of a directory tree.

IcePatch2 supersedes IcePatch, which was a previous version of this service.

IcePatch2 is an efficient file patching service that is easy to configure and use. It includes the following components:

- the IcePatch server (`icepatch2server`)
- a text-based IcePatch client (`icepatch2client`)
- a text-based tool to compress files and calculate checksums (`icepatch2calc`)
- a Slice API and C++ convenience library for developing custom IcePatch2 clients

As with all Ice services, IcePatch2 can be configured to use Ice facilities such as [Glacier2](#) for firewall support and [IceSSL](#) for secure communication.

IcePatch2 is conceptually quite simple. The server is given responsibility for a file system directory (the *data directory*) containing the files and subdirectories that are to be distributed to IcePatch2 clients. You use `icepatch2calc` to compress these files and to generate an index containing a checksum for each file. The server transmits the compressed files to the client, which recreates the data directory and its contents on the client side, patching any files that have changed since the previous run.

IcePatch2 is efficient: transfer rates for files are comparable to what you would get using `ftp`.

IcePatch2 addresses a requirement common to both development and deployment scenarios: the safe, secure, and efficient replication of a directory tree. The IcePatch2 server is easy to configure and efficient. For simple uses, IcePatch2 provides a client that can be used to patch directory hierarchies from the command line. With the C++ utility library, you can also create custom patch clients if you require better integration of the client with your application.

## Using icepatch2calc

This page describes how to prepare a file set using `icepatch2calc`.

On this page:

- [Preparing a File Set using icepatch2calc](#)
- [icepatch2calc Command Line Options](#)

### Preparing a File Set using `icepatch2calc`

Suppose we have the directories and files shown below:

*An example data directory.*

Assume that the file named `emptyFile` is empty (contains zero bytes) and that the remaining files contain data.

To prepare this directory for the transmission by the server, you must first run `icepatch2calc`. (The command shown assumes that the data directory is the current directory.)

```
$ icepatch2calc .
```

After running this command, the contents of the data directory look as follows:

*Contents of the data directory after running `icepatch2calc`.*

Note that `icepatch2calc` compresses the files in the data directory (except for `emptyFile`, which is not compressed). Also note that `icepatch2calc` creates an additional file, `IcePatch2.sum` in the data directory. The contents of this file are as follows:

```
. 3a52ce780950d4d969792a2559cd519d7ee8c727 -1
./bin bd362140a3074eb3edb5e4657561e029092c3d91 -1
./bin/hello 77b11db586a1f20aab8553284241bb3cd532b3d5 70
./emptyFile 082c37fc2641db68d195df83844168f8a464eada 0
./nonEmptyFile aec7301c408e6ce184ae5a34e0ea46e0f0563746 72
```

Each line in the checksum file contains the name of the *uncompressed* file or directory (relative to the data directory), the checksum of the *uncompressed* file, and a byte count. For directories, the count is `-1`; for uncompressed files, the count is `0`; for compressed files, the count is the number of bytes in the *compressed* file. The lines in the file are sorted alphabetically by their pathname.

If you add files or delete files from the data directory or make changes to existing files, you must stop the server, run `icepatch2calc` again to update the `IcePatch2.sum` checksum file, and restart the server.

## icepatch2calc Command Line Options

`icepatch2calc` has the following syntax:

```
icepatch2calc [options] data_dir [file...]
```

Normally, you will run `icepatch2calc` by simply specifying a data directory, in which case the program traverses the data directory, compresses all files, and creates an entry in the checksum file for each file and directory.

You can also nominate specific files or directories on the command line. In this case, `icepatch2calc` only compresses and calculates checksums for the specified files and directories. This is useful if you have a very large file tree and want to refresh the checksum entries for only a few selected files or directories that you have updated. (In this case, the program does not traverse the entire data directory and, therefore, will also not detect any updated, added, or deleted files, except in any of the specified directories.) Any file or directory names you specify on the command line must either be pathnames relative to the data directory or, if you use absolute pathnames, those pathnames must have the data directory as a prefix.

The command supports the following options:

- `-h, --help`  
Displays a help message.
- `-v, --version`  
Displays the version number.
- `-z, --compress`  
Normally, `icepatch2calc` scans the data directory and compresses a file only if no compressed version exists, or if the compressed version of a file has a modification time that predates that of the uncompressed version. If you specify `-z`, the tool re-scans and recompresses the entire data directory, regardless of the time stamps on files. This option is useful if you suspect that time stamps in the data directory may be incorrect.
- `-Z, --no-compress`  
This option allows you to create a client-side checksum file. Do not use this option when creating the checksum file for the server — the option is for creating a client-side `IcePatch2.sum` file for [updates of software on distribution media](#).
- `-i, --case-insensitive`  
This option disallows file names that differ only in case. (An error message will be printed if `icepatch2calc` encounters any files that differ in case only.) This is particularly useful for Unix servers with Windows clients, since Windows folds the case of file names, and therefore such files would override each other on the Windows client.
- `-V, --verbose`  
This option prints a progress message for each file that is compressed and for each checksum that is computed.

## Running the IcePatch2 Server

This page describes how to run the IcePatch2 server.

On this page:

- [Starting icepatch2server](#)
- [icepatch2server Command Line Options](#)

### Starting icepatch2server

Once you have run `icepatch2calc` on the data directory, you can start the `icepatch2server`:

```
$ icepatch2server .
```

The server expects the data directory as its single command-line argument. If you omit to specify the data directory, the server uses the setting of the `IcePatch2.Directory` property to determine the data directory.

You must also specify the endpoints at which the server listens for client requests, by setting the `IcePatch2.Endpoints` property.

### icepatch2server Command Line Options

Regardless of whether you run the server under Windows or a Unix-like operating system, it provides the following options:

- `-h, --help`  
Displays a help message.
- `-v, --version`  
Displays a version number.

Additional command line options are supported, including those that allow the server to run as a [Windows service](#) or [Unix daemon](#).

## Running the IcePatch2 Client

This page describes how to use the IcePatch2 client.

On this page:

- [Patching with icepatch2client](#)
- [Using icepatch2client for Partial Updates](#)
- [Preventing Deletion of Local Files](#)
- [Patching Software Installed from Media](#)
- [Setting Transfer Size for icepatch2client](#)
- [icepatch2client Command Line Options](#)

### Patching with icepatch2client

Once the `icepatch2server` is running, you can use `icepatch2client` to get a copy of the data directory that is maintained by the server. For example:

```
$ icepatch2client --IcePatch2Client.Proxy="IcePatch2Server/server:tcp -h
somehost.com -p 10000" .
```

The client expects the data directory as its single command-line argument. You must provide a proxy to the IcePatch2 server with the `IcePatch2Client.Proxy` property, as shown above.

If you have not run the client previously, it asks you whether you want to do a thorough patch. You must reply "yes" at this point (or run the client with the `-t` option to perform a [thorough update](#)). The client then executes the following steps:

1. It traverses the local data directory and creates a local `IcePatch2.sum` checksum file.
2. It obtains the relevant list of checksums from the server and compares it to the list of checksums it has built locally:
  - The client deletes each file that appears in the local checksum file but not in the server's file.
  - The client retrieves every file that appears in the server's checksum file, but not in the local checksum file.
  - The client patches every file that, locally, has a checksum that differs from the corresponding checksum on the server side.

When the client finishes, the contents of the data directory on the client side exactly match the contents of the data directory on the server side. However, only the uncompressed files are created on the client side — the server stores the compressed version of the files simply to avoid redundantly compressing a file every time it is retrieved by a client.

On the initial patch, any files that exist in the client's data directory are deleted or, if they have the same name as a file on the server, will be overwritten with the corresponding file as it exists on the server.

### Using icepatch2client for Partial Updates

Once you have run the client, the client-side data directory contains an `IcePatch2.sum` file that reflects the contents of the data directory. If you run `icepatch2client` a second time, the program uses the contents of the local checksum file: for each entry in the local checksum file, the client compares the local checksum with the server-side checksum for the same file; if the checksums differ, the client updates the corresponding file. In addition, the client deletes any files that appear in the client's checksum file but not in the server's checksum file, and it fetches any files that appear in the server's checksum file but are missing from the client's checksum file.

If you edit a client-side file and change its contents, `icepatch2client` does *not* realize that this has happened and therefore will not patch the file to be in sync with the version on the server again. This is because the client does not automatically recompute the checksum for a file to see whether the stored checksum in `IcePatch2.sum` still agrees with the actual checksum for the current file contents.

Similarly, if you create an arbitrary file on the client side, but that file is not mentioned in either the client's or the server's checksum file, that file will simply be left alone. In other words, a normal patch operates on the differences between the client's and server's checksum files, not on any differences that could be detected by examining the contents of the file system.

If you have locally created files that have nothing to do with the distribution or if you have locally modified some files and want to make sure that those modified files are updated to reflect the contents of the same files on the server side, you must run a thorough patch with the `-t` option.

ption. This forces the client to traverse the local data directory and recompute the checksum for each file, and then compare these checksums against the server-side ones. As a result, if you edit a file locally so it differs from the server-side version, `-t` forces that file to be updated. Similarly, if you have added a file of your own on the client side that does not have a counterpart on the server side, that file will be deleted by a thorough patch.

## Preventing Deletion of Local Files

By default, a normal patch deletes any files that appear in the client's checksum file but that are absent in the server's checksum file. Similarly, by default, a thorough patch deletes all files in the local data directory that do not appear in the server's checksum file. If you do not want this behavior, you can set the `IcePatch2Client.Remove` property to 0 (the default value is 1). This prevents deletion of files and directories that exist only on the client side, whether the patch is a normal patch or a thorough patch.

## Patching Software Installed from Media

Suppose you distribute your application on a DVD that clients use to install the software. The DVD might be out of date so, after installation, the install script needs to perform a patch to update the application to the latest version. The script can perform a thorough patch to do this but, for large file sets, this is expensive because the client has to recompute the checksum for every file in the distribution.

To avoid this cost, you can place all the files for the distribution into a directory on the server and run `icepatch2calc -Z` on that directory. With the `-Z` option, `icepatch2calc` creates a checksum file with the correct checksums, but with a file size of 0 for each file, that is, the `-Z` option omits compressing the files (and the considerable cost associated with that). Once you have created the new `IcePatch2.sum` file in this way, you can include it on the DVD and install it on the client along with all the other files.

This guarantees that the checksum file on the client is in agreement with the actual files that were just installed and, therefore, it is sufficient for the install script to do a normal patch to update the distribution and so avoid the cost of recomputing the checksum for every file.

## Setting Transfer Size for `icepatch2client`

You can set the `IcePatch2Client.ChunkSize` property to control the number of bytes that the client fetches per request. The default value is 100 kilobytes.

## `icepatch2client` Command Line Options

The client supports the following options:

- `-h, --help`  
Displays a help message.
- `-v, --version`  
Displays a version number.
- `-t, --thorough`  
Do a thorough patch, recomputing all checksums.

- `IcePatch2Client.*`

## IcePatch2 Object Identities

An `IcePatch2` service hosts one well-known object, which implements the `IcePatch2::FileServer` interface and has the default identity `IcePatch2/server`. If an application requires the use of multiple `IcePatch2` services, it is a good idea to assign unique identities to the well-known objects by configuring the services with different values for the `IcePatch2.InstanceName` property, as shown in the following example:

```
$ icepatch2server --IcePatch2.InstanceName=PublicFiles ...
```

This property changes the category of the server object's identity, which becomes `PublicFiles/server`.

## IcePatch2 Client Utility Library

IcePatch2 includes a pair of C++ classes that simplify the task of writing your own patch client, along with a Microsoft Foundation Classes (MFC) example that shows how to use these classes. You can find the MFC example in the subdirectory `demo/IcePatch2/MFC` of your Ice distribution.

The remainder of this section discusses the classes. To incorporate them into a custom patch client, your program must include the header file `IcePatch2/ClientUtil.h` and link with the IcePatch2 library.

On this page:

- [Performing a Patch](#)
  - [Constructing a Patcher](#)
  - [Executing the Patch](#)
- [Monitoring Patch Progress](#)

### Performing a Patch

The `Patcher` class encapsulates all of the patching logic required by a client:

**C++**

```

namespace IcePatch2 {
class Patcher : ... {
public:

 Patcher(const Ice::CommunicatorPtr& communicator,
 const PatcherFeedbackPtr& feedback);

 Patcher(const FileServerPrx& server,
 const PatcherFeedbackPtr& feedback,
 const std::string& dataDir, bool thorough,
 Ice::Int chunkSize, Ice::Int remove);

 bool prepare();

 bool patch(const std::string& dir);

 void finish();
};
typedef IceUtil::Handle<Patcher> PatcherPtr;
}

```

### Constructing a Patcher

The constructors provide two ways of configuring a `Patcher` instance. The first form obtains the following `IcePatch2Client` configuration properties from the supplied communicator:

- `IcePatch2Client.Proxy`
- `IcePatch2Client.Directory`
- `IcePatch2Client.Thorough`
- `IcePatch2Client.ChunkSize`
- `IcePatch2Client.Remove`

The second constructor accepts arguments that correspond to each of these properties.

Both constructors also accept a `PatcherFeedback` object, which allows the client to [monitor the progress](#) of the patch.

## Executing the Patch

`Patcher` provides three methods that reflect the three stages of a patch:

- `bool prepare()`  
The first stage of a patch includes reading the contents of the checksum file (if present), retrieving the file information from the server, and examining the local data directory to compose the list of files that require updates. The `PatcherFeedback` object is notified incrementally about each local task and has the option of aborting the patch at any time. This method returns true if patch preparation completed successfully, or false if the `PatcherFeedback` object aborted the patch. If an error occurs, `prepare` raises an exception in the form of a `std::string` containing a description of the problem.
- `bool patch(const std::string& dir)`  
The second stage of a patch updates the files in the local data directory. If the `dir` argument is an empty string or `""`, `patch` updates the entire data directory. Otherwise, `patch` updates only those files whose path names begin with the path in `dir`. For each file requiring an update, `Patcher` downloads its compressed data from the server and writes it to the local data directory. The `PatcherFeedback` object is notified about the progress of each file and, as in the preparation stage, may abort the patch if necessary. This method returns true if patching completed successfully, or false if the `PatcherFeedback` object aborted the patch. If an error occurs, `patch` raises an exception in the form of a `std::string` containing a description of the problem.
- `void finish()`  
The final stage of a patch writes a new checksum file to the local data directory. If an error occurs, `finish` raises an exception in the form of a `std::string` containing a description of the problem.

The code below demonstrates a simple patch client:

**C++**

```

#include <IcePatch2/ClientUtil.h>
...
Ice::CommunicatorPtr communicator = ...;
IcePatch2::PatcherFeedbackPtr feedback = new MyPatcherFeedbackI;
IcePatch2::PatcherPtr patcher =
 new IcePatch2::Patcher(communicator, feedback);

try {
 bool aborted = !patcher->prepare();
 if(!aborted)
 aborted = !patcher->patch("");
 if(!aborted)
 patcher->finish();
 if(aborted)
 cerr << "Patch aborted" << endl;
} catch(const string& reason) {
 cerr << "Patch error: " << reason << endl;
}

```

For a more sophisticated example, see `demo/IcePatch2/MFC` in your Ice distribution.

## Monitoring Patch Progress

The class `PatcherFeedback` is an abstract base class that allows you to monitor the progress of a `Patcher` object. The class declaration

is shown below:

```

C++

namespace IcePatch2 {
class PatcherFeedback : ... {
public:

 virtual bool noFileSummary(const std::string& reason) = 0;

 virtual bool checksumStart() = 0;
 virtual bool checksumProgress(const std::string& path) = 0;
 virtual bool checksumEnd() = 0;

 virtual bool fileListStart() = 0;
 virtual bool fileListProgress(Ice::Int percent) = 0;
 virtual bool fileListEnd() = 0;

 virtual bool patchStart(
 const std::string& path, Ice::Long size,
 Ice::Long updated, Ice::Long total) = 0;
 virtual bool patchProgress(
 Ice::Long pos, Ice::Long size,
 Ice::Long updated, Ice::Long total) = 0;
 virtual bool patchEnd() = 0;
};
typedef IceUtil::Handle<PatcherFeedback> PatcherFeedbackPtr;
}

```

Each of these methods returns a boolean value:

- true allows `Patcher` to continue
- false directs `Patcher` to abort the patch.

The methods are described below.

- `bool noFileSummary(const std::string& reason)`  
Invoked when the local checksum file cannot be found. Returning true initiates a thorough patch, while returning false causes `Patcher::prepare` to return false.
- `bool checksumStart()`  
`bool checksumProgress(const std::string& path)`  
`bool checksumEnd()`  
Invoked by `Patcher::prepare` during a thorough patch. The `checksumProgress` method is invoked as each file's checksum is being computed.
- `bool fileListStart()`  
`bool fileListProgress(Ice::Int percent)`  
`bool fileListEnd()`  
Invoked by `Patcher::prepare` when collecting the list of files to be updated. The `percent` argument to `fileListProgress` indicates how much of the collection process has completed so far.
- `bool patchStart(const std::string& path, Ice::Long size, Ice::Long updated, Ice::Long total)`  
`bool patchProgress(Ice::Long pos, Ice::Long size, Ice::Long updated, Ice::Long total)`  
`bool patchEnd()`  
For each file that requires updating, `Patcher::patch` invokes `patchStart` to indicate the beginning of the patch, `patchProgre`

ss one or more times as chunks of the file are downloaded and written, and finally `patchEnd` to signal the completion of the file's patch. The `path` argument supplies the path name of the file, and `size` provides the file's compressed size. The `pos` argument denotes the number of bytes written so far, while `updated` and `total` represent the cumulative number of bytes updated so far and the total number of bytes to be updated, respectively, of the entire patch operation.

## IceStorm

IceStorm is an efficient publish/subscribe service for Ice applications. Applications often need to disseminate information to multiple recipients. For example, suppose we are developing a weather monitoring application in which we collect measurements such as wind speed and temperature from a meteorological tower and periodically distribute them to weather monitoring stations. We initially consider using the architecture shown below:

*Initial design for a weather monitoring application.*

However, the primary disadvantage of this architecture is that it tightly couples the collector to its monitors, needlessly complicating the collector implementation by requiring it to manage the details of monitor registration, measurement delivery, and error recovery. We can rid ourselves of these mundane duties by incorporating IceStorm into our architecture, as shown below:

*A weather monitoring application using IceStorm.*

IceStorm simplifies the collector implementation significantly by decoupling it from the monitors. As a publish/subscribe service, IceStorm acts as a mediator between the collector (the publisher) and the monitors (the subscribers), and offers several advantages:

- When the collector is ready to distribute a new set of measurements, it makes a single request to the IceStorm server. The IceStorm server takes responsibility for delivering the request to the monitors, including handling any exceptions caused by ill-behaved or missing subscribers. The collector no longer needs to be aware of its monitors, or whether it even has any monitors at that moment.
- Similarly, monitors interact with the IceStorm server to perform tasks such as subscribing and unsubscribing, thereby allowing the collector to focus on its application-specific responsibilities and not on administrative trivia.
- The collector and monitor applications require very few changes to incorporate IceStorm.

## IceStorm Concepts

This section discusses several concepts that are important for understanding IceStorm's capabilities.

- **Message**

An IceStorm *message* is strongly typed and is represented by an invocation of a Slice operation: the operation name identifies the type of the message, and the operation parameters define the message contents. A message is published by invoking the operation on an IceStorm proxy in the normal fashion. Similarly, subscribers receive the message as a regular servant upcall. As a result, IceStorm uses the "push" model for message delivery; polling is not supported.

- **IceStorm Topics**

An application indicates its interest in receiving messages by subscribing to a *topic*. An IceStorm server supports any number of topics, which are created dynamically and distinguished by unique names. Each topic can have multiple publishers and subscribers.

A topic is essentially equivalent to an application-defined Slice interface: the operations of the interface define the types of messages supported by the topic. A publisher uses a proxy for the topic interface to send its messages, and a subscriber implements the topic interface (or an interface derived from the topic interface) in order to receive the messages. This is no different than if the publisher and subscriber were communicating directly in the traditional client-server style; the interface represents the contract between the client (the publisher) and the server (the subscriber), except IceStorm transparently forwards each message to multiple recipients.

IceStorm does not verify that publishers and subscribers are using compatible interfaces, therefore applications must ensure that topics are used correctly.

- **Unidirectional Messages**

IceStorm messages are *unidirectional*, that is, they must have `void` return type, cannot have out-parameters, and cannot raise user exceptions. It follows that a publisher cannot receive replies from its subscribers. Any of the Ice transports (TCP, SSL, and UDP) can be used to publish and receive messages.

- **Federation**

IceStorm supports the formation of topic graphs, also known as *federation*. A topic graph is formed by creating links between topics, where a *link* is a unidirectional association from one topic to another. Each link has a *cost* that may restrict message delivery on that link. A message published on a topic is also published on all of the topic's links for which the message cost does not exceed the link cost.

Once a message has been published on a link, the receiving topic publishes the message to its subscribers, but does not publish it on any of its links. In other words, IceStorm messages propagate at most one hop from the originating topic in a federation.

The following figure presents an example of topic federation. Topic  $T_1$  has links to  $T_2$  and  $T_3$ , as indicated by the arrows. The subscribers  $S_1$  and  $S_2$  receive all messages published on  $T_2$ , as well as those published on  $T_1$ . Subscriber  $S_3$  receives messages only from  $T_1$ , and  $S_4$  receives messages from both  $T_3$  and  $T_1$ .

*Topic federation.*

IceStorm makes no attempt to prevent a subscriber from receiving duplicate messages. For example, if a subscriber is subscribed to both  $T_2$  and  $T_3$ , then it would receive two requests for each message published on  $T_1$ .

- **Quality of Service**

IceStorm allows each subscriber to specify its own *quality of service* (QoS) parameters that affect the delivery of its messages. Quality of service parameters are represented as a dictionary of name-value pairs.

- **Replication**

IceStorm supports *replication* to provide higher availability for publishers and subscribers.

- **Persistent Mode**

IceStorm's default behavior maintains information about topics, links, and subscribers in a database. However, a message sent via IceStorm is not stored persistently, but rather is discarded as soon as it is delivered to the topic's current set of subscribers. If an error occurs during delivery to a subscriber, IceStorm does not queue messages for that subscriber.

- **Transient Mode**

IceStorm can optionally run in a fully transient mode in which no database is required. Replication is not supported in this mode.

- **Subscriber Errors**

IceStorm automatically removes a subscription from a topic if a subscriber failure occurs while attempting to deliver a message. For example, IceStorm may be unable to establish a connection to the subscriber using the proxy that the subscriber provided, meaning the subscriber is not currently active at the proxy's endpoints, or those endpoints are inaccessible to IceStorm. Another common failure scenario is a subscriber that allows an exception to propagate back to IceStorm. This is important if you make changes to a Slice data type or operation signature: if you do, you must ensure that both publishers and subscribers use the same Slice definitions; if you do not, the subscriber is likely to encounter marshaling errors when receiving an event from IceStorm with a mismatched Slice definition. If the subscriber allows this error to propagate back to IceStorm, its subscription will be canceled.

Use the `retryCount` *quality of service* parameter to configure IceStorm's behavior in error situations.

## IceStorm Interfaces

This page provides a brief introduction to the Slice interfaces comprising the IceStorm service. See the online [Slice API Reference XREF](#) for the Slice documentation.

On this page:

- [The TopicManager Interface](#)
- [The Topic Interface](#)

### The TopicManager Interface

The `TopicManager` is a singleton object that acts as a factory and repository of `Topic` objects. Its interface and related types are shown below:

Slice
<pre> module IceStorm {     dictionary&lt;string, Topic*&gt; TopicDict;      exception TopicExists {         string name;     };      exception NoSuchTopic {         string name;     };      interface TopicManager {         Topic* create(string name) throws TopicExists;         idempotent Topic* retrieve(string name) throws NoSuchTopic;         idempotent TopicDict retrieveAll();         idempotent Ice::SliceChecksumDict getSliceChecksums();     }; }; </pre>

The `create` operation is used to create a new topic, which must have a unique name. The `retrieve` operation allows a client to obtain a proxy for an existing topic, and `retrieveAll` supplies a dictionary of all existing topics. The `getSliceChecksums` operation returns [Slice checksums](#) for the IceStorm definitions.

### The Topic Interface

The `Topic` interface represents a topic and provides several administrative operations for configuring links and managing subscribers.

### Slice

```

module IceStorm {
struct LinkInfo {
 Topic* theTopic;
 string name;
 int cost;
};
sequence<LinkInfo> LinkInfoSeq;

dictionary<string, string> QoS;

exception LinkExists {
 string name;
};

exception NoSuchLink {
 string name;
};

exception AlreadySubscribed {};

exception BadQoS {
 string reason;
};

interface Topic {
 idempotent string getName();
 idempotent Object* getPublisher();
 idempotent Object* getNonReplicatedPublisher();
 Object* subscribeAndGetPublisher(QoS theQoS, Object* subscriber)
 throws AlreadySubscribed, BadQoS;
 idempotent void unsubscribe(Object* subscriber);
 idempotent void link(Topic* linkTo, int cost)
 throws LinkExists;
 idempotent void unlink(Topic* linkTo) throws NoSuchLink;
 idempotent LinkInfoSeq getLinkInfoSeq();
 void destroy();
};
};

```

The `getName` operation returns the name assigned to the topic, while the `getPublisher` and `getNonReplicatedPublisher` operations return proxies for the topic's **publisher object**.

The `subscribeAndGetPublisher` operation adds a subscriber's proxy to the topic; if another subscriber proxy already exists with the same object identity, the operation throws `AlreadySubscribed`. The operation returns a proxy for a **subscriber-specific publisher object**.

The `unsubscribe` operation removes the subscriber from the topic.

A **link** to another topic is created using the `link` operation; if a link already exists to the given topic, the `LinkExists` exception is raised.

Links are destroyed using the `unlink` operation.

Finally, the `destroy` operation permanently destroys the topic.

## Using IceStorm

Now we'll expand on the earlier [weather monitoring example](#), demonstrating how to create, subscribe to and publish messages on a topic. We use the following Slice definitions in our example:

```

Slice

```
struct Measurement {
    string tower; // tower id
    float windSpeed; // knots
    short windDirection; // degrees
    float temperature; // degrees Celsius
};

interface Monitor {
    void report(Measurement m);
};
```

```

Monitor is our topic interface. For the sake of simplicity, it defines just one operation, `report`, taking a `Measurement` struct as its only parameter.

## Implementing an IceStorm Publisher

The implementation of our weather measurement collector application can be summarized easily:

1. Obtain a proxy for the `TopicManager`. This is the primary IceStorm object, used by both publishers and subscribers.
2. Obtain a proxy for the `Weather` topic, either by creating the topic if it does not exist, or retrieving the proxy for the existing topic.
3. Obtain a proxy for the `Weather` topic's "publisher object." This proxy is provided for the purpose of publishing messages, and therefore is narrowed to the topic interface (`Monitor`).
4. Collect and report measurements.

We present collector implementations in C++ and Java below.

On this page:

- [Publisher Example in C++](#)
- [Publisher Example in Java](#)

### Publisher Example in C++

As usual, our C++ example begins by including the necessary header files. The interesting ones are `IceStorm/IceStorm.h`, which is generated from the IceStorm Slice definitions, and `Monitor.h`, containing the generated code for our monitor definitions shown above.

## C++

```

#include <Ice/Ice.h>
#include <IceStorm/IceStorm.h>
#include <Monitor.h>

int main(int argc, char* argv[])
{
 ...
 Ice::ObjectPrx obj = communicator->stringToProxy("IceStorm/TopicManager:tcp -p 9999");
 IceStorm::TopicManagerPrx topicManager =
IceStorm::TopicManagerPrx::checkedCast(obj);
 IceStorm::TopicPrx topic;
 while (!topic) {
 try {
 topic = topicManager->retrieve("Weather");
 } catch (const IceStorm::NoSuchTopic&) {
 try {
 topic = topicManager->create("Weather");
 } catch (const IceStorm::TopicExists&) {
 // Another client created the topic.
 }
 }
 }

 Ice::ObjectPrx pub = topic->getPublisher()->ice_oneway();
 MonitorPrx monitor = MonitorPrx::uncheckedCast(pub);
 while (true) {
 Measurement m = getMeasurement();
 monitor->report(m);
 }
 ...
}

```

Note that this example assumes that IceStorm uses the [instance name](#) IceStorm. The actual instance name may differ, and you need to use it as the category when calling `stringToProxy`.

After obtaining a proxy for the topic manager, the collector attempts to retrieve the topic. If the topic does not exist yet, the collector receives a `NoSuchTopic` exception and then creates the topic:

**C++**

```

IceStorm::TopicPrx topic;
while(!topic) {
 try {
 topic = topicManager->retrieve("Weather");
 } catch (const IceStorm::NoSuchTopic&) {
 try {
 topic = topicManager->create("Weather");
 } catch (const IceStorm::TopicExists&) {
 // Another client created the topic.
 }
 }
}

```

The next step is obtaining a proxy for the publisher object, which the collector narrows to the `Monitor` interface. (We create a oneway proxy for the publisher purely for efficiency reasons.)

**C++**

```

Ice::ObjectPrx pub = topic->getPublisher()->ice_oneway();
MonitorPrx monitor = MonitorPrx::uncheckedCast(pub);

```

Finally, the collector enters its main loop, collecting measurements and publishing them via the `IceStorm` publisher object:

**C++**

```

while (true) {
 Measurement m = getMeasurement();
 monitor->report(m);
}

```

**Publisher Example in Java**

The equivalent Java version is shown below:

## Java

```

public static void main(String[] args)
{
 ...
 Ice.ObjectPrx obj = communicator.stringToProxy("IceStorm/TopicManager:tcp -p 9999");
 IceStorm.TopicManagerPrx topicManager =
IceStorm.TopicManagerPrxHelper.checkedCast(obj);
 IceStorm.TopicPrx topic = null;
 while (topic == null) {
 try {
 topic = topicManager.retrieve("Weather");
 } catch (IceStorm.NoSuchTopic ex) {
 try {
 topic = topicManager.create("Weather");
 } catch (IceStorm.TopicExists ex) {
 // Another client created the topic.
 }
 }
 }

 Ice.ObjectPrx pub = topic.getPublisher().ice_oneway();
 MonitorPrx monitor = MonitorPrxHelper.uncheckedCast(pub);
 while (true) {
 Measurement m = getMeasurement();
 monitor.report(m);
 }
 ...
}

```

Note that this example assumes that IceStorm uses the [instance name](#) IceStorm. The actual instance name may differ, and you need to use it as the category when calling `stringToProxy`.

After obtaining a proxy for the topic manager, the collector attempts to retrieve the topic. If the topic does not exist yet, the collector receives a `NoSuchTopic` exception and then creates the topic:

**Java**

```

IceStorm.TopicPrx topic = null;
while (topic == null) {
 try {
 topic = topicManager.retrieve("Weather");
 } catch (IceStorm.NoSuchTopic ex) {
 try {
 topic = topicManager.create("Weather");
 } catch (IceStorm.TopicExists ex) {
 // Another client created the topic.
 }
 }
}

```

The next step is obtaining a proxy for the publisher object, which the collector narrows to the `Monitor` interface:

**Java**

```

Ice.ObjectPrx pub = topic.getPublisher().ice_oneway();
MonitorPrx monitor = MonitorPrxHelper.uncheckedCast(pub);

```

Finally, the collector enters its main loop, collecting measurements and publishing them via the `IceStorm` publisher object:

**Java**

```

while (true) {
 Measurement m = getMeasurement();
 monitor.report(m);
}

```

## Using an IceStorm Publisher Object

Each topic creates a publisher object for the express purpose of publishing messages. It is a special object in that it implements an Ice interface that allows the object to receive and forward requests (i.e., IceStorm messages) without requiring knowledge of the operation types.

On this page:

- [Type Safety Considerations for the Publisher Object](#)
- [Publish using Oneway or Twoway Invocations?](#)
- [Selecting a Transport for the Publisher Object](#)
- [Using Request Contexts with the Publisher Object](#)

### Type Safety Considerations for the Publisher Object

From the publisher's perspective, the publisher object appears to be an application-specific type. In reality, the publisher object can forward requests for any type, and that introduces a degree of risk: a misbehaving publisher can use `uncheckedCast` to narrow the publisher object to any type and invoke any operation; the publisher object unknowingly forwards those requests to the subscribers.

If a publisher sends a request using an incorrect type, the Ice run time in a subscriber typically responds by raising `OperationNotExistException`. However, since the subscriber receives its messages as oneway invocations, no response can be sent to the publisher object to indicate this failure, and therefore neither the publisher nor the subscriber is aware of the type-mismatch problem. In short, IceStorm places the burden on the developer to ensure that publishers and subscribers are using it correctly.

### Publish using Oneway or Twoway Invocations?

IceStorm messages are unidirectional, but publishers may use either oneway or twoway invocations when sending messages to the publisher object. Each invocation style has advantages and disadvantages that you should consider when deciding which one to use. The differences between the invocation styles affect a publisher in four ways:

- **Efficiency**  
Oneway invocations have the advantage in efficiency because the Ice run time in the publisher does not await a reply to each message (and, of course, no reply is sent by IceStorm on the wire).
- **Ordering**  
The use of oneway invocations by a publisher may affect the order in which subscribers receive messages. If ordering is important, use twoway invocations with a [reliability QoS](#) of `ordered`, or use a single thread in the subscriber.
- **Reliability**  
[Oneway invocations can be lost](#) under certain circumstances, even when they are sent over a reliable transport such as TCP. If the loss of messages is unacceptable, or you are unable to address the potential causes of lost oneway messages, then twoway invocations are recommended.
- **Delays**  
A publisher may experience network-related delays when sending messages to IceStorm if subscribers are slow in processing messages. Twoway invocations are more susceptible to these delays than oneway invocations.

### Selecting a Transport for the Publisher Object

Each publisher can select its own transport for message delivery, therefore the transport used by a publisher to communicate with IceStorm has no effect on how IceStorm delivers messages to its subscribers.

For example, a publisher can use a UDP transport if the possibility of lost messages is acceptable (and if IceStorm provides a UDP endpoint to publishers). However, the TCP or SSL transports are generally recommended for IceStorm's publisher endpoint in order to ensure that published messages are delivered reliably to IceStorm, even if they may not be delivered reliably to some subscribers.

### Using Request Contexts with the Publisher Object

A [request context](#) is an optional argument of all remote invocations. If a publisher supplies a request context when publishing a message, IceStorm will forward it intact to subscribers.

Services such as [Glacier2](#) employ request contexts to provide applications with more control over the service's behavior. For example, if a publisher knows that IceStorm is delivering messages to subscribers via a Glacier2 router, the publisher can influence Glacier2's behavior by including a request context, as shown in the following C++ example:

**C++**

```
Ice::ObjectPrx pub = topic->getPublisher();
Ice::Context ctx;
ctx["_fwd"] = "Oz";
MonitorPrx monitor = MonitorPrx::uncheckedCast(pub->ice_context(ctx
));
```

The `_fwd` context key, when encountered by Glacier2, causes the router to forward the request using compressed [batch oneway](#) messages. The `ice_context` [proxy method](#) is used to obtain a proxy that includes the Glacier2 request context in every invocation, eliminating the need for the publisher to specify it explicitly.

## Implementing an IceStorm Subscriber

Our weather measurement subscriber implementation takes the following steps:

1. Obtain a proxy for the `TopicManager`. This is the primary IceStorm object, used by both publishers and subscribers.
2. Create an object adapter to host our `Monitor` servant.
3. Instantiate the `Monitor` servant and activate it with the object adapter.
4. Subscribe to the `Weather` topic.
5. Process `report` messages until shutdown.
6. Unsubscribe from the `Weather` topic.

We present monitor implementations in C++ and Java below.

On this page:

- [Subscriber Example in C++](#)
- [Subscriber Example in Java](#)

### Subscriber Example in C++

Our C++ monitor implementation begins by including the necessary header files. The interesting ones are `IceStorm/IceStorm.h`, which is generated from the IceStorm Slice definitions, and `Monitor.h`, containing the generated code for our [monitor definitions](#):

**C++**

```

#include <Ice/Ice.h>
#include <IceStorm/IceStorm.h>
#include <Monitor.h>

using namespace std;

class MonitorI : virtual public Monitor {
public:
 virtual void report(const Measurement& m, const Ice::Current&) {
 cout << "Measurement report:" << endl
 << " Tower: " << m.tower << endl
 << " W Spd: " << m.windSpeed << endl
 << " W Dir: " << m.windDirection << endl
 << " Temp: " << m.temperature << endl
 << endl;
 }
};

int main(int argc, char* argv[])
{
 ...
 Ice::ObjectPrx obj = communicator->stringToProxy("IceStorm/TopicManager:tcp -p 9999");
 IceStorm::TopicManagerPrx topicManager =
 IceStorm::TopicManagerPrx::checkedCast(obj);

 Ice::ObjectAdapterPtr adapter = communicator->createObjectAdapter("MonitorAdapter");

 MonitorPtr monitor = new MonitorI;
 Ice::ObjectPrx proxy = adapter->addWithUUID(monitor)->ice_oneway();
 adapter->activate();

 IceStorm::TopicPrx topic;
 try {
 topic = topicManager->retrieve("Weather");
 IceStorm::QoS qos;
 topic->subscribeAndGetPublisher(qos, proxy);
 }
 catch (const IceStorm::NoSuchTopic&) {
 // Error! No topic found!
 ...
 }

 communicator->waitForShutdown();

 topic->unsubscribe(proxy);
 ...
}

```

Our implementation of the `Monitor` servant is currently quite simple. A real implementation might update a graphical display, or incorporate the measurements into an ongoing calculation.

### C++

```
class MonitorI : virtual public Monitor {
public:
 virtual void report(const Measurement& m, const Ice::Current&) {
 cout << "Measurement report:" << endl
 << " Tower: " << m.tower << endl
 << " W Spd: " << m.windSpeed << endl
 << " W Dir: " << m.windDirection << endl
 << " Temp: " << m.temperature << endl
 << endl;
 }
};
```

After obtaining a proxy for the topic manager, the program creates an object adapter, instantiates the `Monitor` servant and activates it:

### C++

```
Ice::ObjectAdapterPtr adapter =
communicator->createObjectAdapter("MonitorAdapter");

MonitorPtr monitor = new MonitorI;
Ice::ObjectPrx proxy = adapter->addWithUUID(monitor)->ice_oneway();
adapter->activate();
```

Note that the code creates a oneway proxy for the `Monitor` servant. This is for efficiency reasons: by subscribing with a oneway proxy, IceStorm will deliver events to the subscriber via [oneway messages](#), instead of via twoway messages. We also activate the object adapter at this time, which means the servant can now begin receiving invocations.

Next, the monitor subscribes to the topic:

**C++**

```

IceStorm::TopicPrx topic;
try {
 topic = topicManager->retrieve("Weather");
 IceStorm::QoS qos;
 topic->subscribeAndGetPublisher(qos, proxy);
}
catch (const IceStorm::NoSuchTopic&) {
 // Error! No topic found!
 ...
}

```

Finally, the monitor blocks until the communicator is shutdown. After `waitForShutdown` returns, the monitor cleans up by unsubscribing from the topic:

**C++**

```

adapter->activate();
communicator->waitForShutdown();

topic->unsubscribe(proxy);

```

**Subscriber Example in Java**

The Java implementation of the monitor is shown below:

## Java

```

class MonitorI extends _MonitorDisp {
 public void report(Measurement m, Ice.Current curr) {
 System.out.println(
 "Measurement report:\n" +
 " Tower: " + m.tower + "\n" +
 " W Spd: " + m.windSpeed + "\n" +
 " W Dir: " + m.windDirection + "\n" +
 " Temp: " + m.temperature + "\n");
 }
}

public static void main(String[] args)
{
 ...
 Ice.ObjectPrx obj = communicator.stringToProxy("IceStorm/TopicManager:tcp -p 9999");
 IceStorm.TopicManagerPrx topicManager =
 IceStorm.TopicManagerPrxHelper.checkedCast(obj);

 Ice.ObjectAdapterPtr adapter =
 communicator.createObjectAdapter("MonitorAdapter");

 Monitor monitor = new MonitorI();
 Ice.ObjectPrx proxy = adapter.addWithUUID(monitor).ice_oneway();
 adapter.activate();

 IceStorm.TopicPrx topic = null;
 try {
 topic = topicManager.retrieve("Weather");
 java.util.Map qos = null;
 topic.subscribeAndGetPublisher(qos, proxy);
 }
 catch (IceStorm.NoSuchTopic ex) {
 // Error! No topic found!
 ...
 }

 communicator.waitForShutdown();

 topic.unsubscribe(proxy);
 ...
}

```

Our implementation of the `Monitor` servant is currently quite simple. A real implementation might update a graphical display, or incorporate the measurements into an ongoing calculation.

### Java

```
class MonitorI extends _MonitorDisp {
 public void report(Measurement m, Ice.Current curr) {
 System.out.println(
 "Measurement report:\n" +
 " Tower: " + m.tower + "\n" +
 " W Spd: " + m.windSpeed + "\n" +
 " W Dir: " + m.windDirection + "\n" +
 " Temp: " + m.temperature + "\n");
 }
}
```

After obtaining a proxy for the topic manager, the program creates an object adapter, instantiates the `Monitor` servant and activates it:

### Java

```
Monitor monitor = new MonitorI();
Ice.ObjectPrx proxy = adapter.addWithUUID(monitor).ice_oneway();
adapter.activate();
```

Note that the code creates a oneway proxy for the `Monitor` servant. This is for efficiency reasons: by subscribing with a oneway proxy, `IceStorm` will deliver events to the subscriber via [oneway messages](#), instead of via twoway messages. We also activate the object adapter at this time, which means the servant can now begin receiving invocations.

Next, the monitor subscribes to the topic:

### Java

```
IceStorm.TopicPrx topic = null;
try {
 topic = topicManager.retrieve("Weather");
 java.util.Map qos = null;
 topic.subscribeAndGetPublisher(qos, proxy);
}
catch (IceStorm.NoSuchTopic ex) {
 // Error! No topic found!
 ...
}
```

Finally, the monitor blocks until the communicator is shutdown. After `waitForShutdown` returns, the monitor cleans up by unsubscribing from the topic:

## Java

```
communicator.waitForShutdown();
```

```
topic.unsubscribe(proxy);
```

### See Also

- [Using IceStorm](#)
- [Oneway Invocations](#)

## Publishing to a Specific Subscriber

If you send events to the publisher object you obtain by calling `Topic::getPublisher`, the event is forwarded to all subscribers for that topic:

### C++

```
IceStorm::TopicPrx topic = ...;
Ice::ObjectPrx pub = topic->getPublisher()->ice_oneway();

MonitorPrx monitor = MonitorPrx::uncheckedCast(pub);
Measurement m = ...;

monitor->report(m); // Sent to all subscribers
```

You can also publish an event to a single specific subscriber, by using the return value of `subscribeAndGetPublisher`. For example:

### C++

```
MonitorPtr monitor = new MonitorI;
Ice::ObjectPrx proxy = adapter->addWithUUID(monitor)->ice_oneway();

IceStorm::topicPrx topic = ...;

Icestorm::QoS qos;
Ice::ObjectPrx pub = topic->subscribeAndGetPublisher(qos, proxy);
MonitorPrx monitor = MonitorPrx::uncheckedCast(pub);

Measurement m = ...;
monitor->report(m); // Sent only to this subscriber
```

Note that, here, we save the return value of `subscribeAndGetPublisher`. The return value is a proxy that connects specifically to the `MonitorI` instance denoted by `proxy`. However, when the code calls `report` on that proxy, instead of directly invoking on the `MonitorI` instance, the request is forwarded via `IceStorm`.

As it stands, this code is not very interesting. After all, the call to `monitor->report` is just a round-about way for the subscriber to publish a message to itself. However, the subscriber can pass this subscriber-specific publisher proxy to another process. When that process publishes an event via the proxy, the event is sent only to the specific subscriber, instead of to all subscribers for the topic. In turn, this is useful if you are using the observer pattern, with all observers attached to an `IceStorm` topic.

As an example, we might have a list whose state is to be monitored by a number of observers. Updates to the list are published to an `IceStorm` topic, say, `ListUpdates`. The observers of the list subscribe with an interface such as:

### Slice

```
interface ListObserver {
 void init(/* The entire state of the list */);
 void itemChange(/* The added or deleted item */);
};
```

The idea is that, when an observer first starts observing the list, the `init` operation is called on the observer and passed the entire list. This initializes the observer with the current state of the list. Thereafter, whenever the list changes, it calls `itemChange` on the observer to inform it of the addition or deletion of an item. (The details of how this happens are secondary; the important point is that the observer is informed of the current state of the list initially and, thereafter, receives incremental updates about modifications to the list, rather than the entire list whenever it changes.)

The list itself might look something like this:

### Slice

```
interface List {
 void add(Item i);
 void remove(Item i);

 void addObserver(ListObserver* lo);
 void removeObserver(ListObserver* lo);
};
```

The list provides operations to add and remove an item, as well as operations to add and remove an observer. Every time `add` or `remove` are called on the list, the list publishes an `itemChange` event to the `ListUpdates` topic; this informs all the subscribed observers of the change to the list. However, when an observer is first added, the observer's `init` operation must be called. Moreover, we want to call that method only once for each observer, so we cannot just publish the initial state of the list on a topic that all observers subscribe to.

The subscriber-specific proxy that is returned by `subscribeAndGetPublisher` solves this nicely: the implementation of `addObserver` calls `subscribeAndGetPublisher`, and then invokes `init` on the observer. This both subscribes the observer to the topic, and `IceStorm` forwards the call to `init` to the observer. This is preferable to the list invoking `init` on the observer directly: if the observer is misbehaved (for example, if its `init` implementation blocks for some time), the list is unaffected because `IceStorm` shields the list from such behavior. ## Highly Available IceStorm

IceStorm offers a highly available (HA) mode that employs master-slave replication with automatic failover in case the master fails.

On this page:

- [IceStorm Replication Algorithm](#)
- [IceStorm Replica States](#)
- [Client Considerations for IceStorm Replication](#)
- [Subscriber Considerations for IceStorm Replication](#)
- [Publisher Considerations for IceStorm Replication](#)

## IceStorm Replication Algorithm

HA IceStorm uses the Garcia-Molina "Invitation Election Algorithm" [1] in which each replica has a priority and belongs to a replica group. The replica with the highest priority in the group becomes the coordinator, and the remaining replicas are slaves of the coordinator.

All replicas are statically configured with information about all other replicas, including their priority. The group combining works as follows:

- When recovering from an error, or during startup, replicas form a single self-coordinated group.
- Coordinators periodically attempt to combine their groups with other groups in order to form larger groups.

At regular intervals, slave replicas contact their coordinator to ensure that the coordinator is still the master of the slave's group. If a failure occurs, the replica considers itself in error and performs error recovery as described above.

Replication commences once a group contains a majority of replicas. A majority is necessary to avoid the possibility of network partitioning, in which two groups of replicas form that cannot communicate and whose database contents diverge. With respect to IceStorm, a consequence of requiring a majority is that a minimum of three replicas are necessary.

An exception to the majority rule is made during full system startup (i.e., when no replica is currently running). In this situation, replication can only commence with the participation of every replica in the group. This requirement guarantees that the databases of all replicas are synchronized, and avoids the risk that the database of an offline replica might contain more recent information.

Once a majority group has been formed, all database states are compared. The most recent database state (as determined by comparing a time stamp recorded upon each database change) is transferred to all replicas and replication commences. IceStorm is now available for use.

## IceStorm Replica States

IceStorm replicas can have one of four states:

- Inactive:  
The node is inactive and awaiting an election.
- Election:  
The node is electing a coordinator.
- Reorganization:  
The replica group is reorganizing.
- Normal:  
The replica group is active and replicating.

For debugging purposes, you can obtain the state of the replicas using the `replica` command of the `icestormadmin` utility, as shown below:

```

$ icestormadmin --Ice.Config=config
>>> replica
replica count: 3
1: id: 1
1: coord: 3
1: group name: 3:191131CC-703A-41D6-8B80-D19F0D5F0410
1: state: normal
1: group:
1: max: 3
2: id: 2
2: coord: 3
2: group name: 3:191131CC-703A-41D6-8B80-D19F0D5F0410
2: state: normal
2: group:
2: max: 3
3: id: 3
3: coord: 3
3: group name: 3:191131CC-703A-41D6-8B80-D19F0D5F0410
3: state: normal
3: group: 1,2
3: max: 3

```

Each line begins with the identifier of the replica. The command displays the following information:

- `id`  
The identifier of the replica.
- `coord`  
The identifier of the group's coordinator.
- `group name`  
The name of the group to which this replica belongs.
- `state`  
The replica's current state.
- `group`  
The identifiers of the other replicas in the group. Note that only the coordinator knows, or cares about, this information.
- `max`  
The maximum number of replicas seen by this replica. This value is used during startup to determine whether full participation is necessary. If the value is less than the total number of replicas, full participation is required.

## Client Considerations for IceStorm Replication

As previously noted, an individual IceStorm replica can be in one of several states. However, IceStorm clients have a different perspective in which the replication group as a whole is in one of the states shown below:

- `Down`  
All requests to IceStorm fail.
- `Inactive`  
All requests to IceStorm block until the replica is either down (in which case the request fails), or becomes Active.
- `Active`  
Requests are processed.

It is also possible, but highly unlikely, for a request to result in an `Ice::UnknownException`. This can happen, for example, if a replica loses the majority and thus progresses to the inactive state during request processing. In this case, the result of the request is indeterminate (the request may or may not have succeeded) and therefore the IceStorm client can draw no conclusion. The client should retry the request and be prepared for the request to fail. Consider this example:

### C++

```
TopicPrx topic = ...;
Ice::ObjectPrx sub = ...;
IceStorm::QoS qos;
topic->subscribeAndGetPublisher(qos, sub);
```

The call to `subscribeAndGetPublisher` may fail in very rare cases with an `UnknownException`, indicating that the subscription may or may not have succeeded. Here is the proper way to deal with the possibility of an `UnknownException`:

### C++

```
TopicPrx topic = ...;
Ice::ObjectPrx sub = ...;
IceStorm::QoS qos;
while(true) {
 try {
 topic->subscriberAndGetPublisher(qos, sub);
 } catch(const Ice::UnknownException&) {
 continue;
 } catch(const IceStorm::AlreadySubscribed&) {
 // Expected.
 }
 break;
}
```

## Subscriber Considerations for IceStorm Replication

Subscribers can receive events from any replica. The subscriber will stop receiving events under two circumstances:

- The subscriber is unsubscribed by calling `Topic::unsubscribe`.
- The subscriber is removed as a result of a failure to deliver events. Subscribers can optionally configure a [quality of service](#) parameter that causes IceStorm to make additional delivery attempts.

## Publisher Considerations for IceStorm Replication

A publisher for HA IceStorm typically receives a proxy containing multiple endpoints. With this proxy, the publisher normally binds to a single replica and continues using that replica unless there is a failure, or until [active connection management](#) (ACM) closes the connection.

As with non-HA IceStorm, [event delivery ordering](#) can be guaranteed if the subscriber and publisher are suitably configured and the publisher continues to use the same replica when publishing events.

Ordering guarantees are lost as soon as a publisher changes to a different replica. Furthermore, a publisher may receive no notification that a change has occurred, which is possible under two circumstances:

- ACM has closed the connection.
- Publishing to a replica fails and the Ice invocation can be [retried](#), in which case the Ice run time in the publisher automatically and

transparently attempts to send the request to another replica. The publisher receives an exception if the invocation cannot be retried.

A publisher has two ways of ensuring that it is notified about a change in replicas:

- The simplest method is to use the `Topic::getNonReplicatedPublisher` operation. The proxy returned by this operation points directly at the current replica and no transparent failover to a different can occur.
- If you never want transparent failover to occur during publishing, you can [configure your publisher proxy](#) so that it contains only one endpoint. In this configuration, the `Topic::getPublisher` operation behaves exactly like `getNonReplicatedPublisher`.

Of the two strategies, using `getNonReplicatedPublisher` is preferable for two reasons:

- It does not involve changes to IceStorm's configuration.
- It is still possible to obtain a replicated publisher proxy by calling `getPublisher`, whereas if you had used the second strategy you would have eliminated that possibility.

The second strategy may be necessary in certain circumstances, such as when an existing IceStorm application is deployed and cannot be changed.

Regardless of the strategy you choose, a publisher can recover from the failure of a replica by requesting another proxy from the replicated topic using `getPublisher` or `getNonReplicatedPublisher`.

## IceStorm Administration

The IceStorm administration tool, `icestormadmin`, is a command-line program that provides administrative control of an IceStorm server.

Configuration properties inform `icestormadmin` about the topic manager(s) that you wish to administer. You have several configuration options:

- Define `IceStormAdmin.Host` and `IceStormAdmin.Port` - `icestormadmin` constructs its own proxy for the topic manager at the specified host and port
- Define `IceStormAdmin.TopicManager.Default` - specifies a proxy for the default topic manager on which administrative commands operate
- Define `IceStormAdmin.TopicManager.name` - specifies the proxies for any number of named topic managers

The tool supports the following command-line options:

```
$ icestormadmin -h
Usage: icestormadmin [options]
Options:
-h, --help Show this message.
-v, --version Display the Ice version.
-e COMMANDS Execute COMMANDS.
-d, --debug Print debug messages.
```

If you specify one or more `-e` options, the tool executes the given commands and exits, otherwise the tool enters an interactive session. The `help` command displays the following usage information:

- `help`  
Print this message.
- `exit, quit`  
Exit this program.
- `create TOPICS`  
Add *TOPICS*.
- `destroy TOPICS`  
Remove *TOPICS*.
- `link FROM TO [COST]`  
Link *FROM* to *TO* with the optional *COST*.
- `unlink FROM TO`  
Unlink *TO* from *FROM*.
- `links [INSTANCE-NAME]`  
Without an argument, `links` displays the links of all topics in the current topic manager. You can specify a different topic manager by providing its instance name.
- `topics [INSTANCE-NAME]`  
Without an argument, `topics` displays the names of all topics in the current topic manager. You can specify a different topic manager by providing its instance name.
- `current [INSTANCE-NAME]`  
Set the current topic manager to the topic manager with instance name *INSTANCE-NAME*. The proxy of the corresponding topic manager must be specified by setting an `IceStormAdmin.TopicManager.name` property. Without an argument, the command shows the current topic manager.
- `replica [INSTANCE-NAME]`  
Display [replication information](#) for the given *INSTANCE-NAME*.
- `subscribers TOPICS`  
Displays the identities of the subscribers for each of the *TOPICS*.

Some of the commands accept one or more topic names (*TOPICS*) as arguments. Topic names containing white space or matching a command keyword must be enclosed in single or double quotes.

By default, `icestormadmin` uses the topic manager specified by your setting for `IceStormAdmin.TopicManager.Default`. For example, without additional arguments, the `create` command operates on that topic manager.

If you are using multiple topic managers, you can specify their proxies by setting `IceStormAdmin.TopicManager.name` for each topic manager. For example:

```
IceStormAdmin.TopicManager.A=A/TopicManager:tcp -h x -p 9995
IceStormAdmin.TopicManager.B=Foo/TopicManager:tcp -h x -p 9996
IceStormAdmin.TopicManager.C=Bar/TopicManager:tcp -h z -p 9995
```

This sets the proxies for three topic managers. Note that `name` need not match the instance name of the corresponding topic manager — `name` simply serves as a tag. With these property settings, the `icestormadmin` commands that accept a topic can now specify a topic manager other than the default topic manager that is configured with `IceStormAdmin.TopicManager.Default`. For example:

```
current Foo
create myTopic
create Bar/myOtherTopic
```

This sets the current topic manager to the one with instance name `Foo`; the first `create` command then creates the topic within that topic manager, whereas the second `create` command uses the topic manager with instance name `Bar`.

## Topic Federation

The ability to link topics together into a federation provides IceStorm applications with a lot of flexibility, while the notion of a "cost" associated with links allows applications to restrict the flow of messages in creative ways. IceStorm applications have complete control of topic federation using the `TopicManager` interface described in the online [XREF Slice API Reference](#), allowing links to be created and removed dynamically as necessary. For many applications, however, the topic graph is static and therefore can be configured using the `administrative tool`.

  - [Administration Tool Script](#)
- [Proxy Considerations for IceStorm Federation](#)

## IceStorm Message Propagation

IceStorm messages are never propagated over more than one link. For example, consider the topic graph shown below:

*Message propagation.*

In this case, messages published on `A` are propagated to `B`, but `B` does not propagate `A`'s messages to `C`. Therefore, subscriber `SB` receives messages published on topics `A` and `B`, but subscriber `SC` only receives messages published on topics `B` and `C`. If the application needs messages to propagate from `A` to `C`, then a link must be established directly between `A` and `C`.

## Using Cost to Limit Message Propagation

As described above, IceStorm messages are only propagated on the originating topic's immediate links. In addition, applications can use the notion of cost to further restrict message propagation.

A cost is associated with messages and links. When a message is published on a topic, the topic compares the cost associated with each of its links against the message cost, and only propagates the message on those links whose cost equals or exceeds the message cost. A cost value of zero (0) has the following implications:

- messages with a cost value of zero (0) are published on all of the topic's links regardless of the link cost;
- links with a cost value of zero (0) accept all messages regardless of the message cost.

For example, consider the following topic graph:

#### Cost semantics.

Publisher  $P_1$  publishes a message on topic  $A$  with a cost of 1. This message is propagated on the link to topic  $B$  because the link has a cost of 0 and therefore accepts all messages. The message is also propagated on the link to topic  $C$ , because the message cost does not exceed the link cost (1). On the other hand, the message published by  $P_2$  with a cost of 2 is only propagated on the link to  $B$ .

#### Request Context for Cost

The cost of a message is specified in an Ice [request context](#). Each Ice proxy operation has an implicit argument of type `Ice::Context` representing the request context. This argument is rarely used, but it is the ideal location for specifying the cost of an IceStorm message because an application only needs to supply a request context if it actually uses IceStorm's cost feature. If the request context does not contain a cost value, the message is assigned the default cost value of zero (0).

#### Publishing a Message with a Cost

The code examples below demonstrate how a collector can publish a measurement with a cost value of 5. First, the C++ version:

##### C++

```
Measurement m = getMeasurement();
Ice::Context ctx;
ctx["cost"] = "5";
monitor->report(m, ctx);
```

And here is the equivalent version in Java:

##### Java

```
Measurement m = getMeasurement();
java.util.HashMap ctx = new java.util.HashMap();
ctx.put("cost", "5");
monitor.report(m, ctx);
```

#### Receiving a Message with a Cost

A subscriber can discover the cost of a message by examining the request context supplied in the `Ice::Current` argument. For example,

here is a C++ implementation of `Monitor::report` that displays the cost value if it is present:

```
C++
```

```

virtual void report(const Measurement& m,
const Ice::Current& curr) {
 Ice::Context::const_iterator p = curr.ctx.find("cost");
 cout << "Measurement report:" << endl
 << " Tower: " << m.tower << endl
 << " W Spd: " << m.windSpeed << endl
 << " W Dir: " << m.windDirection << endl
 << " Temp: " << m.temperature << endl
 << " Temp: " << m.temperature << endl;
 if (p != curr.ctx.end())
 cout << " Cost: " << p->second << endl;
 cout << endl;
}

```

And here is the equivalent Java implementation:

```
Java
```

```

public void report(Measurement m, Ice.Current curr) {
 String cost = null;
 if (curr.ctx != null)
 cost = curr.ctx.get("cost");
 System.out.println(
 "Measurement report:\n" +
 " Tower: " + m.tower + "\n" +
 " W Spd: " + m.windSpeed + "\n" +
 " W Dir: " + m.windDirection + "\n" +
 " Temp: " + m.temperature);
 if (cost != null)
 System.out.println(" Cost: " + cost);
 System.out.println();
}

```

For the sake of efficiency, the Ice for Java run time may supply a null value for the request context in `Ice.Current`, therefore an application is required to check for null before using the request context.

## Automating IceStorm Federation

Given the restrictions on message propagation described in the previous sections, creating a complex topic graph can be a tedious endeavor. Of course, creating a topic graph is not typically a common occurrence, since IceStorm keeps a persistent record of the graph. However, there are situations where an automated procedure for creating a topic graph can be valuable, such as during development when the graph might change significantly and often, or when graphs need to be recomputed based on changing costs.

### Administration Tool Script

A simple way to automate the creation of a topic graph is to create a text file containing commands to be executed by the IceStorm administration tool. For example, the commands to create the topic graph shown [earlier](#) are shown below:

```
create A B C
link A B 0
link A C 1
```

If we store these commands in the file `graph.txt`, we can execute them using the following command:

```
$ icestormadmin --Ice.Config=config < graph.txt
```

We assume that the configuration file `config` contains the definition for the property `IceStormAdmin.TopicManager.Default`.

## Proxy Considerations for IceStorm Federation

Note that, if you federate IceStorm servers, you must ensure that the proxies for the linked topics always use the same host and port (or, alternatively, can be indirectly bound via [IceGrid](#)), otherwise the federation cannot be re-established if one of the servers in the federation shuts down and is restarted later.

## IceStorm Quality of Service

An IceStorm subscriber specifies Quality of Service (QoS) parameters at the time of subscription. The supported QoS parameters are described in the sections below

On this page:

- [Reliability QoS for IceStorm](#)
- [Retry Count QoS for IceStorm](#)
- [IceStorm QoS Example](#)

### Reliability QoS for IceStorm

The QoS parameter `reliability` affects message delivery. The only legal values at this point are `ordered` and the empty string. If not specified, the default value is the empty string (meaning not ordered).

The `ordered` reliability QoS requires a twoway subscriber proxy. If you specify this reliability QoS, IceStorm will forward events in the order they are received but doesn't forward them immediately. Instead, IceStorm waits for the reply from the forwarding of an event before forwarding the next event. This guarantees that the subscriber will process the events in the same order as they were received even if its `thead pool` doesn't serialize incoming requests.

### Retry Count QoS for IceStorm

IceStorm automatically removes a subscriber if `ObjectNotExistException` or `NotRegisteredException` is raised while attempting to deliver an event. IceStorm considers these exceptions as indicators of a hard failure, after which it is unnecessary to continue event delivery.

For other kinds of failures, IceStorm uses the QoS parameter `retryCount` to determine when to remove a subscriber. A value of `-1` means IceStorm retries forever and never automatically removes a subscriber unless a hard failure occurs. A value of zero means IceStorm never retries and immediately removes the subscriber. For positive values, IceStorm decrements the subscriber's retry count for each failure and removes the subscriber once it reaches zero. Linked topics always have a configured retry count of `-1`. The default value of the `retryCount` parameter is zero.

A retry count of `-1` adds some resiliency to your IceStorm application by ignoring intermittent network failures such as `ConnectionRefusedException`. However, there is also some risk inherent in using a retry count of `-1` because an improperly configured subscriber may never be removed. For example, consider what happens when a subscriber registers using a transient endpoint: if that subscriber happens to terminate and resubscribe with a different endpoint, IceStorm will continue trying to deliver events to the subscriber at its old endpoint. IceStorm can only remove the subscriber if it receives a hard error, and that is only possible when the subscriber is reachable.

To use a retry count of `-1` successfully, the subscriber should either register with a fixed endpoint, or use `IceGrid` to take advantage of indirect proxies and automatic activation. Furthermore, if the subscriber is expected to function correctly after a restart of its process, the subscriber must use the same `identity`. The application can rely on the `subscribeAndGetPublisher` operation to raise `AlreadySubscribed` when the subscriber is already subscribed.

### IceStorm QoS Example

The Slice type `IceStorm::QoS` is defined as a dictionary whose key and value types are both `string`, therefore the QoS parameter name and value are both represented as strings. The code we presented in our earlier [subscriber example](#) used an empty dictionary for the QoS argument, meaning default values are used. The C++ and Java examples shown below illustrate how to set the `reliability` parameter to `ordered`.

Here is the C++ example:

```

C++

IceStorm::QoS qos;
qos["reliability"] = "ordered";
topic->subscribeAndGetPublisher(qos, proxy->ice_twoway());
```

Here is the Java example:

### Java

```
java.util.Map qos = new java.util.HashMap();
qos.put("reliability", "ordered");
topic.subscribeAndGetPublisher(qos, proxy.ice_twoway());
```

## IceStorm Delivery Modes

The delivery mode for events sent to subscribers is controlled by the proxy that the subscriber passes to IceStorm. For example, if the subscriber subscribes with a oneway proxy, events will be forwarded by IceStorm as oneway messages.

On this page:

- [Subscribing with a Tway Proxy](#)
- [Subscribing with a Oneway Proxy](#)
- [Subscribing with a Batch Oneway Proxy](#)
- [Subscribing with a Datagram Proxy](#)
- [Subscribing with a Batch Datagram Proxy](#)

### Subscribing with a Tway Proxy

In this mode each event is sent to the subscriber as a separate twoway message. This allows the subscriber to enable server-side [active connection management](#) (ACM) without risking lost messages, because IceStorm will re-send an event if the subscriber happens to close its connection at the wrong moment.

If you combine a twoway proxy with a [reliability QoS](#) of `ordered`, messages will be forwarded to the subscriber in the order in which they are received. This is guaranteed because IceStorm will wait for a reply from the subscriber for each event before sending the next event.

Without ordered delivery, events may be delivered out-of-order to the subscriber because IceStorm will send an event as soon as possible (without waiting for a reply for the preceding event). If the subscriber uses a thread pool with more than one thread, this can result in out-of-order dispatch of messages in the subscriber.

For single-threaded subscribers and subscribers using a [serialized thread pool](#), twoway delivery always produces in-order dispatch of events in the subscriber.

With twoway delivery, IceStorm is informed of any failure to deliver an event by the Ice run time. For example, IceStorm may not be able to establish a connection to a subscriber, or may receive an `ObjectNotExistException` when it forwards an event. Any failure to deliver an event to a subscriber (possibly after a transparent retry by the Ice run time) results in the cancellation of the corresponding subscription.

### Subscribing with a Oneway Proxy

In this mode each event is sent to the subscriber as a [oneway message](#). If more than one event is ready to be delivered, the events are sent in a single batch. This delivery mode is more efficient than using twoway delivery. However, the subscriber cannot use active connection management without the risk of events being lost. In addition, if something goes wrong with the subscriber, such as the subscriber having destroyed its callback object without unsubscribing, or having subscribed an object with the wrong interface, IceStorm does not notice the failure and will continue to send events to the non-existent subscriber object for as long as it can maintain a connection to the subscriber's endpoint.

For multi-threaded subscribers, oneway delivery can result in out-of-order delivery of events. For single-threaded subscribers and subscribers using a serialized thread pool, events are delivered in order.

### Subscribing with a Batch Oneway Proxy

With this delivery mode, IceStorm buffers events from publishers and sends them in [batches](#) to the subscriber. This reduces network overhead and is more efficient than oneway delivery. However, as for oneway delivery, the subscriber cannot use active connection management without the risk of losing events. In addition, events can be delivered out of order if the subscriber is multi-threaded. Batch oneway delivery, while providing better throughput, increases latency because events arrive in "bursts". You can control the interval at which batched events are flushed by setting the `IceStorm.Flush.Timeout` property.

### Subscribing with a Datagram Proxy

With this delivery mode, events are forwarded as UDP messages, optionally with multicast semantics. This means that events can be delivered out of order, can be lost, and can even be duplicated. In addition, IceStorm cannot detect anything about the delivery status of events. This means that if a subscriber disappears without unsubscribing, IceStorm will attempt to forward events to the subscriber

indefinitely. If you use datagram delivery, you need to be careful that subscribers unsubscribe before they disappear; otherwise, stale subscriptions can accumulate in IceStorm over time, bogging down the service as it delivers more and more events to subscribers that no longer exist.

## Subscribing with a Batch Datagram Proxy

With this delivery mode, events are forwarded as batches within a datagram. The same considerations as for datagram delivery and oneway batched delivery apply here. In addition, keep in mind that, due to the size limit for datagrams, batched datagram delivery makes sense only if events are small. (You should also consider enabling compression with this delivery mode.)

## Configuring IceStorm

IceStorm is a relatively lightweight service in that it requires very little configuration and is implemented as an [IceBox](#) service. The configuration properties supported by IceStorm are described in [IceStorm Properties](#); some of them control diagnostic output and are not discussed here.

On this page:

- [IceStorm Property Prefix](#)
- [IceStorm Server Configuration](#)
- [Deploying IceStorm Replicas](#)
  - [IceGrid Deployment](#)
  - [Manual Deployment](#)
- [IceStorm Client Configuration](#)
- [IceStorm Object Identities](#)
- [Using the IceStorm Finder Interface](#)

### IceStorm Property Prefix

As you will see in [IceStorm Properties](#), IceStorm uses its IceBox service name as the prefix for all of its properties. For example, the property `service.TopicManager.Endpoints` becomes `DemoIceStorm.TopicManager.Endpoints` when IceStorm is configured as the IceBox service `DemoIceStorm`.

### IceStorm Server Configuration

The first step is configuring IceBox to run the IceStorm service:

```
IceBox.Service.DemoIceStorm=IceStormService,34:createIceStorm --Ice.Config=config.service
```

In this example, the IceStorm service itself is configured by the properties in the `config.service` file, which might look as follows for a non-replicated service:

```
Freeze.DbEnv.DemoIceStorm.DbHome=db
DemoIceStorm.TopicManager.Endpoints=tcp -p 9999
DemoIceStorm.Publish.Endpoints=tcp -p 10000
```

IceStorm uses [Freeze](#) to manage the service's persistent state, therefore the first property specifies the path name of the Freeze database environment directory for the service. Here the directory `db` is used, which must already exist in the current working directory. This property can be omitted when the service is running in [transient mode](#).

The final two properties specify the endpoints used by the IceStorm object adapters; notice that their property names begin with `DemoIceStorm`, matching the service name. The `TopicManager` property specifies the endpoints on which the `TopicManager` and `Topic` objects reside; these endpoints must use a connection-oriented protocol such as TCP or SSL. The `Publish` property specifies the endpoints used by topic [publisher objects](#); using datagram endpoints in this property is possible but carries additional risk.

IceStorm's default [thread pool](#) configuration is sufficient when the service is running on a single CPU machine. On a host with multiple CPUs, you may be able to improve IceStorm's performance by increasing the size of its client-side thread pool using the `Ice.ThreadPool.Client.*` properties, but the optimal number of threads can only be determined with careful benchmarking.

### Deploying IceStorm Replicas

There are two ways of deploying IceStorm in its [highly available](#) (replicated) mode. In both cases, adding another replica requires that all active replicas be stopped while their configurations are updated; it is not possible to add a replica while replication is running.

To remove a replica, stop all replicas and alter the configuration as necessary. You must be careful not to remove a replica if it has the latest database state. This situation will never occur during normal operation since the database state of all replicas is identical. However, in the

event of a crash it is possible for a coordinator to have later database state than all replicas. The safest approach is to verify that all replicas are active prior to stopping them. You can do this using the `icestormadmin` utility by checking that all replicas are in the `Normal` state.

## IceGrid Deployment

`IceGrid` is a convenient way of deploying IceStorm replicas. The term *replica* is also used in the context of `IceGrid`, specifically when referring to groups of object adapters that participate in *replication*. It is important to be aware of the distinction between IceStorm replication and object adapter replication; IceStorm replication *uses* object adapter replication when deployed with `IceGrid`, but IceStorm does not *require* object adapter replication as you will see below.

An `IceGrid` deployment typically uses two adapter replica groups: one for the publisher proxies, and another for the topics, as shown below:

```
XML
```

```
<replica-group id="DemoIceStorm-PublishReplicaGroup">
</replica-group>

<replica-group id="DemoIceStorm-TopicManagerReplicaGroup">
 <object identity="DemoIceStorm/TopicManager"
type="::IceStorm::TopicManager"/>
</replica-group>
```

The object adapters are then configured to use these replica groups:

```
XML
```

```
<adapter name="{service}.Publish"
 endpoints="tcp"
 replica-group="{instance-name}-PublishReplicaGroup"/>

<adapter name="{service}.TopicManager"
 endpoints="tcp"
 replica-group="{instance-name}-TopicManagerReplicaGroup"/>
```

An application may not want *publisher proxies* to contain multiple endpoints. In this case you should remove `PublishReplicaGroup` from the above deployment.

The next step is defining the endpoints for the adapter `Node`, which is used internally for communication with other IceStorm replicas and is not part of an adapter replica group:

```
XML
```

```
<adapter name="{service}.Node" endpoints="tcp"/>
```

Finally, you must define the node ID for each IceStorm replica using the `NodeId` property. The node ID must be a non-negative integer:

```
XML
```

```
<property name="{service}.NodeId" value="{index}"/>
```

**Example**

You can find a complete C++ example of an IceGrid deployment in the directory `demo/IceStorm/replicated`.

**Manual Deployment**

You can also deploy IceStorm replicas without IceGrid, although it requires more manual configuration; an IceGrid deployment is simpler to maintain.

The first step is defining the set of node proxies using properties of the form `Nodes.id`. These proxies allow replicas to contact each other; their object identities are composed using `instance-name/nodeid`.

For example, assuming we are using the IceBox service name `IceStorm` and have three replicas with the identifiers 0, 1, 2 and an instance name of `DemoIceStorm`, we can configure the proxies as shown below:

```
IceStorm.InstanceName=DemoIceStorm
IceStorm.Nodes.0=DemoIceStorm/node0:tcp -p 13000
IceStorm.Nodes.1=DemoIceStorm/node1:tcp -p 13010
IceStorm.Nodes.2=DemoIceStorm/node2:tcp -p 13020
```

These properties must be defined in each replica. Additionally, each replica must define its node ID, as well as the node's endpoints. For example, we can configure node 0 as follows:

```
IceStorm.NodeId=0
IceStorm.Node.Endpoints=tcp -p 13000
```

The endpoints for each replica and ID must match the proxies configured in the `Nodes.id` properties.

Two additional properties allow you to configure replicated endpoints:

- `service-name.ReplicatedTopicManagerEndpoints`  
Defines the endpoints contained in proxies returned by the topic manager.
- `service-name.ReplicatedPublishEndpoints`  
Defines the endpoints contained in the publisher proxy returned by the topic.

For example, suppose we configure three replicas:

```
IceStorm.NodeId=0
IceStorm.TopicManager.Endpoints=tcp -p 10000
IceStorm.Publish.Endpoints=tcp -p 10001:udp -p 10001

IceStorm.NodeId=1
IceStorm.TopicManager.Endpoints=tcp -p 10010
IceStorm.Publish.Endpoints=tcp -p 10011:udp -p 10011

IceStorm.NodeId=2
IceStorm.TopicManager.Endpoints=tcp -p 10020
IceStorm.Publish.Endpoints=tcp -p 10021:udp -p 10021
```

Each replica should also define these properties:

```
IceStorm.ReplicatedPublishEndpoints=\
tcp -p 10001:tcp -p 10011:tcp -p 10021:udp -p 10001:udp -p 10011:udp -p
10021
IceStorm.ReplicatedTopicManagerEndpoints=tcp -p 10000:tcp -p 10010:tcp
-p 10020
```

An application may not want [publisher proxies](#) to contain multiple endpoints. In this case you should remove the definition of the `ReplicatedPublishEndpoints` property from the above deployment.

#### Example

You can find a complete C++ example of a manual deployment in the directory `demo/IceStorm/replicated2`.

## IceStorm Client Configuration

Clients of the service can define a proxy for the `TopicManager` object as follows:

```
TopicManager.Proxy=IceStorm/TopicManager:tcp -p 9999
```

The name of the property is not relevant, but the endpoint must match that of the `service.TopicManager.Endpoints` property, and the object identity must use the IceStorm [instance name](#) as the category and `TopicManager` as the name.

## IceStorm Object Identities

IceStorm hosts a [well-known object](#) that implements the `IceStorm::TopicManager` interface. The default identity of this object is `IceStorm/TopicManager`, as seen in the stringified proxy example above. If an application requires the use of multiple IceStorm services, it's a good idea to assign unique identities to their well-known objects by configuring the services with different values for the `service.InstanceName` property, as shown in the following example:

```
DemoIceStorm.InstanceName=Measurement
```

This property changes the category of the object's identity, which becomes `Measurement/TopicManager`. The client's configuration must also be changed to reflect the new identity:

```
TopicManager.Proxy=Measurement/TopicManager:tcp -p 9999
```

As of Ice 3.6, IceStorm also hosts an object with the identity `IceStorm/Finder`, as described in the next section. This identity is not affected by the service name or by changes to `service.InstanceName`.

## Using the IceStorm Finder Interface

As of Ice 3.6, IceStorm supports the `IceStorm::Finder` interface:

**Slice**

```

module IceStorm {
interface Finder {
 TopicManager* getTopicManager();
};
};

```

An object supporting this interface is available with the identity `IceStorm/Finder` on the service's topic manager endpoint. By knowing the host and port of this endpoint, a client can discover the topic manager's proxy at run time with a call to `getTopicManager`:

**C++**

```

Ice::ObjectPrx prx = communicator->stringToProxy("IceStorm/Finder:tcp -p
8888 -h icestormhost");
IceStorm::FinderPrx finder = IceStorm::FinderPrx::checkedCast(prx);
IceStorm::TopicManagerPrx topicManager = finder->getTopicManager();

```

## IceStorm Metrics

You can monitor IceStorm using the [Administrative Facility](#) and the [Metrics Facet](#). IceStorm provides two metrics class to monitor topic and subscriber related metrics. These classes are defined in `IceStorm/Metrics.ice` and are shown below.

Slice
<pre> namespace IceMX { class TopicMetrics extends Metrics {     long published = 0;     long forwarded = 0; }; class SubscriberMetrics extends Metrics {     int queued = 0;     int outstanding = 0;     long delivered = 0; }; }; </pre>

IceStorm records metrics in the metrics map described below.

Metrics map name	Slice class	Description	Property prefix
Topic	<code>IceMX::TopicMetrics</code>	Topic metrics	<code>IceMX.Metrics.view-name.Map.Topic</code>
Subscriber	<code>IceMX::SubscriberMetrics</code>	Subscriber metrics	<code>IceMX.Metrics.view-name.Map.Subscriber</code>

To configure a metrics view to record IceStorm topic and subscriber you can use for example:

- `IceMX.Metrics.IceStormView.Map.Topic.GroupBy=id`
- `IceMX.Metrics.IceStormView.Map.Subscriber.GroupBy=id`

This will configure a view containing only the `Topic` and `Subscriber` maps. All the topics and subscribers from the IceStorm service will be monitored individually with separate metrics object.

You can use the following attributes when configuring the IceStorm `Topic` map:

Name	Description
id	The id is the topic name.
parent	The IceStorm service name.
none	The empty string.
topic	The topic name.
service	The IceStorm service name.

The `Subscriber` map can be configured with the following attributes:

Name	Description
id	The id of the subscriber metrics is the stringified proxy of the subscriber.
parent	The name of the topic name to which this subscriber belongs.
none	The empty string.
topic	The name of the topic name to which this subscriber belongs.
service	The IceStorm service name.

identity	The identity of the subscriber proxy.
facet	The facet of the subscriber proxy.
encoding	The encoding of the subscriber proxy.
mode	The mode of the subscriber proxy.
proxy	The subscriber proxy.

## IceStorm Database Utility

The `icestormdb` utility is a command-line tool for importing and exporting an IceStorm database. This tool is especially useful when migrating to Ice 3.7, where IceStorm uses a different database implementation and storage format. Using `icestormdb`, you can export your existing IceStorm 3.6 database and then import the data using the Ice 3.7 version of `icestormdb`.

On this page:

- [Usage](#)
- [Exporting an IceStorm Database](#)
- [Importing an IceStorm Database](#)

### Usage

The IceStorm Database utility supports the following command-line options:

```
Usage: icestormdb <options>
Options:
-h, --help Show this message.
-v, --version Display version.
--import FILE Import database from FILE.
--export FILE Export database to FILE.
--dbhome DIR The database directory.
-d, --debug Print debug messages.
```

### Exporting an IceStorm Database

To export an IceStorm database, use the `--export` option to specify the output file and the `--dbhome` option to specify the path name of the service's database environment. To discover the location of your database environment, review the service's configuration and look for the setting of `Freeze.DbEnv.IceStorm.DbHome`. For example, the IceStorm sample programs typically use this setting:

```
Freeze.DbEnv.IceStorm.DbHome=db
```

Run the following command to export the database:

```
$ icestormdb --export icestorm.ixp --dbhome db
```

The utility will fail with an error message if the given path does not contain an IceStorm database.

### Importing an IceStorm Database

To import an IceStorm database, use the `--import` option to specify the input file and the `--dbhome` option to specify the path name of the service's database environment. For example, use the following command to import a database into the `dbNew` directory from a file named `icestorm.ixp`:

```
$ icestormdb --import icestorm.ixp --dbhome dbNew
```

The target directory must be empty.

# The Ice Protocol

The Ice protocol definition consists of three major parts:

- a set of data encoding rules that determine how the various data types are serialized
- a number of message types that are interchanged between client and server, together with rules as to what message is to be sent under what circumstances
- a set of rules that determine how client and server agree on a particular protocol and encoding version

## Topics

- [Protocol and Encoding Versions](#)

## Data Encoding

The key goals of the Ice data encoding are simplicity and efficiency. In keeping with these principles, the encoding does not align primitive types on word boundaries and therefore eliminates the wasted space and additional complexity that alignment requires. The Ice data encoding simply produces a stream of contiguous bytes; data contains no padding bytes and need not be aligned on word boundaries.

Data is always encoded using little-endian byte order for numeric types. (Most machines use a little-endian byte order, so the Ice data encoding is "right" more often than not.) Ice does not use a "receiver makes it right" scheme because of the additional complexity this would introduce. Consider, for example, a chain of receivers that merely forward data along the chain until that data arrives at an ultimate receiver. (Such topologies are common for event distribution services.) The Ice protocol permits all the intermediates to forward the data without requiring it to be unmarshaled: the intermediates can forward requests by simply copying blocks of binary data. With a "receiver makes it right" scheme, the intermediates would have to unmarshal and remarshal the data whenever the byte order of the next receiver in the chain differs from the byte order of the sender, which is inefficient.

Ice requires clients and servers that run on big-endian machines to incur the extra cost of byte swapping data into little-endian layout, but that cost is insignificant compared to the overall cost of sending or receiving a request.

## Basic Data Encoding

On this page:

- [Encoding for Sizes](#)
- [Encoding for Encapsulations](#)
- [Encoding for Slices](#)
- [Encoding for Basic Types](#)
- [Encoding for Strings](#)
- [Encoding for Sequences](#)
- [Encoding for Dictionaries](#)
- [Encoding for Enumerators](#)
- [Encoding for Structures](#)

### Encoding for Sizes

Many of the types involved in the data encoding, as well as several [protocol message](#) components, have an associated size or count. A size is a non-negative number. Sizes and counts are encoded in one of two ways:

1. If the number of elements is less than 255, the size is encoded as a `byte` indicating the number of elements.
2. If the number of elements is greater than or equal to 255, the size is encoded as a `byte` with value 255, followed by an `int` indicating the number of elements.

Using this encoding to indicate sizes is significantly cheaper than always using an `int` to store the size, especially when marshaling sequences of short strings: counts of up to 254 require only a single byte instead of four. This comes at the expense of counts greater than 254, which require five bytes instead of four. However, for sequences or strings of length greater than 254, the extra byte is insignificant.

### Encoding for Encapsulations

An encapsulation is used to contain variable-length data that an intermediate receiver may not be able to decode, but that the receiver can forward to another recipient for eventual decoding. An encapsulation is encoded as if it were the following structure:

The `size` member specifies the size of the encapsulation in bytes (including the `size`, `major`, and `minor` fields). The `major` and `minor` fields specify the [encoding version](#) of the data contained in the encapsulation. The version information is followed by `size-6` bytes of encoded data.

All the data in an encapsulation is context-free, that is, nothing inside an encapsulation can refer to anything outside the encapsulation. This property allows encapsulations to be forwarded among address spaces as a blob of data.

Encapsulations can be nested, that is, contain other encapsulations.

An encapsulation can be empty, in which case the value of `size` is 6.

### Encoding for Slices

The encoding format of slices changed in version 1.1.

### Slice Encoding version 1.0

[Exceptions](#) and [classes](#) may be subject to *slicing* if the receiver of a value only partially understands the received value (that is, only has knowledge of a base type, but not of the actual run-time derived type). To allow the receiver of an exception or class to ignore those parts of a value that it does not understand, exception and class values are marshaled as a sequence of [slices](#) (one slice for each level of the inheritance hierarchy). A slice is a byte count encoded as a fixed-length four-byte integer, followed by the data for the slice. (The byte count includes the four bytes occupied by the count itself, so an empty slice has a byte count of four and no data.) The receiver of a value can skip over a slice by reading the byte count  $b$ , and then discarding the next  $b-4$  bytes in the input stream.

### Slice Encoding version 1.1

Version 1.1 of the encoding still marshals [exceptions](#) and [classes](#) as [slices](#) in conceptually the same manner as for version 1.0, but bit flags in the leading byte of each slice determine its format and content.

#### Type ID

The initial slice of a class or exception, representing the instance's most-derived type, always includes a type ID. For an exception, the type ID in the initial slice is encoded as a string. For a class, the type ID in the initial slice can either be encoded as a string, an index (if the same type ID has already been encoded in the current encapsulation), or a compact ID.

Whether any subsequent slices include some form of type ID depends on the [format](#) with which the value was encoded: to facilitate slicing an instance to a less-derived type, the sliced format includes a type ID in every slice, whereas the compact format excludes type IDs in subsequent slices to conserve space while sacrificing the slicing feature.

#### Optional Data Members

This flag is true if the slice includes any [optional data members](#), which are encoded after all required members. If a slice encodes its size, the size includes the optional data members.

#### Object Indirection Table

This flag can only be true when using the [sliced format](#). In this case, data members that refer to class instances are encoded as indices into an [indirection table](#) that immediately follows the slice. The slice's size does *not* include the indirection table. This flag should only be set to true when there is at least one non-nil object reference in the slice, that is, when the indirection table is not empty.

#### Slice Size

If this flag is true, a byte count encoded as a fixed-length four-byte integer immediately follows the type ID. (The byte count includes the four bytes occupied by the count itself, so an empty slice has a byte count of four and no data.) The byte count indicates the number of bytes occupied by the encoding for the required and optional data members, but does not include the size of an object indirection table, if present.

A receiver can skip over a slice by reading the byte count  $b$ , and then discarding the next  $b-4$  bytes in the input stream. If an object indirection table is present, the receiver must then decode the table.

If this flag is false, it implies that the sender used the [compact format](#) and therefore skipping slices is not possible. The receiver must know the most-derived type in this situation otherwise decoding will fail.

#### Last Slice

This flag indicates whether the current slice is the last slice of the instance.

#### Slice Flags

The table below shows how to interpret the bit flags in the leading byte of a slice:

Bit number	Description
0-1	0 = no type ID is encoded for the slice
	1 = type ID is encoded as a string
	2 = type ID is an index encoded as a size
	3 = type ID is a compact ID encoded as a size
2	Whether or not the slice contains optional data members
3	Whether or not the slice contains an indirection table
4	Whether or not the slice size follows the type ID
5	If 0, more slices will follow, if 1, this is the last slice
6	Reserved for future use

7	Reserved for future use
---	-------------------------

*Bit flags for a slice.*

## Encoding for Basic Types

The basic types are encoded as shown in the table. Integer types (`short`, `int`, `long`) are represented as two's complement numbers, and floating point types (`float`, `double`) use the IEEE standard formats [1]. All numeric types use a little-endian byte order.

Type	Encoding
<code>bool</code>	A single byte with value 1 for <code>true</code> , 0 for <code>false</code>
<code>byte</code>	An uninterpreted byte
<code>short</code>	Two bytes (LSB, MSB)
<code>int</code>	Four bytes (LSB .. MSB)
<code>long</code>	Eight bytes (LSB .. MSB)
<code>float</code>	Four bytes (23-bit fractional mantissa, 8-bit exponent, sign bit)
<code>double</code>	Eight bytes (52-bit fractional mantissa, 11-bit exponent, sign bit)

*Encoding for basic types.*

## Encoding for Strings

Strings are encoded as a [size](#), followed by the string contents in UTF-8 format [2]. Strings are not NUL-terminated. An empty string is encoded with a size of zero.

## Encoding for Sequences

Sequences are encoded as a [size](#) representing the number of elements in the sequence, followed by the elements encoded as specified for their type.

## Encoding for Dictionaries

Dictionaries are encoded as a [size](#) representing the number of key-value pairs in the dictionary, followed by the pairs. Each key-value pair is encoded as if it were a `struct` containing the key and value as members, in that order.

## Encoding for Enumerators

The encoding format of enumerators changed in version 1.1.

### Enumerator Encoding version 1.0

The number of bytes required to encode an enumerator in version 1.0 is determined by the largest value in the enumeration. In enumerations with no [custom enumerator values](#), the largest value is the number of enumerators less one; the value encoded for an enumerator is its ordinal value in the definition, with the first enumerator having the value zero. For example, the largest value in the following enumeration is 2:

### Slice

```
enum Fruit { Apple, Pear, Orange }; // Encoded values: Apple = 0, Pear = 1, Orange = 2
```

When an enumeration includes custom values, the encoding uses the enumerator's assigned value, which is not necessarily the same as its ordinal value. Consider this example:

### Slice

```
enum Fruit { Apple = 1, Pear = 3, Orange }; // Encoded values: Apple = 1, Pear = 3, Orange = 4
```

The largest value in this case is 4.

An enumerator is encoded as follows:

- If the largest value is in the range 0..126, the enumerator's value is marshaled as a `byte`.
- If the largest value is in the range 127..32766, the enumerator's value is marshaled as a `short`.
- If the largest value is greater than 32766, the enumerator's value is marshaled as an `int`.

Changing the definition of an enumeration can break compatibility with existing applications. For example, if enumerators are added, removed, or changed such that the largest value crosses one of the thresholds shown above, the encoded form of the enumerators will change and cause marshaling errors unless you rebuild all applications that use this definition.

#### Enumerator Encoding version 1.1

An enumerator is encoded as a `size`, meaning the encoding of an enumerator requires one byte if its value is less than 255, or five bytes if its value is 255 or greater. The encoding uses the Slice value of the enumerator, which is not necessarily the same as its ordinal value. Repeating the previous example:

### Slice

```
enum Fruit { Apple = 1, Pear = 3, Orange }; // Encoded values: Apple = 1, Pear = 3, Orange = 4
```

Although enumerator `Pear` may have ordinal value 1 in some language mappings (notably, Java), the encoding uses its Slice value of 3.

## Encoding for Structures

The members of a structure are encoded in the order they appear in the `struct` declaration, as specified for their types.

## Data Encoding for Exceptions

### Exception Encoding version 1.0

An exception is marshaled as shown below:

*Marshaling format for exceptions.*

Every exception instance is preceded by a single byte that indicates whether the exception uses class members: the byte value is 1 if any of the exception members are classes (or if any of the exception members, recursively, contain class members) and 0, otherwise.

Following the header byte, the exception is marshaled as a sequence of pairs: the first member of each pair is the [type ID](#) for an exception slice, and the second member of the pair is a [slice](#) containing the marshaled members of that slice. The sequence of pairs is marshaled in derived-to-base order, with the most-derived slice first, and ending with the least-derived slice. Within each slice, data members are marshaled as for [structures](#): in the order in which they are defined in the Slice definition.

Following the sequence of pairs, any [class instances](#) that are used by the members of the exception are marshaled. This final part is optional: it is present only if the header byte is 1.

To illustrate the marshaling, consider the following exception hierarchy:

Assume that the exception members are initialized to the values shown below:

Member	Type	Value	Marshaled size (in bytes)
baseInt	int	99	4
baseString	string	"Hello"	6

derivedBool	bool	true	1
derivedString	string	"World!"	7
derivedDouble	double	3.14	8

Member values of an exception of type *Derived*.

From the above table, we can see that the total size of the members of `Base` is 10 bytes, and the total size of the members of `Derived` is 16 bytes. None of the exception members are classes. An instance of this exception has the on-the-wire representation shown in the next table. (The size, type, and byte offset of the marshaled representation is indicated for each component.)

Marshaled value	Size in bytes	Type	Byte offset
0 (no class members)	1	bool	0
"::Derived" (type ID)	10	string	1
20 (byte count for slice)	4	int	11
1 (derivedBool)	1	bool	15
"World!" (derivedString)	7	string	16
3.14 (derivedDouble)	8	double	23
"::Base" (type ID)	7	string	31
14 (byte count for slice)	4	int	38
99 (baseInt)	4	int	42
"Hello" (baseString)	6	string	46

Marshaled representation of the exception.

Note that the size of each string is one larger than the actual string length. This is because each string is preceded by a count of its number of bytes, as directed by the [encoding for strings](#).

The receiver of this sequence of values uses the header byte to decide whether it eventually must unmarshal any class instances contained in the exception (none in this example) and then examines the first type ID (`::Derived`). If the receiver recognizes that type ID, it can unmarshal the contents of the first slice, followed by the remaining slices; otherwise, the receiver reads the byte count that follows the unknown type (20) and then skips 20-4 bytes in the input stream, which is the start of the type ID for the second slice (`::Base`). If the receiver does not recognize that type ID either, it again reads the byte count following the type ID (14), skips 14-4 bytes, and attempts to read another type ID. (This can happen only if client and server have been compiled with mismatched Slice definitions that disagree in the exception specification of an operation.) In this case, the receiver will eventually encounter an unmarshaling error, which it can report with a `MarshalException`.

If an exception contains class members, these members are marshaled following the exception slices as described in the [class encoding](#).

## Exception Encoding version 1.1

An exception is marshaled as a collection of [slices](#) whose order matches the inheritance hierarchy, with the most-derived type appearing first. The selected encoding [format](#) affects the content of each slice. The final slice, representing the least-derived type, has its *last slice* bit set to true.

An exception in the compact format is marshaled as follows:

*Compact format for exceptions.*

The leading byte of each slice is a set of bit flags that specifies the features of the slice. The compact format includes a type ID in the initial (most-derived) slice but omits the type ID from all subsequent slices.

The sliced format includes a type ID in every slice, along with a slice size and an optional [indirection table](#):

*Sliced format for exceptions.*

To illustrate the marshaling, consider the following exception hierarchy:

## Slice

```
exception Base {
 int baseInt;
 string baseString;
};

exception Derived extends Base {
 bool derivedBool;
 string derivedString;
 double derivedDouble;
};
```

Assume that the exception members are initialized to the values shown below:

Member	Type	Value	Marshaled size (in bytes)
baseInt	int	99	4
baseString	string	"Hello"	6
derivedBool	bool	true	1
derivedString	string	"World!"	7
derivedDouble	double	3.14	8

*Member values of an exception of type `Derived`.*

From the above table, we can see that the total size of the members of `Base` is 10 bytes, and the total size of the members of `Derived` is 16 bytes. None of the exception members are classes. An instance of this exception using the sliced format has the on-the-wire representation shown in the next table. (The size, type, and byte offset of the marshaled representation is indicated for each component.)

Marshaled value	Size in bytes	Type	Byte offset
18 ( <i>flags: type ID is a string, slice size is present</i> )	1	byte	0
"::Derived" ( <i>type ID</i> )	10	string	1
20 ( <i>byte count for slice</i> )	4	int	11
1 ( <i>derivedBool</i> )	1	bool	15
"World!" ( <i>derivedString</i> )	7	string	16
3.14 ( <i>derivedDouble</i> )	8	double	23
50 ( <i>flags: type ID is a string, slice size is present, last slice</i> )	1	byte	31
"::Base" ( <i>type ID</i> )	7	string	32
14 ( <i>byte count for slice</i> )	4	int	39
99 ( <i>baseInt</i> )	4	int	43
"Hello" ( <i>baseString</i> )	6	string	47

*Marshaled representation of the exception using the sliced format.*

Note that the size of each string is one larger than the actual string length. This is because each string is preceded by a count of its number of bytes, as directed by the [encoding for strings](#).

Repeating this exercise using the compact format produces the following encoding:

Marshaled value	Size in bytes	Type	Byte offset
2 ( <i>flags: type ID is a string</i> )	1	byte	0
"::Derived" ( <i>type ID</i> )	10	string	1
1 ( <i>derivedBool</i> )	1	bool	11
"World!" ( <i>derivedString</i> )	7	string	12
3.14 ( <i>derivedDouble</i> )	8	double	19
32 ( <i>flags: last slice</i> )	1	byte	27
99 ( <i>baseInt</i> )	4	int	28
"Hello" ( <i>baseString</i> )	6	string	32

*Marshaled representation of the exception using the compact format.*

When using the compact format, the receiver *must* know the most-derived type: the only type ID included in the encoding is that of the most-derived type. Furthermore, the lack of slice sizes means the receiver cannot skip a slice without knowing how to decode its contents.

- [Data Encoding for Classes](#)

## Data Encoding for Classes

The marshaling for [classes](#) is complex, due to the need to deal with the pointer semantics for graphs of classes, as well as the need for the receiver to slice or preserve classes of unknown derived type. In addition, the marshaling for classes uses a [type ID](#) compression scheme to avoid repeatedly marshaling the same type IDs for large graphs of class instances.

## Encoding for Class References

Consider the following Slice definitions:

Slice
<pre>class Node {     int value;     Node next; };  struct S {     Node obj; };</pre>

We call the `obj` member a *reference* to a class instance. References can appear as data members, as in the case of `obj` above, or nested inside of other types, such as a sequence element or dictionary value. There are significant differences in the encoding for references between versions 1.0 and 1.1.

### Class Reference Encoding version 1.0

Ice encodes a nil reference as a 32-bit integer with value zero. For non-nil references, the encoder maintains a table per [encapsulation](#) that associates a unique non-zero positive integer with each class instance. We refer to this integer as an *instance ID*. The first time the encoder encounters a reference to a particular instance, it assigns the instance an unused ID, inserts it into the table, and encodes the reference as a 32-bit integer whose value is the *negative* of the ID. If the encoder has already encountered that instance, it simply encodes the instance's previously-assigned ID as a negative 32-bit integer.

All [class instances](#) are encoded at the end of the encapsulation.

### Class Reference Encoding version 1.1

As in version 1.0 of the encoding, each instance is assigned a unique ID per encapsulation. However, to conserve space, version 1.1 encodes a reference as a [size](#) value, with a nil reference encoded as a size value of zero and a non-nil reference encoded as a positive size value. The encoding reserves ID value zero to denote a nil reference, and ID value 1 to denote an *inline* instance in which an instance's state is marshaled at the point of its first reference. Consequently, instance IDs must start at 2. The encoding assigns instance IDs sequentially in order of appearance, with the first instance assigned an ID of 2, the next instance has ID 3, and so on.

The encoding for a reference depends on the [format](#) being used, and may also depend on the context in which the reference occurs:

- **Compact format**

In this format, the encoding always uses the inline scheme. Suppose we are encoding a value of the structure type `S` shown earlier. If its `obj` member refers to a class instance that the encoder has not yet encountered in the current encapsulation, the encoding assigns it the next available sequential ID, marshals a size with value 1 signifying that an instance is about to be written, and then immediately marshals the instance itself. Any subsequent reference to the same instance is encoded as a size whose value is the instance's corresponding ID.

- **Sliced format**

When a reference occurs *outside* the context of a class instance, Ice uses the same inline scheme as in the compact format. For example, suppose a Slice operation declared a parameter of structure type `S` shown above. When marshaling this parameter, its `obj` member is encoded as a size with value 1, followed by the encoding of the `Node` instance itself. Now consider the marshaling of the `Node` instance, where we encounter a class reference in member `next` that occurs *inside* the context of a class instance. To assist the Ice run time in unmarshaling and remarshaling instances, such a reference is encoded as a size whose value is an index into an [indirection table](#).

## Encoding for Class Instances

It is important to understand the distinction between marshaling a reference and marshaling an instance. In C++ terms, this is equivalent to the difference between a pointer and the heap data containing an object's state at which the pointer is pointing. Marshaling an instance means we are encoding the data members of a class instance.

### Class Instance Encoding version 1.0

Classes are marshaled as a number of pairs containing a type ID and a *slice* (one pair for each level of the inheritance hierarchy) and marshaled in derived-to-base order. Only data members are marshaled — no information is sent that would relate to operations. Each marshaled class instance is preceded by a (non-zero) positive integer that provides an identity for the instance. The sender assigns this identity during marshaling such that each marshaled instance has a different identity. The receiver uses that identity to correctly reconstruct graphs of classes. The overall marshaling format for classes is shown below:

*Marshaling format for classes.*

Prior to ending an encapsulation, the sender must encode all instances referenced within that encapsulation in an object table. The encoding may require multiple passes: as the sender processes an instance in the current pass, it may encounter additional instances to be processed in a subsequent pass. For each pass, the sender encodes a *size* denoting the number of objects in the pass. To signify that all instances have been encoded, the sender must marshal a size value of zero.

This object table must be written if any operation parameter or data member has a class type, even if all references are nil.

### Class Instance Encoding version 1.1

The leading byte of a class instance is a *size* value of 1. Following this byte is a collection of *slices* arranged in derived-to-base order. Only data members are marshaled — no information is sent that would relate to operations. The initial (most-derived) slice always includes a *type ID* that may be encoded as a string or as a numeric value, as specified by the flags that begin each slice. Depending on the *format* being used, subsequent slices may or may not include a type ID.

Each slice consists of a leading byte representing the slice flags, an optional type ID, an optional slice size, the required members for that slice in order of declaration, and the *optional members* of that slice. The sender must set the appropriate slice flags to indicate whether the slice includes a type ID, size, and optional data members, and whether this is the last slice of the instance. The compact format only includes a type ID in the initial (most-derived) slice and omits the slice size, as shown in the following diagram:

Compact format for classes.

When using the sliced format, a type ID is included in every slice, along with a slice size:

Sliced format for classes.

A slice that contains at least one non-nil class reference must use an [indirection table](#) for all references in that slice. The table is an array of instances encoded using the inline scheme. A leading size value indicates the number of elements in the table; each element is either an instance ID (if the instance has already been encoded within the current encapsulation), or the instance itself denoted by a leading size of 1. The indirection table appears in the encoding immediately following the required and optional data members, *but is not included in the byte count denoted by the slice size*. To skip a slice for an unknown type, the receiver can advance the input stream by the number of bytes specified in the slice size, but then must process all references or instances in the indirection table, if one is present.

To support [slice preservation](#) for an instance, the receiver must temporarily retain the slices of any unknown derived types, and also be able to reconstruct the indirection table in its original order for each of these slices in case the instance is later remarshaled.

## Data Encoding for Class Type IDs

### Type ID Encoding version 1.0

Unlike for exception [type IDs](#), class type IDs are not simple strings. Instead, a class type ID is marshaled as a boolean followed by either a string or a [size](#), to conserve bandwidth. To illustrate this, consider the following class hierarchy:

**Slice**

```
class Base {
 // ...
};

class Derived extends Base {
 // ...
};
```

The type IDs for the class [slices](#) are `::Derived` and `::Base`. Suppose the sender marshals three instances of `::Derived` as part of a single request. (For example, two instances could be out-parameters and one instance could be the return value.)

The first instance that is sent on the wire contains the type IDs `::Derived` and `::Base` preceding their respective slices. Because marshaling proceeds in derived-to-base order, the first type ID that is sent is `::Derived`. Every time the sender sends a type ID that it has not sent previously in the same request, it sends the boolean value `false`, followed by the type ID. Internally, the sender also assigns a unique positive number to each type ID. These numbers start at 1 and increment by one for each type ID that has not been marshaled previously. This means that the first type ID is encoded as the boolean value `false`, followed by `::Derived`, and the second type ID is encoded as the boolean value `false`, followed by `::Base`.

When the sender marshals the remaining two instances, it consults a lookup table of previously-marshaled type IDs. Because both type IDs were sent previously in the same request (or reply), the sender encodes all further occurrences of `::Derived` as the value `true` followed by the number 1 encoded as a size, and it encodes all further occurrences of `::Base` as the value `true` followed by the number 2 encoded as a size.

When the receiver reads a type ID, it first reads its boolean marker:

- If the boolean is `false`, the receiver reads a string and enters that string into a lookup table that maps integers to strings. The first new class type ID received in a request is numbered 1, the second new class type ID is numbered 2, and so on.
- If the boolean value is `true`, the receiver reads a number encoded as a size and uses it to retrieve the corresponding class type ID from the lookup table.

Note that this numbering scheme is re-established for each new [encapsulation](#). (As we will see in our discussion of [protocol messages](#), parameters, return values, and exceptions are always marshaled inside an enclosing encapsulation.) For subsequent or nested encapsulation, the numbering scheme restarts, with the first new type ID being assigned the value 1. In other words, each encapsulation uses its own independent numbering scheme for class type IDs to satisfy the constraint that encapsulations must not depend on their surrounding context.

Encoding class type IDs in this way provides significant savings in bandwidth: whenever an ID is marshaled a second and subsequent time, it is marshaled as a two-byte value (assuming no more than 254 distinct type IDs per request) instead of as a string. Because type IDs can be long, especially if you are using nested modules, the savings are considerable.

### Type ID Encoding version 1.1

Each [slice](#) of a class instance has a leading byte containing flags that describe various aspects of the slice, including whether the slice includes a type ID and how that type ID is encoded. There are four possibilities:

1. No type ID included
2. Type ID is encoded as a string
3. Type ID is encoded as an index
4. Type ID is encoded as a compact ID

The initial slice of an instance, representing the most-derived type, always contains some form of type ID so that the receiver knows what Slice type is present. Depending on the [format](#) used by the sender, subsequent slices may or may not include a type ID: the compact format omits type IDs in subsequent slices, whereas the sliced format includes a type ID in every slice. A receiver need only examine the slice flags to discover how to decode the type ID.

### String Type IDs

The encoding for string type IDs uses a "compression" scheme similar to that of version 1.0: within an [encapsulation](#), a given type ID is never encoded as a string more than once. The first time a sender encounters a type ID, the sender assigns an integer index to the ID and encodes the ID as a string. For all subsequent occurrences of the same type ID within the encapsulation, the sender encodes the index associated with that type ID as a [size](#). Index values start at 1 and increase sequentially with each new type ID. The sender is responsible for setting the relevant bits in the [flags](#) of each slice to specify how the type ID is encoded.

The slice flags in version 1.1 of the encoding serve the same purpose as the boolean value that precedes each type ID in version 1.0, without consuming an entire byte.

### Compact Type IDs

As a way of further reducing the overhead associated with class instances, version 1.1 adds the ability to substitute numeric values for strings when encoding type IDs. Consider the following Slice definitions:

Slice
<pre>class Base(3) {     // ... };  class Derived(4) extends Base {     // ... };  class MoreDerived extends Derived {     // ... };</pre>

The value in parentheses after the class name represents the *compact* type ID for the class. The sender's [format](#) determines whether each slice includes a type ID. If a given slice includes a type ID, the encoding always uses a compact type ID (if defined) in preference to its string equivalent. Suppose a sender is encoding an instance of `MoreDerived` in the sliced format. The initial slice uses the string type ID for `MoreDerived`, the next slice uses the compact type ID for `Derived`, and the last slice uses the compact type ID for `Base`.

A compact type ID is encoded as a [size](#), with the relevant bits set in the [slice flags](#).

The developer is responsible for ensuring compact type IDs are sufficiently unique. Using values less than 255 produces the most efficient encoding.

  - [Class Encoding in the Sliced Format](#)
  - [Class Encoding in the Compact Format](#)
  - [Class Encoding in the Compact Format with Compact Type IDs](#)

### Sample Class Definitions

We have separately discussed the primary components of the class encoding: [slices](#), [references](#), and [type IDs](#). To make the preceding discussions more concrete, consider the following class definitions:

**Slice**

```

class Base
{
 int baseInt;
 string baseString;
}

class Derived extends Base
{
 bool derivedBool;
 string derivedString;
 double derivedDouble;
}

```

Suppose the sender marshals two instances of `Derived` (for example, as two in-parameters in the same request) with these member values:

**First instance:**

Member	Type	Value	Marshaled size (in bytes)
baseInt	int	99	4
baseString	string	"Hello"	6
derivedBool	bool	true	1
derivedString	string	"World!"	7
derivedDouble	double	3.14	8

**Second instance:**

Member	Type	Value	Marshaled size (in bytes)
baseInt	int	115	4
baseString	string	"Cave"	5
derivedBool	bool	false	1
derivedString	string	"Canem"	6
derivedDouble	double	6.32	8

We describe how to marshal these instances using versions 1.0 and 1.1 of the encoding in separate sections below.

## Class Encoding version 1.0

The sender arbitrarily assigns a non-zero `identity` to each instance. Typically, the sender will simply consecutively number the instances starting at 1. For this example, assume that the two instances have the identities 1 and 2. The marshaled representation for the two instances (assuming that they are marshaled immediately following each other) is shown below:

Marshaled value	Size in bytes	Type	Byte offset
1 ( <i>identity</i> )	4	int	0
0 ( <i>marker for class type ID</i> )	1	bool	4
"::Derived" ( <i>class type ID</i> )	10	string	5
20 ( <i>byte count for slice</i> )	4	int	15
1 ( <i>derivedBool</i> )	1	bool	19
"World!" ( <i>derivedString</i> )	7	string	20
3.14 ( <i>derivedDouble</i> )	8	double	27
0 ( <i>marker for class type ID</i> )	1	bool	35
"::Base" ( <i>type ID</i> )	7	string	36
14 ( <i>byte count for slice</i> )	4	int	43
99 ( <i>baseInt</i> )	4	int	47
"Hello" ( <i>baseString</i> )	6	string	51
0 ( <i>marker for class type ID</i> )	1	bool	57
"::Ice::Object" ( <i>class type ID</i> )	14	string	58
5 ( <i>byte count for slice</i> )	4	int	72
0 ( <i>number of dictionary entries</i> )	1	size	76
2 ( <i>identity</i> )	4	int	77
1 ( <i>marker for class type ID</i> )	1	bool	81
1 ( <i>class type ID</i> )	1	size	82
19 ( <i>byte count for slice</i> )	4	int	83
0 ( <i>derivedBool</i> )	1	bool	87
"Canem" ( <i>derivedString</i> )	6	string	88
6.32 ( <i>derivedDouble</i> )	8	double	94
1 ( <i>marker for class type ID</i> )	1	bool	102
2 ( <i>class type ID</i> )	1	size	103
13 ( <i>byte count for slice</i> )	4	int	104
115 ( <i>baseInt</i> )	4	int	108
"Cave" ( <i>baseString</i> )	5	string	112
1 ( <i>marker for class type ID</i> )	1	bool	117
3 ( <i>class type ID</i> )	1	size	118
5 ( <i>byte count for slice</i> )	4	int	119
0 ( <i>number of dictionary entries</i> )	1	size	123

Note that, because classes (like `exceptions`) are sent as a sequence of `slices`, the receiver of a class can slice off any derived parts of a class it does not understand. Also note that (as shown in the above table) each class instance contains three slices. The third slice is for the type `::Ice::Object`, which is the base type of all classes. The class `type ID ::Ice::Object` has the number 3 in this example because

it is the third distinct type ID that is marshaled by the sender. (See entries at byte offsets 58 and 118 in the above table.) All class instances have this final slice of type `::Ice::Object`.

Marshaling a separate slice for `::Ice::Object` dates back to Ice versions 1.3 and earlier. In those versions, classes carried a facet map that was marshaled as if it were defined as follows:

**Slice**

```

module Ice
{
 class Object;

 dictionary<string, Object> FacetMap;

 class Object
 {
 FacetMap facets; // No longer exists
 }
}

```

As of Ice version 1.4, this facet map is always empty, that is, the count of entries for the dictionary that is marshaled in the `::Ice::Object` slice is always zero. If a receiver receives a class instance with a non-empty facet map, it must throw a `MarshalException`.

Note that if a class has no data members, a type ID and slice for that class is still marshaled. The byte count of the slice will be 4 in this case, indicating that the slice contains no data.

### Class Encoding version 1.1

A leading [size](#) value of 1 marks the beginning of an instance, followed by one or more [slices](#).

#### Class Encoding in the Sliced Format

The marshaled representation for the two instances (assuming that they are marshaled immediately following each other) in the [sliced format](#) is shown below:

Marshaled value	Size in bytes	Type	Byte offset
1 ( <i>instance marker</i> )	1	size	0
17 ( <i>slice flags: string type ID, size is present</i> )	1	byte	1
"::Derived" ( <i>type ID - assigned index 1</i> )	10	string	2
20 ( <i>byte count for slice</i> )	4	int	12
1 ( <i>derivedBool</i> )	1	bool	16
"World!" ( <i>derivedString</i> )	7	string	17
3.14 ( <i>derivedDouble</i> )	8	double	24
49 ( <i>slice flags: string type ID, size is present, last slice</i> )	1	byte	32
"::Base" ( <i>type ID - assigned index 2</i> )	7	string	33
14 ( <i>byte count for slice</i> )	4	int	40
99 ( <i>baseInt</i> )	4	int	44
"Hello" ( <i>baseString</i> )	6	string	48
1 ( <i>instance marker</i> )	1	size	54
18 ( <i>slice flags: index type ID, size is present</i> )	1	byte	55

1 ( <i>type ID index for Derived</i> )	1	size	56
19 ( <i>byte count for slice</i> )	4	int	57
0 ( <i>derivedBool</i> )	1	bool	61
"Canem" ( <i>derivedString</i> )	6	string	62
6.32 ( <i>derivedDouble</i> )	8	double	68
50 ( <i>slice flags: index type ID, size is present, last slice</i> )	1	byte	76
2 ( <i>type ID index for Base</i> )	1	size	77
13 ( <i>byte count for slice</i> )	4	int	78
115 ( <i>baseInt</i> )	4	int	82
"Cave" ( <i>baseString</i> )	5	string	86

The sliced format allows the receiver of a class to slice off any derived parts of a class it does not understand, as in version 1.0 of the encoding. Although the sliced format provides equivalent functionality to that of version 1.0, it is significantly more efficient, requiring only 91 bytes to encode our example compared to the 124 bytes required by version 1.0. We could reduce the encoded size even further, while still retaining the ability to slice off unknown types, by using [compact type IDs](#).

Note that if a class has no data members, a type ID and slice for that class is still marshaled. The byte count of the slice will be 4 in this case, indicating that the slice contains no data.

#### Class Encoding in the Compact Format

The marshaled representation for the two instances (assuming that they are marshaled immediately following each other) in the [compact format](#) is shown below:

Marshaled value	Size in bytes	Type	Byte offset
1 ( <i>instance marker</i> )	1	size	0
1 ( <i>slice flags: string type ID</i> )	1	byte	1
"::Derived" ( <i>type ID - assigned index 1</i> )	10	string	2
1 ( <i>derivedBool</i> )	1	bool	12
"World!" ( <i>derivedString</i> )	7	string	13
3.14 ( <i>derivedDouble</i> )	8	double	20
32 ( <i>slice flags: last slice</i> )	1	byte	28
99 ( <i>baseInt</i> )	4	int	29
"Hello" ( <i>baseString</i> )	6	string	33
1 ( <i>instance marker</i> )	1	size	39
2 ( <i>slice flags: index type ID</i> )	1	byte	40
1 ( <i>type ID index for Derived</i> )	1	size	41
0 ( <i>derivedBool</i> )	1	bool	42
"Canem" ( <i>derivedString</i> )	6	string	43
6.32 ( <i>derivedDouble</i> )	8	double	49
32 ( <i>slice flags: last slice</i> )	1	byte	57
115 ( <i>baseInt</i> )	4	int	58
"Cave" ( <i>baseString</i> )	5	string	62

In an effort to conserve bandwidth, the compact format omits certain details that would allow a receiver to slice off derived parts of a class, such as the slice size and the type IDs for base classes. The result is an encoding that requires only 67 bytes for the two sample instances.

Note that if a class has no data members, a type ID and slice for that class is still marshaled. The byte count of the slice will be 4 in this case, indicating that the slice contains no data.

### Class Encoding in the Compact Format with Compact Type IDs

Compact type IDs can be used regardless of the sender's chosen format. For the sake of example, we will use compact type IDs together with the compact format to produce the smallest encoding possible. The Slice definitions below reflect the addition of the compact type IDs:

**Slice**

```

class Base(10)
{
 int baseInt;
 string baseString;
}

class Derived(11) extends Base
{
 bool derivedBool;
 string derivedString;
 double derivedDouble;
}

```

We assign the compact type ID 10 to `Base` and 11 to `Derived`. Note however that assigning a compact type ID to `Base` does not affect the size of the encoded data in our example because the compact format omits type IDs altogether for base types.

The marshaled representation for the two instances (assuming that they are marshaled immediately following each other) in the compact format is shown below:

Marshaled value	Size in bytes	Type	Byte offset
1 ( <i>instance marker</i> )	1	size	0
3 ( <i>slice flags: compact type ID</i> )	1	byte	1
11 ( <i>compact type ID for Derived</i> )	1	size	2
1 ( <i>derivedBool</i> )	1	bool	3
"World!" ( <i>derivedString</i> )	7	string	4
3.14 ( <i>derivedDouble</i> )	8	double	11
32 ( <i>slice flags: last slice</i> )	1	byte	19
99 ( <i>baseInt</i> )	4	int	20
"Hello" ( <i>baseString</i> )	6	string	24
1 ( <i>instance marker</i> )	1	size	30
3 ( <i>slice flags: compact type ID</i> )	1	byte	31
11 ( <i>compact type ID for Derived</i> )	1	size	32
0 ( <i>derivedBool</i> )	1	bool	33
"Canem" ( <i>derivedString</i> )	6	string	34
6.32 ( <i>derivedDouble</i> )	8	double	40
32 ( <i>slice flags: last slice</i> )	1	byte	48
115 ( <i>baseInt</i> )	4	int	49
"Cave" ( <i>baseString</i> )	5	string	53

Substituting a compact type ID for its string equivalent reduces the encoded size for the two instances by another nine bytes to 58, less than half the size of version 1.0.

## Data Encoding for Class Graphs

Classes support pointer semantics, that is, you can construct graphs of classes. It follows that classes can arbitrarily point at each other, and therefore the encoding must provide a scheme for serializing and deserializing a class graph. Note that the marshaling format for [class references](#) and [instances](#) differs significantly between versions 1.0 and 1.1 of the encoding.

On this page:

- [Encoding a Class Graph version 1.0](#)
- [Encoding a Class Graph version 1.1](#)
  - [Class Graph in the Compact Format](#)
  - [Class Graph in the Sliced Format](#)
  - [Importance of the Indirection Table](#)
- [Impact of Slicing on Class Graph Decoding](#)

### Encoding a Class Graph version 1.0

In version 1.0 of the encoding, an [instance ID](#) is used to distinguish instances and pointers as follows:

- An instance ID of 0 denotes a null pointer.
- An instance ID  $> 0$  precedes the marshaled contents of an instance.
- An instance ID  $< 0$  denotes a pointer to an instance.

Instance ID values less than zero are pointers. For example, if the receiver receives the instance ID  $-57$ , this means that the corresponding class member that is currently being unmarshaled will eventually point at the instance with ID 57.

For structures, classes, exceptions, sequences, and dictionary members that do not contain class members, the Ice encoding uses a simple depth-first traversal algorithm to marshal the members. For example, structure members are marshaled in the order of their Slice definition; if a structure member itself is of complex type, such as a sequence, the sequence is marshaled in toto where it appears inside its enclosing structure. For complex types that contain class members, this depth-first marshaling is suspended: instead of marshaling the actual class instance at this point, a negative instance ID is marshaled that indicates which class instance that member must eventually denote. For example, consider the following definitions:

**Slice**

```
class C {
 // ...
};

struct S {
 int i;
 C firstC;
 C secondC;
 C thirdC;
 int j;
};
```

Suppose we initialize a structure of type `S` as follows:

## C++

```

S myS;
myS.i = 99;
myS.firstC = new C; // New instance
myS.secondC = 0; // null
myS.thirdC = myS.firstC; // Same instance as previously
myS.j = 100;

```

When this structure is marshaled, the contents of the three class members are not marshaled in-line. Instead, the sender marshals the negative instance IDs of the corresponding instances. Assuming that the sender has assigned the instance ID 78 to the instance assigned to `myS.firstC`, `myS` is marshaled as shown in the table.

Marshaled Value	Size in Bytes	Type	Byte offset
99 ( <i>myS.i</i> )	4	int	0
-78 ( <i>myS.firstC</i> )	4	int	4
0 ( <i>myS.secondC</i> )	4	int	8
-78 ( <i>mys.thirdC</i> )	4	int	12
100 ( <i>myS.j</i> )	4	int	16

Note that `myS.firstC` and `myS.thirdC` both use the instance ID -78. This allows the receiver to recognize that `firstC` and `thirdC` point to the same class instance (rather than at two different instances that happen to have the same contents).

Marshaling the negative instance IDs instead of the contents of an instance allows the receiver to accurately reconstruct the class graph that was sent by the sender. However, this begs the question of *when* the actual instances are to be marshaled as described at the beginning of this section. In Ice [protocol messages](#), parameters and return values are marshaled as if they were members of a structure. For example, if an operation invocation has five input parameters, the client marshals the five parameters end-to-end as if they were members of a single structure. If any of the five parameters are class instances, or are of complex type (recursively) containing class instances, the sender marshals the parameters in multiple passes: the first pass marshals the parameters end-to-end, using the usual depth-first algorithm:

- If the sender encounters a class member during marshaling, it checks whether it has marshaled the same instance previously for the current request or reply:
  - If the instance has not been marshaled before, the sender assigns a new instance ID to the instance and marshals the negative ID.
  - Otherwise, if the instance was marshaled previously, the sender sends the same negative ID that it previously sent for that instance.

In effect, during marshaling, the sender builds a table that is indexed by the address of each instance; the lookup value for the instance is its ID.

Once the first pass ends, the sender has marshaled all the parameters, but has not yet marshaled any of the class instances that may be pointed at by various parameters or members. The instance table at this point contains all those instances for which negative IDs (pointers) were marshaled, so whatever is in the table at this point are the classes that the receiver still needs. The sender now marshals those instances in the table, but with positive IDs and followed by their contents, as described in [our earlier example](#). The outstanding instances are marshaled as a sequence, that is, the sender marshals the number of instances as a [size](#), followed by the actual instances.

In turn, the instances just sent may themselves contain class members; when those class members are marshaled, the sender assigns IDs to new instances or uses a negative ID for previously marshaled instances as usual. This means that, by the end of the second pass, the table may have grown, necessitating a third pass. That third pass again marshals the outstanding class instances as a size followed by the actual instances. The third pass contains all those instances that were not marshaled in the second pass. Of course, the third pass may trigger yet more passes until, finally, the sender has sent all outstanding instances, that is, marshaling is complete. At this point, the sender terminates the sequence of passes by marshaling an empty sequence (the value 0 encoded as a size).

To illustrate this with an example, consider the definitions shown in [Classes with Operations](#) once more:

### Slice

```

enum UnaryOp { UnaryPlus, UnaryMinus, Not };
enum BinaryOp { Plus, Minus, Multiply, Divide, And, Or };

class Node {
 idempotent long eval();
};

class UnaryOperator extends Node {
 UnaryOp operator;
 Node operand;
};

class BinaryOperator extends Node {
 BinaryOp op;
 Node operand1;
 Node operand2;
};

class Operand {
 long val;
};

```

These definitions allow us to construct expression trees. Suppose the client initializes a tree to the shape shown in the illustration below, representing the expression  $(1 + 6 / 2) * (9 - 3)$ . The values outside the nodes are the identities assigned by the client.

Expression tree for the expression  $(1 + 6 / 2) * (9 - 3)$ . Both  $p1$  and  $p2$  denote the root node.

The client passes the root of the tree to the following operation in the parameters  $p1$  and  $p2$ , as shown in the illustration above. (Even though it does not make sense to pass the same parameter value twice, we do it here for illustration purposes):

### Slice

```
interface Tree {
 void sendTree(Node p1, Node p2);
};
```

The client now marshals the two parameters `p1` and `p2` to the server, resulting in the value `-1` being sent twice in succession. (The client arbitrarily assigns an instance ID to each node. The value of the ID does not matter, as long as each node has a unique ID. For simplicity, the Ice implementation numbers instances with a counter that starts counting at 1 and increments by one for each unique instance.) This completes the marshaling of the parameters and results in a single instance with ID 1 in the instance table. The client now marshals a sequence containing a single element, node 1, as described in [the example](#). In turn, node 1 results in nodes 2 and 3 being added to the table, so the next sequence of nodes contains two elements, nodes 2 and 3. The next sequence of nodes contains nodes 4, 5, 6, and 7, followed by another sequence containing nodes 8 and 9. At this point, no more class instances are outstanding, and the client marshals an empty sequence to indicate to the receiver that the final sequence has been marshaled.

Within each sequence, the order in which class instances are marshaled is irrelevant. For example, the third sequence could equally contain nodes 7, 6, 4, and 5, in that order. What is important here is that each sequence contains nodes that are an equal number of "hops" away from the initial node: the first sequence contains the initial node(s), the second sequence contains all nodes that can be reached by traversing a single link from the initial node(s), the third sequence contains all nodes that can be reached by traversing two links from the initial node(s), and so on.

Now consider the same example once more, but with different parameter values for `sendTree`: `p1` denotes the root of the tree, and `p2` denotes the `-` operator of the right-hand sub-tree, as shown below:

*The expression tree of with `p1` and `p2` denoting different nodes.*

The graph that is marshaled is exactly the same, but instances are marshaled in a different order and with different IDs:

- During the first pass, the client sends the IDs `-1` and `-2` for the parameter values.
- The second pass marshals a sequence containing nodes 1 and 2.
- The third pass marshals a sequence containing nodes 3, 4, and 5.
- The fourth pass marshals a sequence containing nodes 6 and 7.
- The fifth pass marshals a sequence containing nodes 8 and 9.
- The final pass marshals an empty sequence.

In this way, any graph of nodes can be transmitted (including graphs that contain cycles). The receiver reconstructs the graph by filling in a patch table during unmarshaling:

- Whenever the receiver unmarshals a negative ID, it adds that ID to a patch table; the lookup value is the memory address of the parameter or member that eventually will point at the corresponding instance.
- Whenever the receiver unmarshals an actual instance, it adds the instance to an unmarshaled table; the lookup value is the memory address of the instantiated class. The receiver then uses the address of the instance to patch any parameters or members with the actual memory address.

Note that the receiver may receive negative IDs that denote class instances that have been unmarshaled already (that is, point "backward" in the unmarshaling stream), as well as instances that are yet to be unmarshaled (that is, point "forward" in the unmarshaling stream). Both scenarios are possible, depending on the order in which instances are marshaled, as well as their in-degree.

To provide another example, consider the following definition:

Slice
<pre>class C {     // ... };  sequence&lt;C&gt; CSeq;</pre>

Suppose the client marshals a sequence of 100 `C` instances to the server, with each instance being distinct. (That is, the sequence contains 100 pointers to 100 different instances, not 100 pointers to the same single instance.) In that case, the sequence is marshaled as a size of 100, followed by 100 negative IDs, `-1` to `-100`. Following that, the client marshals a single sequence containing the 100 instances, each instance with its positive ID in the range `1` to `100`, and completes by marshaling an empty sequence.

On the other hand, if the client sends a sequence of 100 elements that all point to the same single class instance, the client marshals the sequence as a size of 100, followed by 100 negative IDs, all with the value `-1`. The client then marshals a sequence containing a single element, namely instance `1`, and completes by marshaling an empty sequence.

### Encoding a Class Graph version 1.1

The most significant difference in the class encoding between version 1.0 and 1.1 is the location of class instances in the output stream. In version 1.0, instances are always marshaled at the end of the encapsulation, whereas in version 1.1 it is possible for instances to be marshaled *inline* at the point of first reference. Our previous discussion of [class references](#) describes the factors that determine whether a given class reference is marshaled as a reference or as an inline instance. The encoding rules can be summarized as follows:

- When using the compact *format*, always marshal an instance inline at the point of its first reference, and marshal all subsequent occurrences of the same instance as a reference.
- When using the sliced *format*, the encoding depends on the context in which a reference occurs: if the reference occurs while encoding a slice of an object or exception, encode it as an index into an indirection table that appears at the end of the slice, otherwise encode it as an inline instance or reference.

We can use the Slice definitions below to explore these situations:

Slice
<pre>class Node {     int value;     Node next; };  struct S {     Node obj; };</pre>

Suppose we create an instance of structure `s` and assign it to the variable `s`, then construct the following class graph:

*Class graph with circular reference.*

We discuss the encoding for these values in separate sections below.

### Class Graph in the Compact Format

As we marshal the structure's `obj` member, the compact format produces the following encoding:

Marshaled value	Size in bytes	Type	Byte offset
1 ( <i>obj</i> - inline instance marker - assigned ID 2)	1	size	0
33 ( <i>slice flags: string type ID, last slice</i> )	1	byte	1
"::Node" ( <i>type ID - assigned index 1</i> )	7	string	2
7 ( <i>value</i> )	4	int	9
1 ( <i>next</i> - inline instance marker - assigned ID 3)	1	size	13
34 ( <i>slice flags: type ID index, last slice</i> )	1	byte	14
1 ( <i>type ID index</i> )	1	size	15
9 ( <i>value</i> )	4	int	16
2 ( <i>next</i> - reference to ID 2)	1	size	20

This example shows that inline instances are marshaled immediately upon discovery. As we encode the `obj` member, we encounter a new `Node` instance, assign it the ID 2, and begin to encode it inline using the reserved instance marker value 1. Next, we encode the instance's `value` member and then examine its `next` member. Since we have not encountered this instance yet, we assign it the ID 3 and begin to encode this new instance inline. Its `next` member is a circular reference to the object with ID 2, so we simply encode a reference to this instance to complete the structure.

### Class Graph in the Sliced Format

The need to support both slicing and slice preservation makes the sliced format more complex than the compact format. The encoding for our example values shows how class instances are handled differently depending on their context:

Marshaled value	Size in bytes	Type	Byte offset
1 ( <i>obj</i> - inline instance marker - assigned ID 2)	1	size	0
57 ( <i>slice flags: string type ID, size is present, indirection table is present, last slice</i> )	1	byte	1
"::Node" ( <i>type ID - assigned index 1</i> )	7	string	2
9 ( <i>byte count for slice</i> )	4	int	9
7 ( <i>value</i> )	4	int	13
1 ( <i>next</i> - indirection table index)	1	size	17
1 ( <i>size of indirection table</i> )	1	size	18
1 ( <i>indirection table entry - inline instance marker - assigned ID 3</i> )	1	size	19

58 ( <i>slice flags: type ID index, size is present, indirection table is present, last slice</i> )	1	byte	20
1 ( <i>type ID index</i> )	1	size	21
9 ( <i>byte count for slice</i> )	4	int	22
9 ( <i>value</i> )	4	int	26
1 ( <i>next - indirection table index - ID 2</i> )	1	size	30
1 ( <i>size of indirection table</i> )	1	size	31
2 ( <i>indirection table entry - reference to ID 2</i> )	1	size	32

For this example, let us assume that the structure value is an operation parameter, and therefore the structure member `obj` occurs *outside* the context of a class or exception slice. As a result, we encode the instance with ID 2 as an inline instance. However, when we process the instance's `next` member, we are now *inside* the context of a class slice, so we must use an indirection table. The sender adds an entry to the indirection table for each unique class reference in the slice; instead of encoding a reference or inline instance, the sender encodes the index of the corresponding entry in the table. As shown above, the value encoded for the `next` member is 1, representing the first entry in the table (0 is still reserved for nil references).

The indirection table follows immediately after the last data member in the slice, but the table is *not* included in the byte count for the slice. A leading size denotes the number of entries in the table. The one and only entry in this table, the instance with ID 3, has not yet been encoded, therefore it is marshaled immediately as an inline instance. This instance also uses an indirection table, although in this case the table entry is simply a reference to instance ID 2, which has already been encoded.

#### Importance of the Indirection Table

The indirection table is necessary for implementing the [slice preservation](#) feature. Normally, when a receiver does not recognize the type ID in a slice, it has the option of ignoring that slice by skipping ahead in the stream by the number of bytes in the slice. However, when slice preservation is enabled, the receiver must keep a copy of the slice data in case the instance is later remmarshaled. The need for the indirection table becomes apparent when you consider that an opaque blob of slice data may contain class references, and those class references can change during remmarshaling. For example, without an indirection table, the sender might encode the instance ID 3 as the value of member `next`, but what happens if the receiver assigns that instance a different ID, such as 12, when it remmarshals the preserved slice? The receiver preserved the slice because it did not understand the type ID, which means it does not know the contents of the slice data and therefore it cannot "patch" any class references the slice might contain. The indirection table serves as an external "patch table" to solve this problem, essentially making the opaque slice data *relocatable* with respect to class references.

The byte count for a slice does not include the indirection table because the receiver must process the table regardless of whether it recognizes that slice's type ID. Consequently, to "skip" a slice, the receiver can skip (or preserve) the number of bytes specified by the slice's byte count, but still must decode the indirection table if the slice flags indicate that a table is present. If the receiver preserves the slice, it must also associate an indirection table with that slice; during remmarshaling, the sender copies the opaque slice data into the stream, and then reconstructs the indirection table using (potentially) new instance IDs for the instances referenced in the table.

It is possible that the *only* reference to an instance is in an indirection table. To properly implement slice preservation, a receiver must therefore retain *every* instance that is referenced by a preserved indirection table. This is true even if the receiver does not recognize any of the type IDs in an instance; in effect, the receiver must construct a temporary "unknown object" placeholder for the instance, whose only purpose is to encapsulate the data comprising its slices in case the instance is later remmarshaled.

#### Impact of Slicing on Class Graph Decoding

It is important to note that when a graph of class instances is sent, it always forms a connected graph. However, when the receiver rebuilds the graph, it may end up with a disconnected graph, due to slicing. Consider:

### Slice

```
class Base {
 // ...
};

class Derived extends Base {
 // ...
 Base b;
};

interface Example {
 void op(Base p);
};
```

Suppose the client has complete type knowledge, that is, understands both types `Base` and `Derived`, but the server only understands type `Base`, so the derived part of a `Derived` instance is sliced. The client can instantiate classes to be sent as parameter `p` as follows:

### C++

```
DerivedPtr p = new Derived;
p->b = new Derived;
ExamplePrx e = ...;
e->op(p);
```

As far as the client is concerned, the graph looks like the one shown below:

*Sender-side view of a graph containing derived instances.*

However, the server does not understand the derived part of the instances and slices them. Yet, the server unmarshals all the class instances, leading to the situation where the class graph has become disconnected, as shown here:

*Receiver-side view of the graph.*

Of course, more complex situations are possible, such that the receiver ends up with multiple disconnected graphs, each containing many instances.

The [slice preservation](#) feature in version 1.1 of the encoding allows a receiver to remarshal the original graph intact, despite the fact that the receiver's in-memory object graph may appear to be disconnected.

## Data Encoding for Interfaces

Interfaces can be [marshaled by value](#). For an interface marshaled by value (as opposed to a class instance derived from that interface), only the [type ID](#) of the most-derived interface is encoded. We use the following Slice definitions in our discussion:

**Slice**

```

interface Base { /* ... */ };

interface Derived extends Base { /* ... */ };

interface Example {
 void doSomething(Base b);
};

```

We assume that the client passes a class instance to `doSomething` that does not have a Slice definition (but implements `Derived`).

### Interface Encoding version 1.0

The on-the-wire representation of the interface parameter using encoding version 1.0 is as follows:

Marshaled Value	Size in Bytes	Type	Byte offset
1 ( <i>identity</i> )	4	int	0
0 ( <i>marker for class type ID</i> )	1	bool	4
"::Derived" ( <i>class type ID</i> )	10	string	5
4 ( <i>byte count for slice</i> )	4	int	15
0 ( <i>marker for class type ID</i> )	1	bool	19
"::Ice::Object" ( <i>class type ID</i> )	14	string	20
5 ( <i>byte count for slice</i> )	4	int	34
0 ( <i>number of dictionary entries</i> )	1	size	38

### Interface Encoding version 1.1

With encoding version 1.1, the interface parameter is encoded as if it was a class with no data members. Here is the on-the-wire representation using the [sliced format](#):

Marshaled value	Size in bytes	Type	Byte offset
1 ( <i>instance marker</i> )	1	size	0
17 ( <i>slice flags: string type ID, size is present</i> )	1	byte	1
"::Derived" ( <i>type ID - assigned index 1</i> )	10	string	2
4 ( <i>byte count for slice</i> )	4	int	12

The compact format omits the byte count for the slice:

Marshaled value	Size in bytes	Type	Byte offset
1 ( <i>instance marker</i> )	1	size	0
1 ( <i>slice flags: string type ID</i> )	1	byte	1

"::Derived" ( <i>type ID - assigned index 1</i> )	10	string	2
---------------------------------------------------	----	--------	---

## Data Encoding for Proxies

On this page:

- [Encoding for General Proxy Parameters](#)
- [Encoding for Endpoint Parameters](#)
- [Encoding for TCP Endpoint Parameters](#)
- [Encoding for UDP Endpoint Parameters](#)
- [Encoding for SSL Endpoint Parameters](#)
- [Encoding for WS Endpoint Parameters](#)
- [Encoding for WSS Endpoint Parameters](#)

### Encoding for General Proxy Parameters

The encoding format of proxies changed in version 1.1.

#### Proxy Parameter Encoding version 1.0

The first component of an encoded proxy is a value of type `Ice::Identity`. If the proxy is a nil value, the `category` and `name` members are empty strings, and no additional data is encoded. The encoding for a non-null proxy consists of general parameters followed by endpoint parameters.

The general proxy parameters are encoded as if they were members of the following structure:

**Slice**

```

struct ProxyData {
 Ice::Identity id;
 Ice::StringSeq facet;
 byte mode;
 bool secure;
};

```

The general proxy parameters are described in the table below:

Parameter	Description
<code>id</code>	The <a href="#">object identity</a>
<code>facet</code>	The <a href="#">facet</a> name (zero- or one-element sequence)
<code>mode</code>	The proxy mode (0=twoway, 1=oneway, 2=batch oneway, 3=datagram, 4=batch datagram)
<code>secure</code>	true if secure endpoints are required, otherwise false

The `facet` field has either zero elements or one element. An empty sequence denotes the default facet, and a one-element sequence provides the facet name in its first member. If a receiver receives a proxy with a `facet` field with more than one element, it must throw a `ProxyUnmarshalException`.

#### Proxy Parameter Encoding version 1.1

Version 1.1 of the encoding appends two attributes to the existing proxy parameters in version 1.0: [protocol and encoding versions](#). The general proxy parameters are encoded as if they were members of the following structure:

## Slice

```

struct ProtocolVersion {
 byte major;
 byte minor;
};

struct EncodingVersion {
 byte major;
 byte minor;
};

struct ProxyData {
 Ice::Identity id;
 Ice::StringSeq facet;
 byte mode;
 bool secure;
 ProtocolVersion protocol;
 EncodingVersion encoding;
};

```

The additional parameters are described in the table below:

Parameter	Description
protocol	The maximum protocol version supported by the server. Currently this value is always 1.0.
encoding	The maximum encoding version supported by the server.

The encoding for [UDP endpoints](#) also changed in version 1.1.

## Encoding for Endpoint Parameters

A proxy optionally contains an [endpoint list](#) or an [adapter identifier](#), but not both:

- If a proxy contains endpoints, they are encoded immediately following the general parameters. A [size](#) specifying the number of endpoints is encoded first, followed by the endpoints. Each endpoint is encoded as a `short` specifying the endpoint type (1=TCP, 2=SSL, 3=UDP, 4=WS, 5=WSS), followed by an [encapsulation](#) of type-specific parameters. The type-specific parameters for TCP, UDP, SSL, WS and WSS are presented in the sections that follow.
- If a proxy does not have endpoints, a single byte with value 0 immediately follows the general parameters and a string representing the object adapter identifier is encoded immediately following the zero byte.
- For a proxy to a [well-known object](#), which has neither endpoints nor an object adapter identifier, a single byte with value 0 immediately follows the general parameters and an empty string is encoded immediately following the zero byte.

Type-specific endpoint parameters are encapsulated because a receiver may not be capable of decoding them. For example, a receiver can only decode SSL endpoint parameters if it is configured with the [IceSSL](#) plug-in. However, the receiver must be able to re-encode the proxy with all of its original endpoints, in the order they were received, even if the receiver does not understand the type-specific parameters for an endpoint. Encapsulation of the parameters into an [opaque endpoint](#) allows the receiver to do this.

## Encoding for TCP Endpoint Parameters

A TCP endpoint is encoded as an encapsulation containing the following structure:

### Slice

```
struct TCPEndpointData {
 string host;
 int port;
 int timeout;
 bool compress;
};
```

The endpoint parameters are described in the following table.

Parameter	Description
host	The server host (a host name or IP address)
port	The server port (1-65535)
timeout	The <i>timeout</i> in milliseconds for socket operations
compress	true if <i>compression</i> should be used (if possible), otherwise <i>false</i>

### Encoding for UDP Endpoint Parameters

The encoding format of UDP endpoints changed in version 1.1.

#### UDP Endpoint Encoding version 1.0

A UDP endpoint is encoded as an encapsulation containing the following structure:

### Slice

```
struct UDPEndpointData {
 string host;
 int port;
 byte protocolMajor;
 byte protocolMinor;
 byte encodingMajor;
 byte encodingMinor;
 bool compress;
};
```

The endpoint parameters are described in the following table.

Parameter	Description
host	The server host (a host name or IP address)
port	The server port (1-65535)
protocolMajor	The major protocol version supported by the endpoint

protocolMinor	The highest minor protocol version supported by the endpoint
encodingMajor	The major encoding version supported by the endpoint
encodingMinor	The highest minor encoding version supported by the endpoint
compress	true if <a href="#">compression</a> should be used (if possible), otherwise false

### UDP Endpoint Encoding version 1.1

Version 1.1 of the encoding omits the protocol and encoding versions because these attributes are handled as general proxy parameters instead:

Slice
<pre> struct UDPEndpointData {     string host;     int port;     bool compress; }; </pre>

The endpoint parameters are described in the following table.

Parameter	Description
host	The server host (a host name or IP address)
port	The server port (1-65535)
compress	true if <a href="#">compression</a> should be used (if possible), otherwise false

### Encoding for SSL Endpoint Parameters

An SSL endpoint is encoded as an encapsulation containing the following structure:

Slice
<pre> struct SSLEndpointData {     string host;     int port;     int timeout;     bool compress; }; </pre>

The endpoint parameters are described in the following table.

Parameter	Description
host	The server host (a host name or IP address)

port	The server port (1-65535)
timeout	The <code>timeout</code> in milliseconds for socket operations
compress	true if <code>compression</code> should be used (if possible), otherwise <code>false</code>

## Encoding for WS Endpoint Parameters

A WebSocket endpoint is encoded as an encapsulation containing the following structure:

The endpoint parameters are described in the following table.

Parameter	Description
host	The server host (a host name or IP address)
port	The server port (1-65535)
timeout	The <code>timeout</code> in milliseconds for socket operations
compress	true if <code>compression</code> should be used (if possible), otherwise <code>false</code>
resource	A URI representing the web server resource associated with this endpoint

## Encoding for WSS Endpoint Parameters

A WebSocket endpoint is encoded as an encapsulation containing the following structure:

The endpoint parameters are described in the following table.

Parameter	Description
-----------	-------------

host	The server host (a host name or IP address)
port	The server port (1-65535)
timeout	The <code>timeout</code> in milliseconds for socket operations
compress	<code>true</code> if <code>compression</code> should be used (if possible), otherwise <code>false</code>
resource	A URI representing the web server resource associated with this endpoint

## Data Encoding for Optional Values

Slice definitions can use [optional values](#) as parameters and as data members. To make optional values truly useful, the receiver needs the ability to gracefully ignore an optional value that it does not recognize. Although the Ice encoding omits type information and therefore is not self-describing, the encoding for optional values must include enough information for a receiver to determine how many bytes an optional value occupies so that it can skip to the next value in the stream. Despite this requirement, the encoding rules minimize the overhead associated with optional values, as you will see below.

On this page:

- [Overview of the Optional Value Encoding](#)
- [Encoding for Optional Types and Tags](#)
- [Examples of Optional Value Encoding](#)
  - [Optional Parameters Example](#)
  - [Optional Data Members Example](#)

## Overview of the Optional Value Encoding

The encoding for optional parameters and data members follows these general rules:

- Each optional value has a corresponding integer tag that uniquely identifies it.
- Optional values always appear *after* any required values.
- Optional values must be sorted by their tags. (Unlike required values, order of declaration does not affect optional values.)
- An optional value is encoded only if the sender has supplied a value.

Optional data members of a class or exception appear in the [slice](#) after any required data members and before the indirection table, if present. The slice flags must indicate the presence of optional data members, which are included in the byte count for the slice. If a slice contains optional data members, the byte value 255 must be written after the last optional data member; this marker denotes the end of the optional data members and is also included in the byte count for the slice.

The encoding does not use an explicit end marker for optional parameters; the end of the encapsulation also marks the end of any optional parameters.

An optional value is encoded as the tuple *<type, tag, value>*, where *type* is the *optional type* that tells the receiver how to determine the number of bytes occupied by the value. The value itself is marshaled using the standard Ice encoding rules for its Slice type.

Optional values require encoding version 1.1.

## Encoding for Optional Types and Tags

The first byte of an encoded optional value includes the optional type, and may also include the tag. The optional type occupies the first three bits of this byte, as described in the table below:

Name	Value	Description	Used for Slice type
F1	0	The value is encoded in one byte.	bool, byte
F2	1	The value is encoded in two bytes.	short
F4	2	The value is encoded in four bytes.	int, float
F8	3	The value is encoded in eight bytes.	double, long
Size	4	The value is encoded as a <a href="#">size</a> .	enum
VSize	5	A leading <a href="#">size</a> value indicates the number of bytes occupied by the value.	string, fixed-size structure, container of fixed-size elements
FSize	6	A leading 32-bit integer indicates the number of bytes occupied by the value.	variable-size structure, container of variable-size elements
Class	7	A <a href="#">class reference</a> or inline instance.	class

The next five bits of the leading byte contain the tag, but only if the tag value is less than 30. Otherwise, the next five bits contain the value 30 as a marker to indicate that the tag value is encoded as a [size](#) starting with the next byte. As you can see, using tag values in the range 0 to 29 produces the most compact encoding.

Variable-size types whose encoded size cannot be determined in advance use the FSize optional type, where "FSize" denotes a leading fixed-length (32-bit) size. For these types, the sender reserves four bytes to hold the size, encodes the value as usual, then replaces the four bytes with the actual encoded size. This strategy avoids the need to shift the encoded data in the buffer, at the expense of potentially consuming more bytes than necessary to encode the size.

Fixed-size types use the VSize optional type, where "VSize" denotes a leading variable-length size. The sender can determine the encoded size of these types in advance, and therefore encodes it as a size followed by the value as usual.

Strings also use the VSize optional type but do not require an additional size because the string encoding already includes a leading size. The same is true for sequences of `bool` and `byte`.

The optional type `Class` represents a class reference or inline instance. Note that a receiver must decode an inline instance even if it does not recognize the tag value because the instance may be referenced by other parameters.

The following table describes the encoding of Slice types:

Slice type	Optional type	Data encoding	Notes
<code>bool</code> , <code>byte</code>	F1	value	
<code>short</code>	F2	value	
<code>int</code> , <code>float</code>	F4	value	
<code>long</code> , <code>double</code>	F8	value	
<code>Proxy</code>	FSize	int + data	32-bit integer holds the size of the encoded proxy
<code>class</code>	Class	reference or instance	
<code>enum</code>	Size	size	Enumerator encoded as a size
<code>string</code>	VSize	value	The encoded data for the string already contains a leading size
<code>sequence&lt;bool&gt;</code> , <code>sequence&lt;byte&gt;</code>	VSize	value	The encoded data for the sequence already contains a leading size
<code>sequence&lt;fixed-size type&gt;</code> , <code>dictionary&lt;fixed-size key, fixed-size value&gt;</code>	VSize	size + value	Size can be computed before encoding the container
<code>sequence&lt;variable size type&gt;</code> , <code>dictionary&lt;variable-size key, variable-size value&gt;</code>	FSize	int + value	32-bit integer holds the size of the container

## Examples of Optional Value Encoding

The examples presented below demonstrate the encoding for optional values with typical use cases.

### Optional Parameters Example

The following Slice operation makes use of optional input and output parameters:

Slice
<pre>bool op1(byte b,          optional(2) string name,          short sh,          optional(1) long count,          out double d,          out optional(300) Object* p);</pre>

Suppose the parameters have the values shown in the table below:

Member	Type	Value	Marshaled size (in bytes)
b	byte	77	1
name	string	"joe"	4
sh	short	99	2
count	long	88	8
d	double	3.14	8
p	proxy	nil	2
<i>return value</i>	bool	true	1

The parameters of the outgoing request are encoded in an [encapsulation](#) with all required parameters first, in order of declaration, followed by the optional parameters sorted by tag:

Marshaled value	Size in bytes	Type	Byte offset
77 ( <i>b</i> )	1	byte	0
99 ( <i>sh</i> )	2	short	1
11 ( <i>optional type F8 + tag 1</i> )	1	byte	3
88 ( <i>count</i> )	8	long	4
21 ( <i>optional type VSize + tag 2</i> )	1	byte	12
"joe" ( <i>name</i> )	4	long	13

Using tag values less than 30 allows the encoding to combine the optional type and the tag into the same byte using the expression  $(\text{Tag} \ll 3) + \text{Type}$ .

Now consider the contents of the reply message:

Marshaled value	Size in bytes	Type	Byte offset
3.14 ( <i>d</i> )	8	double	0
true ( <i>return value</i> )	1	bool	8
246 ( <i>optional type FSize + marker 30</i> )	1	byte	9
300 ( <i>tag</i> )	5	size	10
2 ( <i>32-bit FSize</i> )	4	int	15
nil ( <i>p</i> )	2	Object*	19

The body of the reply message contains the out parameter *d*, the return value, and the optional parameter *p*. The tag value 300 is too large to combine with the optional type, therefore it appears immediately following the optional type encoded as a size. A proxy value uses the *FSize* optional type, meaning a 32-bit integer precedes the encoded value to specify its size.

Although the return value is required in this example, an optional return value is treated as if it were an optional out parameter.

The server here supplies a nil value for the optional proxy parameter. The client must not interpret this to mean that the optional parameter is unset; rather, the parameter is set, it just happens to be set to a nil value. If the server had supplied no value for the parameter, it would not appear in the encoding at all.

As an example, if the client does not recognize the optional proxy parameter, it can skip the parameter as follows:

1. Extract the byte containing the optional type
2. Examine the first three bits to determine the type
3. Examine the five remaining bits to determine the tag's status
4. A value of 30 means the tag is encoded separately
5. Extract the tag as a size
6. The optional type *FSize* means a 32-bit integer holds the value's size; extract the integer
7. Skip ahead the specified number of bytes

8. If we have reached the end of the encapsulation, there are no more optional parameters remaining

### Optional Data Members Example

The only difference between the encoding for optional parameters and the encoding for optional data members is the latter uses a marker byte to signify the end of optional parameters in a slice. Consider the following definitions:

**Slice**

```

struct Color
{
 short red;
 short green;
 short blue;
};

class Shape
{
 optional(1) string label;
};

class Rectangle extends Shape
{
 int width;
 int height;
 optional(10) Color fill;
 optional(9) Color border;
 optional(11) float scale;
};

```

Suppose we are encoding an instance of `Rectangle` with the member values shown in the table below:

Member	Type	Value	Marshaled size (in bytes)
label	string	"r1"	3
width	int	41	4
height	int	16	4
fill	Color	0,0,0	6
border	Color	255,255,255	6
scale	float	2.0	4

Using the sliced format, the instance data looks as follows:

Marshaled value	Size in bytes	Type	Byte offset
1 ( <i>instance marker</i> )	1	byte	0
21 ( <i>slice flags: string type ID, size is present, optional members are present</i> )	1	byte	1
"::Rectangle" ( <i>type ID</i> )	12	string	2
34 ( <i>byte count for slice</i> )	4	int	14
41 ( <i>width</i> )	4	int	18

16 ( <i>height</i> )	4	int	22
77 ( <i>optional type VSize + tag 9</i> )	1	byte	26
6 ( <i>VSize</i> )	1	size	27
{0,0,0} ( <i>border</i> )	6	Color	28
85 ( <i>optional type VSize + tag 10</i> )	1	byte	34
6 ( <i>VSize</i> )	1	size	35
{255,255,255} ( <i>fill</i> )	6	Color	36
90 ( <i>optional type F4 + tag 11</i> )	1	byte	42
2.0 ( <i>scale</i> )	4	float	43
255 ( <i>end marker</i> )	1	byte	47
53 ( <i>slice flags: string type ID, size is present, optional members are present, last slice</i> )	1	byte	48
"::Shape" ( <i>type ID</i> )	8	string	49
9 ( <i>byte count for slice</i> )	4	int	57
13 ( <i>optional type VSize + tag 1</i> )	1	byte	61
"r1" ( <i>label</i> )	3	string	62
255 ( <i>end marker</i> )	1	byte	65

Notice the use of an end marker (byte value 255) denoting the end of the optional data members in each slice.

## Protocol Messages

The Ice protocol uses five messages:

- Request (from client to server)
- Batch request (from client to server)
- Reply (from server to client)
- Validate connection (from server to client)
- Close connection (client to server or server to client)

Of these messages, validate and close connection only apply to connection-oriented transports.

As with the [data encoding](#), protocol messages have no alignment restrictions. Each message consists of a message header and (except for validate and close connection) a message body that immediately follows the header.

On this page:

- [Message Header](#)
- [Request Message Body](#)
- [Batch Request Message Body](#)
- [Reply Message Body](#)
- [Validate Connection Message](#)
- [Close Connection Message](#)
- [Protocol State Machine](#)
- [Disorderly Connection Closure](#)

## Message Header

Each protocol message has a 14-byte header that is encoded as if it were the following structure:

The message header members are described in the following table.

Member	Description
magic	A four-byte magic number consisting of the ASCII-encoded values of 'I', 'c', 'e', 'P' (0x49, 0x63, 0x65, 0x50)
protocolMajor	The protocol major version number
protocolMinor	The protocol minor version number
encodingMajor	The encoding major version number
encodingMinor	The encoding minor version number
messageType	The message type

compressionStatus	The <a href="#">compression</a> status of the message
messageSize	The size of the message in bytes, including the header

Currently, both the protocol and the encoding are at version 1.0. The valid message types are shown in the following table.

Message Type	Encoding
Request	0
Batch request	1
Reply	2
Validate connection	3
Close connection	4

The encoding for the message bodies of each of these message types is described in the sections that follow.

## Request Message Body

A request message contains the data necessary to perform an invocation on an object, including the identity of the object, the operation name, and input parameters. A request message is encoded as if it were the following structure:

Slice
<pre> struct RequestData {     int requestId;     Ice::Identity id;     Ice::StringSeq facet;     string operation;     byte mode;     Ice::Context context;     Encapsulation params; }; </pre>

The request members are described in the following table.

Member	Description
requestId	The request identifier
id	The <a href="#">object identity</a>
facet	The <a href="#">facet</a> name (zero- or one-element sequence)
operation	The operation name
mode	A byte representation of <code>Ice::OperationMode</code> (0=normal, 2=idempotent)
context	The invocation <a href="#">context</a>
params	The <a href="#">encapsulated</a> input parameters, in order of declaration

The request identifier zero (0) is reserved for use in [oneway](#) requests and indicates that the server must not send a reply to the client. A non-zero request identifier must uniquely identify the request on a connection, and must not be reused while a reply for the identifier is outstanding.

The `facet` field has either zero elements or one element. An empty sequence denotes the default facet, and a one-element sequence provides the facet name in its first member. If a receiver receives a request with a `facet` field with more than one element, it must throw a `MarshalException`.

## Batch Request Message Body

A `batch` request message contains one or more oneway requests, bundled together for the sake of efficiency. A batch request message is encoded as integer (not a size) that specifies the number of requests in the batch, followed by the corresponding number of requests, encoded as if each request were the following structure:

The batch request members are described in the following table.

Member	Description
<code>id</code>	The object identity
<code>facet</code>	The <code>facet</code> name (zero- or one-element sequence)
<code>operation</code>	The operation name
<code>mode</code>	A byte representation of <code>Ice::OperationMode</code>
<code>context</code>	The invocation <code>context</code>
<code>params</code>	The encapsulated input parameters, in order of declaration

Note that no request ID is necessary for batch requests because only oneway invocations can be batched.

The `facet` field has either zero elements or one element. An empty sequence denotes the default facet, and a one-element sequence provides the facet name in its first member. If a receiver receives a batch request with a `facet` field with more than one element, it must throw a `MarshalException`.

## Reply Message Body

A reply message body contains the results of a twoway invocation, including any return value, out-parameters, or exception. A reply message body is encoded as if it were the following structure:

```

struct ReplyData {
 int requestId;
 byte replyStatus;
 Encapsulation body; // messageSize - 19 bytes
};

```

The first four bytes of a reply message body contain a request ID. The request ID matches an outgoing request and allows the requester to associate the reply with the [original request](#).

The byte following the request ID indicates the status of the request; the remainder of the reply message body following the status byte is an [encapsulation](#) whose contents depend on the status value. The possible reply status values are shown in the table below (most of these values correspond to [common exceptions](#)).

Reply status	Success	Description								
Success	0	A successful reply message is encoded as an <a href="#">encapsulation</a> containing out-parameters (in the order of declaration), followed by the return value for the invocation, encoded according to their types as specified in <a href="#">Data Encoding</a> . If an operation declares a <code>void</code> return type and no out-parameters, an empty encapsulation is encoded.								
User exception	1	A user exception reply message contains an <a href="#">encapsulation</a> containing the <a href="#">encoded user exception</a> .								
Object does not exist	2	<p>If the target object does not exist, the reply message is encoded as if it were the following structure inside an <a href="#">encapsulation</a>:</p> <div data-bbox="436 932 1446 1268" style="border: 1px solid black; padding: 10px; margin: 10px 0;"> <p style="text-align: center;"><b>Slice</b></p> <pre> struct ReplyData {     Ice::Identity id;     Ice::StringSeq facet;     string operation; }; </pre> </div> <p>The invalid object reply members are described below:</p> <table border="1" data-bbox="397 1329 902 1488"> <thead> <tr> <th>Member</th> <th>Description</th> </tr> </thead> <tbody> <tr> <td><code>id</code></td> <td>The object identity</td> </tr> <tr> <td><code>facet</code></td> <td>The <a href="#">facet</a> name (zero- or one-element sequence)</td> </tr> <tr> <td><code>operation</code></td> <td>The operation name</td> </tr> </tbody> </table> <p>The <code>facet</code> field has either zero elements or one element. An empty sequence denotes the default facet, and a one-element sequence provides the facet name in its first member. If a receiver receives a reply with a <code>facet</code> field with more than one element, it must throw a <code>MarshalException</code>.</p>	Member	Description	<code>id</code>	The object identity	<code>facet</code>	The <a href="#">facet</a> name (zero- or one-element sequence)	<code>operation</code>	The operation name
Member	Description									
<code>id</code>	The object identity									
<code>facet</code>	The <a href="#">facet</a> name (zero- or one-element sequence)									
<code>operation</code>	The operation name									
Facet does not exist	3	If the target object does not support the facet encoded in the request message, the reply message is encoded as for reply status 2.								
Operation does not exist	4	If the target object does not support the operation encoded in the request message, the reply message is encoded as for reply status 2.								
Unknown Ice local exception	5	The reply message for an unknown Ice local exception is encoded as an <a href="#">encapsulation</a> containing a single string that describes the exception.								

Unknown Ice user exception	6	The reply message for an unknown Ice user exception is encoded as an <a href="#">encapsulation</a> containing a single string that describes the exception.
Unknown exception	7	The reply message for an unknown exception is encoded as an <a href="#">encapsulation</a> containing a single string that describes the exception.

## Validate Connection Message

A server sends a validate connection message when it receives a new connection.

Validate connection messages are only used for connection-oriented transports.

The message indicates that the server is ready to receive requests; the client must not send any messages on the connection until it has received the validate connection message from the server. No reply to the message is expected by the server.

The purpose of the validate connection message is two-fold:

- It confirms to the client that the server is indeed an Ice server and not another type of server reached by accident.
- It prevents the client from writing a request message to its local transport buffers until after the server has acknowledged that it can actually process the request. This avoids a race condition caused by the server's TCP/IP stack accepting connections in its backlog while the server is in the process of shutting down: if the client were to send a request in this situation, the request would be lost but the client could not safely re-issue the request because that might violate at-most-once semantics. The validate connection message guarantees that a server is not in the middle of shutting down when the server's TCP/IP stack accepts an incoming connection and so avoids the race condition.

As of Ice 3.6, validate connection messages may also be sent at any time by either side as a heartbeat. See [Active Connection Management](#) for more information.

The [message header](#) comprises the entire validate connection message. The [compression](#) status of a validate connection message is always 0.

## Close Connection Message

A close connection message is sent when a peer is about to gracefully shutdown a [connection](#).

Close connection messages are only used for connection-oriented transports.

The [message header](#) comprises the entire close connection message. The [compression](#) status of a close connection message is always 0.

Either client or server can initiate connection closure. On the client side, connection closure is triggered by [Active Connection Management \(ACM\)](#), which automatically reclaims connections that have been idle for some time.

This means that connection closure can be initiated at will by either end of a connection; most importantly, no state is associated with a connection as far as the object model or application semantics are concerned.

The client side can close a connection whenever no reply for a request is outstanding on the connection. The sequence of events is:

1. The client sends a close connection message.
2. The client closes the writing end of the connection.
3. The server responds to the client's close connection message by closing the connection.

The server side can close a connection whenever no operation invocation is in progress that was invoked via that connection. This guarantees that the server will not violate [at-most-once semantics](#): an operation, once invoked in a servant, is allowed to complete and its results are returned to the client. Note that the server can close a connection even after it has received a request from the client, provided that the request has not yet been passed to a servant. In other words, if the server decides that it wants to close a connection, the sequence of events is:

1. The server discards all incoming requests on the connection.
2. The server waits until all still executing requests have completed and their results have been returned to the client.
3. The server sends a close connection message to the client.

4. The server closes its writing end of the connection.
5. The client responds to the server's close connection message by closing both its reading and writing ends of the connection.
6. If the client has outstanding requests at the time it receives the close connection message, it re-issues these requests on a new connection. Doing so is guaranteed not to violate at-most-once semantics because the server guarantees not to close a connection while requests are still in progress on the server side.

## Protocol State Machine

From a client's perspective, the Ice protocol behaves according to the state machine shown below:

*Protocol state machine.*

To summarize, a new connection is inactive until a [validate connection](#) message has been received by the client, at which point the active state is entered. The connection remains in the active state until it is shut down, which can occur when there are no more proxies using the connection, or after the connection has been idle for a while. At this point, the connection is [gracefully closed](#), meaning that a [close connection](#) message is sent, and the connection is closed.

## Disorderly Connection Closure

Any violation of the protocol or encoding rules results in a disorderly connection closure: the side of the connection that detects a violation unceremoniously closes it (without sending a close connection message or similar). There are many potential error conditions that can lead to disorderly connection closure; for example, the receiver might detect that a message has a bad magic number or incompatible version, receive a reply with an ID that does not match that of an outstanding request, receive a validate connection message when it should not, or find illegal data in a request (such as a negative size, or a size that disagrees with the actual data that was unmarshaled).

## Protocol Compression

Compression is an optional feature of the Ice protocol; whether it is used for a particular message is determined by several factors:

1. Compression may not be supported on all platforms or in all language mappings.
2. Compression can be used in a request or batch request only if the endpoint [advertises](#) the ability to accept compressed messages.
3. For efficiency reasons, the Ice protocol engine does not compress messages smaller than 100 bytes.

A compliant implementation of the protocol is free to compress messages that are smaller than 100 bytes — the choice is up to the protocol implementation.

If compression is used, the entire message excluding the [header](#) is compressed using the bzip2 algorithm [1]. The `messageSize` member of the message header therefore reflects the size of the compressed message, including the uncompressed header, plus an additional four bytes.

The `compressionStatus` field of the message header indicates whether a message is compressed and whether the sender can accept a compressed reply, as shown in the table below.

Reply status	Encoding	Applies to	Description
Message is uncompressed, sender cannot accept a compressed reply.	0	Request, Batch Request, Reply, Validate Connection, Close Connection	A client that does not support compression always uses this value. A client that supports compression sets the value to 0 if the endpoint via which the request is dispatched indicates that it does not support compression. A server uses this value for uncompressed replies.
Message is uncompressed, sender can accept a compressed reply.	1	Request, Batch Request	A client uses this value if the endpoint via which the request is dispatched indicates that it supports compression, but the client has decided not to use compression for this particular request (presumably because the request is too small, so compression does not provide any saving).
Message is compressed and sender can accept a compressed reply.	2	Request, Batch Request, Reply	A client that supports compression sets this value only if the endpoint via which the request is dispatched indicates that it supports compression. A server uses this value for compressed replies.

The message body of a compressed request, batch request, or reply message is encoded by first writing the size of the uncompressed message (including its header) as a four-byte integer, followed by the compressed message body (excluding the header). It follows that the size of a compressed message is 14 bytes for the header, plus four bytes to record the size of the uncompressed message, plus the number of bytes occupied by the compressed message body. Writing the uncompressed message size prior to the body enables the receiver to allocate a buffer that is large enough to accommodate the uncompressed message body.

Note that compression is likely to improve performance only over lower-speed links, for which bandwidth is the overall limiting factor. Over high-speed LAN links, the CPU time spent on compressing and uncompressing messages is longer than the time it takes to just send the uncompressed data.

## Protocol and Encoding Versions

On this page:

- [Version Flexibility](#)
- [Version Ground Rules](#)

### Version Flexibility

As we saw in the preceding sections, both the Ice protocol and encoding have separate major and minor version numbers. Separate versioning of protocol and encoding has the advantage that neither depends on the other: any version of the Ice protocol can be used with any version of the encoding, so they can evolve independently. For example, you could send a request with Ice protocol version 1.1, and encode the parameters with encoding version 2.3.

The Ice versioning mechanism provides the maximum possible amount of interoperability between clients and servers that use different versions of the Ice run time. In particular, older deployed clients can communicate with newer deployed servers and vice versa, provided that the message contents use types that are understandable to both sides. Intermediary servers, such as a Glacier2 router, do not and should not check the contents of the requests and responses they forward; this way, an older intermediary server can forward messages encoded with a newer encoding that it does not understand.

Due to a bug, a Glacier2 router prior to version 3.5 can only forward messages encoded using the 1.0 encoding.

Ice 3.5 introduced a new encoding, encoding version 1.1, in support of several new features such as the ability to define optional parameters in operations. In order to send a request with an optional parameter, you need to use encoding 1.1 or greater.

Ice 3.5 (or newer) is capable of marshaling and unmarshaling messages with both the 1.0 and 1.1 encodings (it uses the 1.1 encoding by default). This allows interoperability to the maximum extent possible:

Client Ice Version	Server Ice Version	Encoding Version	Operation without Optional Parameter	Operation with Optional Parameter
3.4 or earlier	3.4 or earlier	1.0	Yes	No
3.4 or earlier	3.5 or newer	1.0	Yes	No
3.5 or newer	3.4 or earlier	1.0	Yes	No
3.5 or newer	3.5 or newer	1.1	Yes	Yes

When an Ice 3.5 (or newer) client sends a request to an Ice 3.4 server, it must naturally use the 1.0 encoding. This is achieved by setting correctly (and often automatically) the encoding version on the proxy used. If this proxy is received by the client through a response using the 1.0 encoding, the decoded proxy will automatically have the desired 1.0 encoding (all proxies in a 1.0-encoded message implicitly have 1.0 as their encoding version and 1.0 as their protocol version). If this proxy is created with `stringToProxy` or `propertyToProxy`, the client will need to set this proxy's encoding version to 1.0 through one of the following methods:

- with `-e 1.0` in the source stringified proxy
- by creating a new proxy with the desired encoding version, by calling `ice_encodingVersion("1.0")` on the proxy
- by setting `Ice.Default.EncodingVersion` to 1.0.

### Version Ground Rules

For versioning of the protocol and encoding to be possible, all versions (present and future) of the Ice run time adhere to a few ground rules:

1. **Encapsulations** always have a six-byte header; the first four bytes are the size of the encapsulation (including the size of the header), followed by two bytes that indicate the major and minor version. How to interpret the remainder of the encapsulation depends on the major and minor version.
2. The first eight bytes of a **message header** always contain the magic number 'I', 'c', 'e', 'P', followed by four bytes of version information (two bytes for the protocol major and minor number, and two bytes for the encoding major and minor number). How to interpret the remainder of the header and the message body depends on the major and minor version.

These ground rules ensure that all current and future versions of the Ice run time can at least identify the version and size of an encapsulation and a message. This is particularly important for message switches such as [IceStorm](#); by keeping the version and size information in a fixed format, it is possible to forward messages that are, for example, at version 2.0, even though the message switch itself may still be at version 1.0.

- [Servant Evictors](#)
- [Object Life Cycle](#)

## Optional Values

Version 1.1 of the Ice [encoding](#) introduces a convenient new feature that allows you to declare data members and parameters as optional. Collectively called *optional values*, this feature provides two main benefits for Ice applications:

- It offers a simple and natively-supported mechanism for representing values that may or may not be present, without consuming any additional space in a message when an optional value is not used.
- It significantly improves the ability to gradually evolve components of an Ice application while maintaining backward compatibility with existing deployments.

On this page:

- [Motivation for Optional Values](#)
  - [Alternative Strategies for Modeling Optional Values](#)
  - [Addressing the Versioning Problem](#)

  - [Optional Parameters in Operations](#)
  - [Optional Data Members in Classes and Exceptions](#)
- [Guidelines for using Optional Values](#)
- [Backward Compatibility with Encoding Version 1.0](#)
- [Using Optional Values Efficiently](#)

### Motivation for Optional Values

This section describes the issues that prompted the development of this new feature.

### Alternative Strategies for Modeling Optional Values

Prior to Ice 3.5, developers did not have a convenient way to model an optional value. One possibility was to wrap the value in a Slice class:

```

class OptionalInt
{
 int i;
};

interface Example
{
 void compute(int input, OptionalInt scale);
};

```

The ability to pass a nil value for a class instance means the receiver can interpret nil to mean "not present", and the four bytes required to encode a nil value are a reasonable price to pay. Although this is a workable strategy, it incurs significantly more overhead when the optional value is present because the encoding for class instances is expensive. In the example above, an integer value that would have consumed just four bytes when encoded becomes a class instance that could require ten times as much space in the encoding.

The new "compact" encoding for Slice classes would lower the overhead of this strategy, but it still cannot match the [efficiency](#) of the encoding for optional values.

A much more efficient alternative was to use a sequence:

### Slice

```
sequence<int> OptionalInt;

interface Example
{
 void compute(int input, OptionalInt scale);
};
```

Passing an empty sequence signifies the "not present" case and consumes only a single byte in the encoding. When the value is present, passing a sequence with one element adds just one byte of overhead to the encoded value. Despite its minimal overhead, constructing temporary sequences in application code becomes awkward and tedious. Furthermore, depending on the language mapping in use, it is not always obvious that a given sequence parameter actually represents an optional value. Consider the Java language mapping for `compute`:

### Java

```
public interface Example : ...
{
 void compute(int input, int[] scale, ...);
}
```

A developer looking at this API for the first time has no indication that the `scale` parameter is optional, which can lead to unintentional misuse and programming errors.

## Addressing the Versioning Problem

Aside from the inability to conveniently model an optional value, another motivating factor is versioning. As an application evolves over time, it is only natural for its Slice definitions to change. However, there are only a few kinds of changes you can make to your Slice definitions if your goal is to maintain "on-the-wire" compatibility with existing deployments:

- Adding new interfaces
- Adding new data types that are only used by new operations and interfaces
- Adding new operations to existing interfaces
- Renaming existing parameters and data members
- Renaming structures, sequences, dictionaries, enumerations, and enumerators

The nature of the Ice [encoding rules](#) make these changes possible. For example, the encoding does not include the names of data members or parameters, therefore changing their names does not affect backward compatibility. Similarly, the fact that the encoding for an invocation uses the operation's name to select the target operation, and not some other identification scheme such as a numeric index, means you can add new operations to an existing interface without breaking backward compatibility.

Making any of the following modifications is considered a "breaking" change:

- Changing the type of a data member or parameter
- Changing the declaration order of data members or parameters
- Renaming an operation, interface, class, or exception

These changes directly impact the encoding and prevent an existing receiver from successfully decoding the message. Before the introduction of optional values, we recommended using [facets](#) to manage a breaking change. Now optional values give you an alternative solution, but only for [certain types of changes](#).

## Overview of Optional Values

The optional syntax is the same for both parameters and data members:

```
optional(tag) type name
```

The `optional` keyword, new in Ice 3.5, denotes an optional value with the given tag. The value for `tag` must be a non-negative integer.

If your Slice definitions currently use `optional` as an identifier, you can continue using it as an identifier by escaping it as `\optional`.

Data members and parameters not marked as optional are considered *required*; a sender must supply values for all required parameters and members.

Each language mapping defines APIs for passing an optional value, indicating that an optional value is not set, and testing whether an optional value is set. For example, the three strongly-typed languages that Ice currently supports (C++, C#, and Java) all use a similar API: an `Optional` type wraps the optional value and provides methods for examining and changing its value. C++ and C# also define the "marker" value `None` that can be substituted for any optional value to indicate that it is unset. No `Optional` type is necessary for the scripting languages, where you simply pass the value (if set) or the marker value `Unset`. Refer to the language mapping sections for more details on optional values.

A well-behaved program must not assume that an optional data member or parameter always has a value.

An optional value incurs no additional overhead in the encoding when its value is unset. If an optional parameter or member has a value, its overhead depends on [several factors](#), including your choice of tag values.

## Optional Parameters in Operations

An operation may [declare as optional](#) its return value and any of its parameters. The ordering rules for parameters remain unchanged: all input parameters must precede the output parameters.

The following Slice operation declares a mix of optional and required parameters, as well as an optional return value:

**Slice**

```
interface Database
{
 optional(3) Record
 lookup(string key, optional(1) Filter f, out optional(2) Cursor
 matches);
};
```

We can invoke `lookup` in C++ as shown below:

**C++**

```

DatabasePrx proxy = ...;
Optional<Record> rec;
Optional<Cursor> matches;
rec = proxy->lookup("someKey", IceUtil::None, matches);
if(rec)
{
 // lookup returned a value

 if(matches)
 {
 // there are more matches
 }
}

```

Notice that we pass `IceUtil::None` for the `Filter` value to indicate that this parameter is unset.

### Optional Data Members in Classes and Exceptions

Data members can be declared as optional in classes and exceptions. Structures do not support optional data members.

Consider the following example:

**Slice**

```

class Account
{
 string accountNo;
 optional(9) Account referrer;
};

```

We can use `Account` in C# as shown below:

**C#**

```

void printAccount(Account acct)
{
 Console.WriteLine("Account #: " + acct.accountNo);
 if(acct.referrer.HasValue)
 Console.WriteLine("Referrer: " + acct.referrer.Value.accountNo);
 else
 Console.WriteLine("Referrer: None");
}

Account a1 = new Account("100-21807", Ice.Util.None);
printAccount(a1);
Account a2 = new Account("165-75122", a1);
printAccount(a2);

```

Implicit conversion operators in C# allow us to pass a value of the declared type, or `Ice.Util.None` for an unset value, where an optional value is expected.

## Guidelines for using Optional Values

Keep the following guidelines in mind while using optional values:

- Consider an optional value as a logical unit composed of its tag and type. The parameter or member name is not included in the Ice encoding, therefore changes to the name do not affect on-the-wire compatibility. Changing the tag of a value is equivalent to adding a new value: the previous iteration of the value still exists as long as there is at least one deployed program that might use it.
- To change the type of an optional value without affecting compatibility with existing deployments, you must also change its tag. You are essentially deprecating the old value and adding a new one.
- Whenever you change the tag of a value, we recommend making a note of the old definition (such as in a Slice comment) so that you do not accidentally reuse its tag.
- Adding a new optional parameter or member does not affect compatibility with existing deployments as long as its tag is not currently in use.
- Removing an optional parameter or member does not affect compatibility with existing deployments if programs are written correctly to test for the presence of the value prior to using it.
- The order of declaration is important for required members and parameters, but is not important for optional members and parameters. If you wish to maintain compatibility with existing deployments, do not change the order of declaration for required members and parameters. Compatibility is not affected by changes to the order of optional members and parameters.

## Backward Compatibility with Encoding Version 1.0

Optional values require version 1.1 of the Ice encoding. If the intended receiver only supports version 1.0 of the encoding, the Ice run time in the sender will omit all optional parameters when marshaling the operation's parameters or results, and omit all optional data members. This behavior makes it possible for you to add optional parameters to an operation, or optional members to a class or exception, without affecting backward compatibility with existing deployments that use version 1.0 of the encoding, while gaining the ability to exchange optional values with new deployments that use version 1.1 of the encoding.

For example, suppose existing deployments use the following class definition:

### Slice

```
// Version 1
class Person
{
 string firstName;
 string lastName;
};
```

We can safely add an optional member without affecting compatibility:

### Slice

```
// Version 2
class Person
{
 string firstName;
 string lastName;
 optional(1) Date birthDate;
};
```

It is even safe to insert an optional member between two existing members:

### Slice

```
// Version 3
class Person
{
 string firstName;
 optional(2) string middleName;
 string lastName;
 optional(1) Date birthDate;
};
```

When sending an instance of `Person` to a receiver that supports only encoding version 1.0, the optional members are omitted and the encoded form matches our initial version of the class.

A similar situation exists for operations. For example, the following three operations are compatible when using encoding version 1.0:

### Slice

```

Person createPerson(string firstName, string lastName); // V1

Person createPerson(string firstName, string lastName, optional(1) Date
birthDate); // V2

Person createPerson(string firstName, optional(2) string middleName,
string lastName,
 optional(1) Date birthDate); // V3

```

Note however that other types of changes can easily [break compatibility](#).

## Using Optional Values Efficiently

The Ice [encoding](#) uses a self-describing format to minimize the overhead associated with optional data members and allow for efficient decoding in a receiver. The amount of overhead required for a member depends on the member's type and its tag. The type contributes between one and five bytes of overhead, while the tag value contributes an additional zero to five bytes. Tag values less than 30 add no additional overhead; tag values between 30 and 254 add a single byte, and tag values of 255 or greater add five bytes.

The overhead associated with the member's type is out of your control, but you have direct control of the overhead for tags. To minimize this overhead, use tags in the range zero to 29.

The table below describes the overhead associated with several common Slice types:

Type	Overhead (bytes)
Primitive (including <code>string</code> )	1
Proxy	5
Object	1
Sequence of <code>byte</code> , <code>bool</code>	1
Sequence	2-5
Enumerator	1
Structure	2-5
Dictionary	2-5

Refer to the encoding specification for more details on marshaling optional data members.

## Server Implementation Techniques

As mentioned in [Servant Locators](#), instantiating a servant for each Ice object on server start-up is a viable design, provided that you can afford the amount of memory required by the servants, as well as the delay in start-up of the server. However, Ice supports more flexible mappings between Ice objects and servants; these alternate mappings allow you to precisely control the trade-off between memory consumption, scalability, and performance. We outline a few of the more common implementation techniques here.

On this page:

- [Incremental Server Initialization](#)
- [Implementing a Server using Default Servants](#)
  - [Overriding ice\\_ping](#)
- [Combining Server Implementation Techniques](#)

### Incremental Server Initialization

If you use a [servant locator](#), the servant returned by `locate` is used only for the current request, that is, the Ice run time does not add the servant to the [Active Servant Map](#) (ASM). Of course, this means that if another request comes in for the same Ice object, `locate` must again retrieve the object state and instantiate a servant. A common implementation technique is to add each servant to the ASM as part of `locate`. This means that only the first request for each Ice object triggers a call to `locate`; thereafter, the servant for the corresponding Ice object can be found in the ASM and the Ice run time can immediately dispatch another incoming request for the same Ice object without having to call the servant locator.

An implementation of `locate` to do this would look something like the following:

```

C++

Ice::ObjectPtr
MyServantLocator::locate(const Ice::Current& c, Ice::LocalObjectPtr&)
{
 // Get the object identity. (We use the name member
 // as the database key.)
 //
 std::string name = c.id.name;

 // Use the identity to retrieve the state from the database.
 //
 ServantDetails d;
 try {
 d = DB_lookup(name);
 } catch (const DB_error&)
 return 0;
 }

 // We have the state, instantiate a servant.
 //
 Ice::ObjectPtr servant = new PhoneEntryI(d);

 // Add the servant to the ASM.
 //
 c.adapter->add(servant, c.id); // NOTE: Incorrect!

 return servant;
}
```

This is almost identical to the implementation seen in our [earlier example](#) — the only difference is that we also [add the servant to the ASM](#) by calling `ObjectAdapter::add`. Unfortunately, this implementation is wrong because it suffers from a race condition. Consider the situation where we do not have a servant for a particular Ice object in the ASM, and two clients more or less simultaneously send a request for the same Ice object. It is entirely possible for the thread scheduler to schedule the two incoming requests such that the Ice run time completes the lookup in the ASM for both requests and, for each request, concludes that no servant is in memory. The net effect is that `locate` will be called twice for the same Ice object, and our servant locator will instantiate two servants instead of a single servant. Because the second call to `ObjectAdapter::add` will raise an `AlreadyRegisteredException`, only one of the two servants will be added to the ASM.

Of course, this is hardly the behavior we expect. To avoid the race condition, our implementation of `locate` must check whether a concurrent invocation has already instantiated a servant for the incoming request and, if so, return that servant instead of instantiating a new one. The Ice run time provides the `ObjectAdapter::find` operation to allow us to test whether an entry for a specific identity already exists in the ASM:

Slice
<pre> module Ice {     local interface ObjectAdapter {         // ...          Object find(Identity id);          // ...     }; }; </pre>

`find` returns the servant if it exists in the ASM and null, otherwise. Using this lookup function, together with a mutex, allows us to correctly implement `locate`. The class definition of our servant locator now has a private mutex so we can establish a critical region inside `locate`:

C++
<pre> class MyServantLocator : public virtual Ice::ServantLocator { public:      virtual Ice::ObjectPtr locate(const Ice::Current&amp; c, Ice::LocalObjectPtr&amp;);      // Declaration of finished() and deactivate() here...  private:     IceUtil::Mutex _m; }; </pre>

The `locate` member locks the mutex and tests whether a servant is already in the ASM: if so, it returns that servant; otherwise, it instantiates a new servant and adds it to the ASM as before:

**C++**

```

Ice::ObjectPtr
MyServantLocator::locate(const Ice::Current& c, Ice::LocalObjectPtr&)
{
 IceUtil::Mutex::Lock lock(_m);

 // Check if we have instantiated a servant already.
 //
 Ice::ObjectPtr servant = c.adapter.find(c.id);

 if (!servant) { // We don't have a servant already

 // Instantiate a servant.
 //
 ServantDetails d;
 try {
 d = DB_lookup(c.id.name);
 } catch (const DB_error&) {
 return 0;
 }
 servant = new PhoneEntryI(d);

 // Add the servant to the ASM.
 //
 c.adapter->add(servant, c.id);
 }

 return servant;
}

```

The Java version of this locator is almost identical, but we use the `synchronized` qualifier instead of a mutex to make `locate` a critical region:

### Java

```
synchronized public Ice.Object
locate(Ice.Current c, Ice.LocalObjectHolder cookie)
{
 // Check if we have instantiated a servant already.
 //
 Ice.Object servant = c.adapter.find(c.id);

 if (servant == null) { // We don't have a servant already

 // Instantiate a servant
 //
 ServantDetails d;
 try {
 d = DB.lookup(c.id.name);
 } catch (DB.error&) {
 return null;
 }
 servant = new PhoneEntryI(d);

 // Add the servant to the ASM.
 //
 c.adapter.add(servant, c.id);
 }

 return servant;
}
```

In C#, you can place the body of `locate` into a `lock(this)` statement.

Using a servant locator that adds the servant to the ASM has a number of advantages:

- Servants are instantiated on demand, so the cost of initializing the servants is spread out over many invocations instead of being incurred all at once during server start-up.
- The memory requirements for the server are reduced because servants are instantiated only for those Ice objects that are actually accessed by clients. If clients only access a subset of the total number of Ice objects, the memory savings can be substantial.

In general, incremental initialization is beneficial if instantiating servants during start-up is too slow. The memory savings can be worthwhile as well but, as a rule, are realized only for comparatively short-lived servers: for long-running servers, chances are that, sooner or later, every Ice object will be accessed by some client or another; in that case, there are no memory savings because we end up with an instantiated servant for every Ice object regardless.

## Implementing a Server using Default Servants

[Default servants](#) are a very effective tool for conserving memory when a server hosts a large number of Ice objects.

To create a default servant implementation, we need as many default servants as there are non-abstract interfaces in the system. For example, for our [file system application](#), we require two default servants, one for directories and one for files. In addition, the [object identities](#) we create use the `category` member of the object identity to encode the type of interface of the corresponding Ice object. The value of the `category` field can be anything that identifies the interface, such as the 'd' and 'f' convention we [suggested earlier](#). Alternatively, you could use "Directory" and "File", or use the type ID of the corresponding interface, such as ":::Filesystem:::Directory" and ":::File

`system::File`". The `name` member of the object identity must be set to whatever identifier we can use to retrieve the persistent state of each directory and file from secondary storage. (For our file system application, we used a UUID as a unique identifier.)

Registration of the default servants is as follows:

### C++

```
adapter->addDefaultServant(new DirectoryI, "d");
adapter->addDefaultServant(new FileI, "f");
```

All the action happens in the implementation of the operations, using the following steps for each operation:

1. Use the passed `Current` object to get the identity for the current request.
2. Use the `name` member of the identity to locate the persistent state of the servant on secondary storage. If no record can be found for the identity, throw an `ObjectNotExistException`.
3. Implement the operation to operate on that retrieved state (returning the state or updating the state as appropriate for the operation).

This might look something like the following:

### C++

```
Filesystem::NodeSeq
Filesystem::DirectoryI::list(const Ice::Current& c) const
{
 // Use the identity of the directory to retrieve
 // its contents.
 DirectoryContents dc;
 try {
 dc = DB_getDirectory(c.id.name);
 } catch(const DB_error&) {
 throw Ice::ObjectNotExistException(__FILE__, __LINE__);
 }

 // Use the records retrieved from the database to
 // initialize return value.
 //
 Filesystem::NodeSeq ns;
 // ...

 return ns;
}
```

Note that the servant implementation is completely stateless: the only state it operates on is the identity of the Ice object for the current request (and that identity is passed as part of the `Current` parameter).

## Overriding `ice_ping`

We **recommended** that a default servant implementation take steps to preserve the semantics of the `ice_ping` operation, which is used to test whether an Ice object exists. If a default servant fails to override `ice_ping`, clients may mistakenly believe that a non-existent Ice object still exists. The code below demonstrates how we can override the operation in our file system application:

**C++**

```

void
Filesystem::DirectoryI::ice_ping(const Ice::Current& c) const
{
 try {
 d = DB_lookup(c.id.name);
 } catch (const DB_error&) {
 throw Ice::ObjectNotExistException(__FILE__, __LINE__);
 }
}

```

It is good practice to override `ice_ping` if you are using default servants.

## Combining Server Implementation Techniques

Depending on the nature of your application, you may be able to steer a middle path that provides better performance while keeping memory requirements low: if your application has a number of frequently-accessed objects that are performance-critical, you can add servants for those objects to the ASM. If you store the state of these objects in data members inside the servants, you effectively have a cache of these objects.

The remaining, less-frequently accessed objects can be implemented with a default servant. For example, in our file system implementation, we could choose to instantiate directory servants permanently, but to have file objects implemented with a default servant. This provides efficient navigation through the directory tree and incurs slower performance only for the (presumably less frequent) file accesses.

This technique could be augmented with a cache of recently-accessed files, along similar lines to the buffer pool used by the Unix kernel [1]. The point is that you can combine use of the ASM with servant locators and default servants to precisely control the trade-offs among scalability, memory consumption, and performance to suit the needs of your application.

## Servant Evictors

A particularly interesting use of a [servant locator](#) is as an *evictor* [1]. An evictor is a servant locator that maintains a cache of servants:

- Whenever a request arrives (that is, `locate` is called by the Ice run time), the evictor checks to see whether it can find a servant for the request in its cache. If so, it returns the servant that is already instantiated in the cache; otherwise, it instantiates a servant and adds it to the cache.
- The cache is a queue that is maintained in least-recently used (LRU) order: the least-recently used servant is at the tail of the queue, and the most-recently used servant is at the head of the queue. Whenever a servant is returned from or added to the cache, it is moved from its current queue position to the head of the queue, that is, the "newest" servant is always at the head, and the "oldest" servant is always at the tail.
- The queue has a configurable length that corresponds to how many servants will be held in the cache; if a request arrives for an Ice object that does not have a servant in memory and the cache is full, the evictor removes the least-recently used servant at the tail of the queue from the cache in order to make room for the servant about to be instantiated at the head of the queue.

The figure below illustrates an evictor with a cache size of five after five invocations have been made, for object identities 1 to 5, in that order.

*An evictor after five invocations for object identities 1 to 5.*

At this point, the evictor has instantiated five servants, and has placed each servant onto the evictor queue. Because requests were sent by the client for object identities 1 to 5 (in that order), servant 5 ends up at the head of the queue (at the most-recently used position), and servant 1 ends up at the tail of the queue (at the least-recently used position).

Assume that the client now sends a request for servant 3. In this case, the servant is found on the evictor queue and moved to the head position. The resulting ordering is shown below:

*The evictor after accessing servant 3.*

Assume that the next client request is for object identity 6. The evictor queue is fully populated, so the evictor creates a servant for object identity 6, places that servant at the head of the queue, and evicts the servant with identity 1 (the least-recently used servant) at the tail of the queue, as you can see here:

*The evictor after evicting servant 1.*

The evictor pattern combines the advantages of the ASM with the advantages of a [default servant](#): provided that the cache size is sufficient to hold the working set of servants in memory, most requests are served by an already instantiated servant, without incurring the overhead of creating a servant and accessing the database to initialize servant state. By setting the cache size, you can control the trade-off between performance and memory consumption as appropriate for your application.

The following pages show how to implement an evictor in several languages. (You can also find the source code for the evictor with the code examples for this manual in the Ice distribution.)

## Implementing a Servant Evictor in C++

On this page:

- [The EvictorBase Class in C++](#)
- [Using Servant Evictors in C++](#)

### The EvictorBase Class in C++

The `evictor` we show here is designed as an abstract base class: in order to use it, you derive a class from the `EvictorBase` base class and implement two methods that are called by the evictor when it needs to add or evict a servant. This leads to a class definition as follows:

```

C++

```

class EvictorBase : public Ice::ServantLocator {
public:
    EvictorBase(int size = 1000);

    virtual Ice::ObjectPtr locate(const Ice::Current& c,
Ice::LocalObjectPtr& cookie);

    virtual void finished(const Ice::Current& c, const Ice::ObjectPtr&,
                        const Ice::LocalObjectPtr& cookie);

    virtual void deactivate(const std::string&);

protected:
    virtual Ice::ObjectPtr add(const Ice::Current&,
Ice::LocalObjectPtr&) = 0;

    virtual void evict(const Ice::ObjectPtr&,
const Ice::LocalObjectPtr&) = 0;

private:
    // ...
};

typedef IceUtil::Handle<EvictorBase> EvictorBasePtr;

```

```

Note that the evictor has a constructor that sets the size of the queue, with a default argument to set the size to 1000.

The `locate`, `finished`, and `deactivate` functions are inherited from the `ServantLocator` base class; these functions implement the logic to maintain the queue in LRU order and to add and evict servants as needed.

The `add` and `evict` functions are called by the evictor when it needs to add a new servant to the queue and when it evicts a servant from the queue. Note that these functions are pure virtual, so they must be implemented in a derived class. The job of `add` is to instantiate and initialize a servant for use by the evictor. The `evict` function is called by the evictor when it evicts a servant, allowing the subclass to perform any cleanup. Note that `add` can return a cookie that the evictor passes to `evict`, so you can move context information from `add` to `evict`.

Next, we need to consider the data structures that are needed to support our evictor implementation. We require two main data structures:

1. A map that maps [object identities](#) to servants, so we can efficiently decide whether we have a servant for an incoming request in memory or not.
2. A list that implements the evictor queue. The list is kept in LRU order at all times.

The evictor map not only stores servants but also keeps track of some administrative information:

1. The map stores the cookie that is returned from `add`, so we can pass that same cookie to `evict`.
2. The map stores an iterator into the evictor queue that marks the position of the servant in the queue. Storing the queue position is not strictly necessary — we store the position for efficiency reasons because it allows us to locate a servant's position in the queue in constant time instead of having to search through the queue in order to maintain its LRU property.
3. The map stores a use count that is incremented whenever an operation is dispatched into a servant, and decremented whenever an operation completes.

The need for the use count deserves some extra explanation: suppose a client invokes a long-running operation on an Ice object with identity *I*. In response, the evictor adds a servant for *I* to the evictor queue. While the original invocation is still executing, other clients invoke operations on various Ice objects, which leads to more servants for other object identities being added to the queue. As a result, the servant for identity *I* gradually migrates toward the tail of the queue. If enough client requests for other Ice objects arrive while the operation on object *I* is still executing, the servant for *I* could be evicted while it is still executing the original request.

By itself, this will not do any harm. However, if the servant is evicted and a client then invokes another request on object *I*, the evictor would have no idea that a servant for *I* is still around and would add a second servant for *I*. However, having two servants for the same Ice object in memory is likely to cause problems, especially if the servant's operation implementations write to a database.

The use count allows us to avoid this problem: we keep track of how many requests are currently executing inside each servant and, while a servant is busy, avoid evicting that servant. As a result, the queue size is not a hard upper limit: long-running operations can temporarily cause more servants than the limit to appear in the queue. However, as soon as excess servants become idle, they are evicted as usual.

The evictor queue does not store the identity of the servant. Instead, the entries on the queue are iterators into the evictor map. This is useful when the time comes to evict a servant: instead of having to search the map for the identity of the servant to be evicted, we can simply delete the map entry that is pointed at by the iterator at the tail of the queue. We can get away with storing an iterator into the evictor queue as part of the map, and storing an iterator into the evictor map as part of the queue because both `std::list` and `std::map` do not invalidate forward iterators when we add or delete entries (except for invalidating iterators that point at a deleted entry, of course).

Reverse iterators *can* be invalidated by modification of list entries: if a reverse iterator points at `rend` and the element at the head of the list is erased, the iterator pointing at `rend` is invalidated.

Finally, our `locate` and `finished` implementations will need to exchange a cookie that contains a smart pointer to the entry in the evictor map. This is necessary so that `finished` can decrement the servant's use count.

This leads to the following definitions in the private section of our evictor:

## C++

```

class EvictorBase : public Ice::ServantLocator {
 // ...

private:

 struct EvictorEntry;
 typedef IceUtil::Handle<EvictorEntry> EvictorEntryPtr;

 typedef std::map<Ice::Identity, EvictorEntryPtr> EvictorMap;
 typedef std::list<EvictorMap::iterator> EvictorQueue;

 struct EvictorEntry : public Ice::LocalObject
 {
 Ice::ObjectPtr servant;
 Ice::LocalObjectPtr userCookie;
 EvictorQueue::iterator queuePos;
 int useCount;
 };

 EvictorMap _map;
 EvictorQueue _queue;
 Ice::Int _size;

 IceUtil::Mutex _mutex;

 void evictServants();
};

```

Note that the evictor stores the evictor map, queue, and the queue size in the private data members `_map`, `_queue`, and `_size`. In addition, we use a private `_mutex` data member so we can correctly serialize access to the evictor's data structures.

The `evictServants` member function takes care of evicting servants when the queue length exceeds its limit — we will discuss this function in more detail shortly.

The `EvictorEntry` structure serves as the cookie that we pass from `locate` to `finished`; it stores the servant, the servant's position in the evictor queue, the servant's use count, and the cookie that we pass from `add` to `evict`.

The implementation of the constructor is trivial. The only point of note is that we ignore negative sizes:

## C++

```

EvictorBase::EvictorBase(Ice::Int size) : _size(size)
{
 if (_size < 0)
 _size = 1000;
}

```

We could have stored the size as a `size_t` instead. However, for consistency with the Java implementation, which cannot use unsigned integers, we use `Ice::Int` to store the size.

Almost all the action of the evictor takes place in the implementation of `locate`:

## C++

```

Ice::ObjectPtr
EvictorBase::locate(const Ice::Current& c, Ice::LocalObjectPtr& cookie)
{
 IceUtil::Mutex::Lock lock(_mutex);

 //
 // Check if we have a servant in the map already.
 //
 EvictorEntryPtr entry;
 EvictorMap::iterator i = _map.find(c.id);
 if (i != _map.end()) {
 //
 // Got an entry already, dequeue the entry from
 // its current position.
 //
 entry = i->second;
 _queue.erase(entry->queuePos);
 } else {
 //
 // We do not have an entry. Ask the derived class to
 // instantiate a servant and add a new entry to the map.
 //
 entry = new EvictorEntry;
 entry->servant = add(c, entry->userCookie); // Down-call
 if (!entry->servant) {
 return 0;
 }
 entry->useCount = 0;
 i = _map.insert(std::make_pair(c.id, entry)).first;
 }

 //
 // Increment the use count of the servant and enqueue
 // the entry at the front, so we get LRU order.
 //
 ++(entry->useCount);
 entry->queuePos = _queue.insert(_queue.begin(), i);

 cookie = entry;

 return entry->servant;
}

```

The first step in `locate` is to lock the `_mutex` data member. This protects the evictor's data structures from concurrent access. The next step is to instantiate a smart pointer to an `EvictorEntry`. That smart pointer acts as the cookie that is returned from `locate` and will be passed by the Ice run time to the corresponding call to `finished`. That same smart pointer is also the value type of our map entries, so we

do not store two copies of the same information redundantly — instead, smart pointers ensure that a single copy of each `EvictorEntry` structure is shared by both the cookie and the map.

The next step is to look in the evictor map to see whether we already have an entry for this object identity. If so, we remove the entry from its current queue position.

Otherwise, we do not have an entry for this object identity yet, so we have to create one. The code creates a new evictor entry, and then calls `add` to get a new servant. This is a down-call to the concrete class that will be derived from `EvictorBase`. The implementation of `add` must attempt to locate the object state for the Ice object with the identity passed inside the `Current` object and either return a servant as usual, or return null or throw an exception to indicate failure. If `add` returns null, we return zero to let the Ice run time know that no servant could be found for the current request. If `add` succeeds, we initialize the entry's use count to zero and insert the entry into the evictor map.

The last few lines of `locate` add the entry for the current request to the head of the evictor queue to maintain its LRU property, increment the use count of the entry, set the cookie that is returned from `locate` to point at the `EvictorEntry`, and finally return the servant to the Ice run time.

The implementation of `finished` is comparatively simple. It decrements the use count of the entry and then calls `evictServants` to get rid of any servants that might need to be evicted:

```

C++

```

void
EvictorBase::finished(const Ice::Current&,
                    const Ice::ObjectPtr&,
                    const Ice::LocalObjectPtr& cookie)
{
    IceUtil::Mutex::Lock lock(_mutex);

    EvictorCookiePtr ec = EvictorCookiePtr::dynamicCast(cookie);

    // Decrement use count and check if
    // there is something to evict.
    //
    --(ec->entry->useCount);
    evictServants();
}

```

```

In turn, `evictServants` examines the evictor queue: if the queue length exceeds the evictor's size, the excess entries are scanned. Any entries with a zero use count are then evicted:

## C++

```

void
EvictorBase::evictServants()
{
 //
 // If the evictor queue has grown larger than the limit,
 // look at the excess elements to see whether any of them
 // can be evicted.
 //
 EvictorQueue::reverse_iterator p = _queue.rbegin();
 int excessEntries = static_cast<int>(_map.size() - _size);

 for (int i = 0; i < excessEntries; ++i) {
 EvictorMap::iterator mapPos = *p;
 if (mapPos->second->useCount == 0) {
 evict(mapPos->second->servant, mapPos->second->userCookie);
 p = EvictorQueue::reverse_iterator(_queue.erase(mapPos->second->queuePos));
 _map.erase(mapPos);
 }
 else
 ++p;
 }
}

```

The code scans the excess entries, starting at the tail of the evictor queue. If an entry has a zero use count, it is evicted: after calling the `evict` member function in the derived class, the code removes the evicted entry from both the map and the queue.

Finally, the implementation of `deactivate` sets the evictor size to zero and then calls `evictServants`. This results in eviction of all servants. The Ice run time [guarantees](#) to call `deactivate` only once no more requests are executing in an object adapter; as a result, it is guaranteed that all entries in the evictor will be idle and therefore will be evicted.

## C++

```

void
EvictorBase::deactivate(const std::string& category)
{
 IceUtil::Mutex::Lock lock(_mutex);

 _size = 0;
 evictServants();
}

```

Note that, with this implementation of `evictServants`, we only scan the tail section of the evictor queue for servants to evict. If we have long-running operations, this allows the number of servants in the queue to remain above the evictor size if the servants in the tail section have a non-zero use count. This means that, even immediately after calling `evictServants`, the queue length can still exceed the evictor size.

We can adopt a more aggressive strategy for eviction: instead of scanning only the excess entries in the queue, if, after looking in the tail section of the queue, we still have more servants in the queue than the queue size, we keep scanning for servants with a zero use count until the queue size drops below the limit. This alternative version of `evictServants` looks as follows:

### C++

```
void
EvictorBase::evictServants()
{
 //
 // If the evictor queue has grown larger than the limit,
 // try to evict servants until the length drops
 // below the limit.
 //
 EvictorQueue::reverse_iterator p = _queue.rbegin();
 int numEntries = static_cast<int>_map.size();

 for (int i = 0; i < numEntries && _map.size() > _size; ++i) {
 EvictorMap::iterator mapPos = *p;
 if (mapPos->second->useCount == 0) {
 evict(mapPos->second->servant, mapPos->second->userCookie);
 p = EvictorQueue::reverse_iterator(_queue.erase(mapPos->second->queuePos));
 _map.erase(mapPos);
 }
 else
 ++p;
 }
}
```

The only difference in this version is that the terminating condition for the `for`-loop has changed: instead of scanning only the excess entries for servants with a use count, this version keeps scanning until the evictor size drops below the limit.

Which version is more appropriate depends on your application: if locating and evicting servants is expensive, and memory is not at a premium, the first version (which only scans the tail section) is more appropriate; if you want to keep memory consumption to a minimum, the second version is more appropriate. Also keep in mind that the difference between the two versions is significant only if you have long-running operations and many concurrent invocations from clients; otherwise, there is no point in more aggressively scanning for servants to remove because they are going to become idle again very quickly and get evicted as soon as the next request arrives.

## Using Servant Evictors in C++

Using a servant evictor is simply a matter of deriving a class from `EvictorBase` and implementing the `add` and `evict` methods. You can turn a servant locator into an evictor by simply taking the code that you wrote for `locate` and placing it into `add` — `EvictorBase` then takes care of maintaining the cache in least-recently used order and evicting servants as necessary. Unless you have clean-up requirements for your servants (such as closing network connections or database handles), the implementation of `evict` can be left empty.

One of the nice aspects of evictors is that you do not need to change anything in your servant implementation: the servants are ignorant of the fact that an evictor is in use. This makes it very easy to add an evictor to an already existing code base with little disturbance of the source code.

Evictors can provide substantial performance improvements over [default servants](#): especially if initialization of servants is expensive (for example, because servant state must be initialized by reading from a network), an evictor performs much better than a default servant, while keeping memory requirements low.

### The `EvictorBase` Class in Java

The `evictor` we show here is designed as an abstract base class: in order to use it, you derive a class from the `Evictor.EvictorBase` base class and implement two methods that are called by the evictor when it needs to add or evict a servant. This leads to a class definition as follows:

## Java

```

package Evictor;

public abstract class EvictorBase implements Ice.ServantLocator
{
 public
 EvictorBase()
 {
 _size = 1000;
 }

 public
 EvictorBase(int size)
 {
 _size = size < 0 ? 1000 : size;
 }

 public abstract Ice.Object
 add(Ice.Current c, Ice.LocalObjectHolder cookie);

 public abstract void
 evict(Ice.Object servant, java.lang.Object cookie);

 synchronized public final Ice.Object
 locate(Ice.Current c, Ice.LocalObjectHolder cookie)
 {
 // ...
 }

 synchronized public final void
 finished(Ice.Current c, Ice.Object o, java.lang.Object cookie)
 {
 // ...
 }

 synchronized public final void
 deactivate(String category)
 {
 // ...
 }

 // ...

 private int _size;
}

```

Note that the evictor has constructors to set the size of the queue, with a default size of 1000.

The `locate`, `finished`, and `deactivate` methods are inherited from the `ServantLocator` base class; these methods implement the logic to maintain the queue in LRU order and to add and evict servants as needed. The methods are synchronized, so the evictor's internal data structures are protected from concurrent access.

The `add` and `evict` methods are called by the evictor when it needs to add a new servant to the queue and when it evicts a servant from the queue. Note that these functions are abstract, so they must be implemented in a derived class. The job of `add` is to instantiate and initialize a servant for use by the evictor. The `evict` function is called by the evictor when it evicts a servant, allowing the subclass to perform any cleanup. Note that `add` can return a cookie that the evictor passes to `evict`, so you can move context information from `add` to `evict`.

Next, we need to consider the data structures that are needed to support our evictor implementation. We require two main data structures:

1. A map that maps `object identities` to servants, so we can efficiently decide whether we have a servant for an incoming request in memory or not.
2. A list that implements the evictor queue. The list is kept in LRU order at all times.

The evictor map not only stores servants but also keeps track of some administrative information:

1. The map stores the cookie that is returned from `add`, so we can pass that same cookie to `evict`.
2. The map stores an iterator into the evictor queue that marks the position of the servant in the queue.
3. The map stores a use count that is incremented whenever an operation is dispatched into a servant, and decremented whenever an operation completes.

The last two points deserve some extra explanation.

- The evictor queue must be maintained in least-recently used order, that is, every time an invocation arrives and we find an entry for the identity in the evictor map, we also must locate the servant's identity on the evictor queue and move it to the front of the queue. However, scanning for that entry is inefficient because it requires  $O(n)$  time. To get around this, we store an iterator in the evictor map that marks the corresponding entry's position in the evictor queue. This allows us to dequeue the entry from its current position and enqueue it at the head of the queue in  $O(1)$  time.

Unfortunately, the various lists provided by `java.util` do not allow us to keep an iterator to a list position without invalidating that iterator as the list is updated. To deal with this, we use a special-purpose linked list implementation, `Evictor.LinkedList`, that does not have this limitation. `LinkedList` has an interface similar to `java.util.LinkedList` but does not invalidate iterators other than iterators that point at an element that is removed. For brevity, we do not show the implementation of this list here — you can find the implementation in the code examples for this manual in the Ice distribution.

- We maintain a use count as part of the map in order to avoid incorrect eviction of servants. Suppose a client invokes a long-running operation on an Ice object with identity *I*. In response, the evictor adds a servant for *I* to the evictor queue. While the original invocation is still executing, other clients invoke operations on various Ice objects, which leads to more servants for other object identities being added to the queue. As a result, the servant for identity *I* gradually migrates toward the tail of the queue. If enough client requests for other Ice objects arrive while the operation on object *I* is still executing, the servant for *I* could be evicted while it is still executing the original request.

By itself, this will not do any harm. However, if the servant is evicted and a client then invokes another request on object *I*, the evictor would have no idea that a servant for *I* is still around and would add a second servant for *I*. However, having two servants for the same Ice object in memory is likely to cause problems, especially if the servant's operation implementations write to a database.

The use count allows us to avoid this problem: we keep track of how many requests are currently executing inside each servant and, while a servant is busy, avoid evicting that servant. As a result, the queue size is not a hard upper limit: long-running operations can temporarily cause more servants than the limit to appear in the queue. However, as soon as excess servants become idle, they are evicted as usual.

Finally, our `locate` and `finished` implementations will need to exchange a cookie that contains a smart pointer to the entry in the evictor map. This is necessary so that `finished` can decrement the servant's use count.

This leads to the following definitions in the private section of our evictor:

## Java

```

package Evictor;

public abstract class EvictorBase implements Ice.ServantLocator
{
 // ...

 private class EvictorEntry
 {
 Ice.Object servant;
 java.lang.Object userCookie;
 java.util.Iterator<Ice.Identity> queuePos;
 int useCount;
 }

 private void evictServants()
 {
 // ...
 }

 private java.util.Map<Ice.Identity, EvictorEntry> _map =
 new java.util.HashMap<Ice.Identity, EvictorEntry>();
 private Evictor.LinkedList<Ice.Identity> _queue =
 new Evictor.LinkedList<Ice.Identity>();
 private int _size;
}

```

Note that the evictor stores the evictor map, queue, and the queue size in the private data members `_map`, `_queue`, and `_size`. The map key is the identity of the Ice object, and the lookup value is of type `EvictorEntry`. The queue simply stores identities, of type `Ice::Identity`.

The `evictServants` member function takes care of evicting servants when the queue length exceeds its limit — we will discuss this function in more detail shortly.

Almost all the action of the evictor takes place in the implementation of `locate`:

## Java

```

synchronized public final Ice.Object
locate(Ice.Current c, Ice.LocalObjectHolder cookie)
{
 //
 // Check if we have a servant in the map already.
 //
 EvictorEntry entry = _map.get(c.id);
 if (entry != null) {
 //
 // Got an entry already, dequeue the entry from
 // its current position.
 //
 entry.queuePos.remove();
 } else {
 //
 // We do not have entry. Ask the derived class to
 // instantiate a servant and add a new entry to the map.
 //
 entry = new EvictorEntry();
 Ice.LocalObjectHolder cookieHolder =
new Ice.LocalObjectHolder();
 entry.servant = add(c, cookieHolder); // Down-call
 if (entry.servant == null) {
 return null;
 }
 entry.userCookie = cookieHolder.value;
 entry.useCount = 0;
 _map.put(c.id, entry);
 }

 //
 // Increment the use count of the servant and enqueue
 // the entry at the front, so we get LRU order.
 //
 ++(entry.useCount);
 _queue.addFirst(c.id);
 entry.queuePos = _queue.iterator();
 entry.queuePos.next(); // Position iterator on the element.

 cookie.value = entry;
 return entry.servant;
}

```

The code uses an `EvictorEntry` as the cookie that is returned from `locate` and will be passed by the Ice run time to the corresponding call to `finished`.

We first look for an existing entry in the evictor map, using the object identity as the key. If we have an entry in the map already, we dequeue

the corresponding identity from the evictor queue. (The `queuePos` member of `EvictorEntry` is an iterator that marks that entry's position in the evictor queue.)

Otherwise, we do not have an entry in the map, so we create a new one and call the `add` method. This is a down-call to the concrete class that will be derived from `EvictorBase`. The implementation of `add` must attempt to locate the object state for the Ice object with the identity passed inside the `Current` object and either return a servant as usual, or return null or throw an exception to indicate failure. If `add` returns null, we return null to let the Ice run time know that no servant could be found for the current request. If `add` succeeds, we initialize the entry's use count to zero and insert the entry into the evictor map.

The final few lines of code increment the entry's use count, add the entry at the head of the evictor queue, store the entry's position in the queue, and assign the entry to the cookie that is returned from `locate`, before returning the servant to the Ice run time.

The implementation of `finished` is comparatively simple. It decrements the use count of the entry and then calls `evictServants` to get rid of any servants that might need to be evicted:

#### Java

```
synchronized public final void
finished(Ice.Current c, Ice.Object o, java.lang.Object cookie)
{
 EvictorEntry entry = (EvictorEntry)cookie;

 // Decrement use count and check if
 // there is something to evict.
 //
 --(entry.useCount);
 evictServants();
}
```

In turn, `evictServants` examines the evictor queue: if the queue length exceeds the evictor's size, the excess entries are scanned. Any entries with a zero use count are then evicted:

## Java

```

private void evictServants()
{
 //
 // If the evictor queue has grown larger than the limit,
 // look at the excess elements to see whether any of them
 // can be evicted.
 //
 java.util.Iterator<Ice.Identity> p = _queue.riterator();
 int excessEntries = _map.size() - _size;
 for (int i = 0; i < excessEntries; ++i) {
 Ice.Identity id = p.next();
 EvictorEntry e = _map.get(id);
 if (e.useCount == 0) {
 evict(e.servant, e.userCookie); // Down-call
 e.queuePos.remove();
 _map.remove(id);
 }
 }
}

```

The code scans the excess entries, starting at the tail of the evictor queue. If an entry has a zero use count, it is evicted: after calling the `evict` member function in the derived class, the code removes the evicted entry from both the map and the queue.

Finally, the implementation of `deactivate` sets the evictor size to zero and then calls `evictServants`. This results in eviction of all servants. The Ice run time [guarantees](#) to call `deactivate` only once no more requests are executing in an object adapter; as a result, it is guaranteed that all entries in the evictor will be idle and therefore will be evicted.

## Java

```

synchronized public final void
deactivate(String category)
{
 _size = 0;
 evictServants();
}

```

Note that, with this implementation of `evictServants`, we only scan the tail section of the evictor queue for servants to evict. If we have long-running operations, this allows the number of servants in the queue to remain above the evictor size if the servants in the tail section have a non-zero use count. This means that, even immediately after calling `evictServants`, the queue length can still exceed the evictor size.

We can adopt a more aggressive strategy for eviction: instead of scanning only the excess entries in the queue, if, after looking in the tail section of the queue, we still have more servants in the queue than the queue size, we keep scanning for servants with a zero use count until the queue size drops below the limit. This alternative version of `evictServants` looks as follows:

## Java

```

private void evictServants()
{
 //
 // If the evictor queue has grown larger than the limit,
 // look at the excess elements to see whether any of them
 // can be evicted.
 //
 java.util.Iterator<Ice.Identity> p = _queue.riterator();
 int numEntries = _map.size();
 for (int i = 0; i < excessEntries && _map.size() > _size;
 ++i) {
 Ice.Identity id = p.next();
 EvictorEntry e = _map.get(id);
 if (e.useCount == 0) {
 evict(e.servant, e.userCookie); // Down-call
 e.queuePos.remove();
 _map.remove(id);
 }
 }
}

```

The only difference in this version is that the terminating condition for the `for`-loop has changed: instead of scanning only the excess entries for servants with a use count, this version keeps scanning until the evictor size drops below the limit.

Which version is more appropriate depends on your application: if locating and evicting servants is expensive, and memory is not at a premium, the first version (which only scans the tail section) is more appropriate; if you want to keep memory consumption to a minimum, the second version is more appropriate. Also keep in mind that the difference between the two versions is significant only if you have long-running operations and many concurrent invocations from clients; otherwise, there is no point in more aggressively scanning for servants to remove because they are going to become idle again very quickly and get evicted as soon as the next request arrives.

## Using Servant Evictors in Java

Using a servant evictor is simply a matter of deriving a class from `EvictorBase` and implementing the `add` and `evict` methods. You can turn a servant locator into an evictor by simply taking the code that you wrote for `locate` and placing it into `add` — `EvictorBase` then takes care of maintaining the cache in least-recently used order and evicting servants as necessary. Unless you have clean-up requirements for your servants (such as closing network connections or database handles), the implementation of `evict` can be left empty.

One of the nice aspects of evictors is that you do not need to change anything in your servant implementation: the servants are ignorant of the fact that an evictor is in use. This makes it very easy to add an evictor to an already existing code base with little disturbance of the source code.

Evictors can provide substantial performance improvements over [default servants](#): especially if initialization of servants is expensive (for example, because servant state must be initialized by reading from a network), an evictor performs much better than a default servant, while keeping memory requirements low.

### A Linked List to Support Eviction in C#

The `System.Collections` classes do not provide a container that does not invalidate iterators when we modify the contents of the container but, to efficiently implement an `evictor`, we need such a container. To deal with this, we use a special-purpose linked list implementation, `Evictor.LinkedList`, that does not invalidate iterators when we delete or add an element. For brevity, we only show the interface of `LinkedList` here — you can find the implementation in the code examples for this manual in the Ice distribution.

## C#

```

namespace Evictor
{
 public class LinkedList<T> : ICollection<T>, ICollection, ICloneable
 {
 public LinkedList();

 public int Count { get; }

 public void Add(T value);
 public void AddFirst(T value);
 public void Clear();
 public bool Contains(T value);
 public bool Remove(T value);

 public IEnumerator GetEnumerator();

 public class Enumerator : IEnumerator<T>, IEnumerator,
 IDisposable
 {
 public void Reset();

 public T Current { get; }

 public bool MoveNext();
 public bool MovePrev();
 public void Remove();
 public void Dispose();
 }

 public void CopyTo(T[] array, int index);
 public void CopyTo(Array array, int index);

 public object Clone();

 public bool IsReadOnly { get; }
 public bool IsSynchronized { get; }
 public object SyncRoot { get; }
 }
}

```

The `Add` method appends an element to the list, and the `AddFirst` method prepends an element to the list. `GetEnumerator` returns an enumerator for the list elements; immediately after calling `GetEnumerator`, the enumerator does not point at any element until you call either `MoveNext` or `MovePrev`, which position the enumerator at the first and last element, respectively. `Current` returns the element at the enumerator position, and `Remove` deletes the element at the current position and leaves the enumerator pointing at no element. Calling `MoveNext` or `MovePrev` after calling `Remove` positions the enumerator at the element following or preceding the deleted element, respectively. `MoveNext` and `MovePrev` return true if they have positioned the enumerator on an element; otherwise, they return false and leave the enumerator position on the last and first element, respectively.

```

namespace Evictor
{
 public abstract class EvictorBase : Ice.ServantLocator
 {
 public EvictorBase()
 {
 _size = 1000;
 }

 public EvictorBase(int size)
 {
 _size = size < 0 ? 1000 : size;
 }

 protected abstract Ice.Object add(Ice.Current c,
out object cookie);

 protected abstract void evict(Ice.Object servant,
object cookie);

 public Ice.Object locate(Ice.Current c, out object cookie)
 {
 lock(this)
 {
 // ...
 }
 }

 public void finished(Ice.Current c, Ice.Object o, object cookie)
 {
 lock(this)
 {
 // ...
 }
 }

 public void deactivate(string category)
 {
 lock(this)
 {
 // ...
 }
 }

 private int _size;
 }
}

```

Note that the evictor has constructors to set the size of the queue, with a default size of 1000.

The `locate`, `finished`, and `deactivate` methods are inherited from the `ServantLocator` base class; these methods implement the logic to maintain the queue in LRU order and to add and evict servants as needed. The methods use a `lock(this)` statement for their body, so the evictor's internal data structures are protected from concurrent access.

The `add` and `evict` methods are called by the evictor when it needs to add a new servant to the queue and when it evicts a servant from the queue. Note that these functions are abstract, so they must be implemented in a derived class. The job of `add` is to instantiate and initialize a servant for use by the evictor. The `evict` function is called by the evictor when it evicts a servant, allowing the subclass to perform any cleanup. Note that `add` can return a cookie that the evictor passes to `evict`, so you can move context information from `add` to `evict`.

Next, we need to consider the data structures that are needed to support our evictor implementation. We require two main data structures:

1. A map that maps `object identities` to servants, so we can efficiently decide whether we have a servant for an incoming request in memory or not.
2. A list that implements the evictor queue. The list is kept in LRU order at all times.

The evictor map not only stores servants but also keeps track of some administrative information:

1. The map stores the cookie that is returned from `add`, so we can pass that same cookie to `evict`.
2. The map stores an iterator into the evictor queue that marks the position of the servant in the queue.
3. The map stores a use count that is incremented whenever an operation is dispatched into a servant, and decremented whenever an operation completes.

The last two points deserve some extra explanation.

- The evictor queue must be maintained in least-recently used order, that is, every time an invocation arrives and we find an entry for the identity in the evictor map, we also must locate the servant's identity on the evictor queue and move it to the front of the queue. However, scanning for that entry is inefficient because it requires  $O(n)$  time. To get around this, we store an iterator in the evictor map that marks the corresponding entry's position in the evictor queue. This allows us to dequeue the entry from its current position and enqueue it at the head of the queue in  $O(1)$  time, using the `Evictor.LinkedList` implementation.
- We maintain a use count as part of the map in order to avoid incorrect eviction of servants. Suppose a client invokes a long-running operation on an Ice object with identity *I*. In response, the evictor adds a servant for *I* to the evictor queue. While the original invocation is still executing, other clients invoke operations on various Ice objects, which leads to more servants for other object identities being added to the queue. As a result, the servant for identity *I* gradually migrates toward the tail of the queue. If enough client requests for other Ice objects arrive while the operation on object *I* is still executing, the servant for *I* could be evicted while it is still executing the original request.

By itself, this will not do any harm. However, if the servant is evicted and a client then invokes another request on object *I*, the evictor would have no idea that a servant for *I* is still around and would add a second servant for *I*. However, having two servants for the same Ice object in memory is likely to cause problems, especially if the servant's operation implementations write to a database.

The use count allows us to avoid this problem: we keep track of how many requests are currently executing inside each servant and, while a servant is busy, avoid evicting that servant. As a result, the queue size is not a hard upper limit: long-running operations can temporarily cause more servants than the limit to appear in the queue. However, as soon as excess servants become idle, they are evicted as usual.

Finally, our `locate` and `finished` implementations will need to exchange a cookie that contains a reference to the entry in the evictor map. This is necessary so that `finished` can decrement the servant's use count.

This leads to the following definitions in the private section of our evictor:

**C#**

```

namespace Evictor
{
 using System.Collections.Generic;

 public abstract class EvictorBase : Ice.ServantLocator
 {
 // ...

 private class EvictorEntry
 {
 internal Ice.Object servant;
 internal object userCookie;
 internal LinkedList<Ice.Identity>.Enumerator queuePos;
 internal int useCount;
 }

 private void evictServants()
 {
 // ...
 }

 private Dictionary<Ice.Identity, EvictorEntry> _map =
 new Dictionary<Ice.Identity, EvictorEntry>();
 private LinkedList<Ice.Identity> _queue =
 new LinkedList<Ice.Identity>();
 private int _size;
 }
}

```

Note that the evictor stores the evictor map, queue, and the queue size in the private data members `_map`, `_queue`, and `_size`. The map key is the identity of the Ice object, and the lookup value is of type `EvictorEntry`. The queue simply stores identities, of type `Ice.Identity`.

The `evictServants` member function takes care of evicting servants when the queue length exceeds its limit — we will discuss this function in more detail shortly.

Almost all the action of the evictor takes place in the implementation of `locate`:

**C#**

```

public Ice.Object locate(Ice.Current c, out object cookie)
{
 lock(this)
 {
 //
 // Check if we a servant in the map already.
 //
 EvictorEntry entry = _map[c.id];
 if (entry != null) {
 //
 // Got an entry already, dequeue the entry from
 // its current position.
 //
 entry.queuePos.Remove();
 } else {
 //
 // We do not have an entry. Ask the derived class to
 // instantiate a servant and add an entry to the map.
 //
 entry = new EvictorEntry();
 entry.servant = add(c, out entry.userCookie);
 if (entry.servant == null) {
 cookie = null;
 return null;
 }
 entry.useCount = 0;
 _map[c.id] = entry;
 }

 //
 // Increment the use count of the servant and enqueue
 // the entry at the front, so we get LRU order.
 //
 ++(entry.useCount);
 _queue.AddFirst(c.id);
 entry.queuePos = (LinkedList<Ice.Identity>.Enumerator)_queue.Ge
tEnumerator();
 entry.queuePos.MoveNext();

 cookie = entry;

 return entry.servant;
 }
}

```

The code uses an `EvictorEntry` as the cookie that is returned from `locate` and will be passed by the Ice run time to the corresponding call to `finished`.

We first look for an existing entry in the evictor map, using the object identity as the key. If we have an entry in the map already, we dequeue the corresponding identity from the evictor queue. (The `queuePos` member of `EvictorEntry` is an iterator that marks that entry's position in the evictor queue.)

Otherwise, we do not have an entry in the map, so we create a new one and call the `add` method. This is a down-call to the concrete class that will be derived from `EvictorBase`. The implementation of `add` must attempt to locate the object state for the Ice object with the identity passed inside the `Current` object and either return a servant as usual, or return null or throw an exception to indicate failure. If `add` returns null, we return null to let the Ice run time know that no servant could be found for the current request. If `add` succeeds, we initialize the entry's use count to zero and insert the entry into the evictor map.

The final few lines of code increment the entry's use count, add the entry at the head of the evictor queue, store the entry's position in the queue, and initialize the cookie that is returned from `locate`, before returning the servant to the Ice run time.

The implementation of `finished` is comparatively simple. It decrements the use count of the entry and then calls `evictServants` to get rid of any servants that might need to be evicted:

```

C#

public void finished(Ice.Current c, Ice.Object o, object cookie)
{
 lock(this)
 {
 EvictorEntry entry = (EvictorEntry)cookie;

 //
 // Decrement use count and check if
 // there is something to evict.
 //
 --(entry.useCount);
 evictServants();
 }
}

```

In turn, `evictServants` examines the evictor queue: if the queue length exceeds the evictor's size, the excess entries are scanned. Any entries with a zero use count are then evicted:

## C#

```

private void evictServants()
{
 //
 // If the evictor queue has grown larger than the limit,
 // look at the excess elements to see whether any of them
 // can be evicted.
 //
 LinkedList<Ice.Identity>.Enumerator p =
 (LinkedList<Ice.Identity>.Enumerator)_queue.GetEnumerator();
 int excessEntries = _map.Count - _size;
 for (int i = 0; i < excessEntries; ++i) {
 p.MovePrev();
 Ice.Identity id = p.Current;
 EvictorEntry e = _map[id];
 if (e.useCount == 0) {
 evict(e.servant, e.userCookie); // Down-call
 p.Remove();
 _map.Remove(id);
 }
 }
}

```

The code scans the excess entries, starting at the tail of the evictor queue. If an entry has a zero use count, it is evicted: after calling the `evict` member function in the derived class, the code removes the evicted entry from both the map and the queue.

Finally, the implementation of `deactivate` sets the evictor size to zero and then calls `evictServants`. This results in eviction of all servants. The Ice run time [guarantees](#) to call `deactivate` only once no more requests are executing in an object adapter; as a result, it is guaranteed that all entries in the evictor will be idle and therefore will be evicted.

## C#

```

public void deactivate(string category)
{
 lock(this)
 {
 _size = 0;
 evictServants();
 }
}

```

Note that, with this implementation of `evictServants`, we only scan the tail section of the evictor queue for servants to evict. If we have long-running operations, this allows the number of servants in the queue to remain above the evictor size if the servants in the tail section have a non-zero use count. This means that, even immediately after calling `evictServants`, the queue length can still exceed the evictor size.

We can adopt a more aggressive strategy for eviction: instead of scanning only the excess entries in the queue, if, after looking in the tail section of the queue, we still have more servants in the queue than the queue size, we keep scanning for servants with a zero use count until the queue size drops below the limit. This alternative version of `evictServants` looks as follows:

**C#**

```

private void evictServants()
{
 //
 // If the evictor queue has grown larger than the limit,
 // look at the excess elements to see whether any of them
 // can be evicted.
 //
 LinkedList<Ice.Identity>.Enumerator p =
 (LinkedList<Ice.Identity>.Enumerator)_queue.GetEnumerator();
 int numEntries = _map.Count;
 for (int i = 0; i < numEntries && _map.Count > _size; ++i) {
 p.MovePrev();
 Ice.Identity id = p.Current;
 EvictorEntry e = _map[id];
 if (e.useCount == 0) {
 evict(e.servant, e.userCookie); // Down-call
 p.Remove();
 _map.Remove(id);
 }
 }
}

```

The only difference in this version is that the terminating condition for the `for`-loop has changed: instead of scanning only the excess entries for servants with a use count, this version keeps scanning until the evictor size drops below the limit.

Which version is more appropriate depends on your application: if locating and evicting servants is expensive, and memory is not at a premium, the first version (which only scans the tail section) is more appropriate; if you want to keep memory consumption to a minimum, the second version is more appropriate. Also keep in mind that the difference between the two versions is significant only if you have long-running operations and many concurrent invocations from clients; otherwise, there is no point in more aggressively scanning for servants to remove because they are going to become idle again very quickly and get evicted as soon as the next request arrives.

## Using Servant Evictors in C#

Using a servant evictor is simply a matter of deriving a class from `EvictorBase` and implementing the `add` and `evict` methods. You can turn a servant locator into an evictor by simply taking the code that you wrote for `locate` and placing it into `add` — `EvictorBase` then takes care of maintaining the cache in least-recently used order and evicting servants as necessary. Unless you have clean-up requirements for your servants (such as closing network connections or database handles), the implementation of `evict` can be left empty.

One of the nice aspects of evictors is that you do not need to change anything in your servant implementation: the servants are ignorant of the fact that an evictor is in use. This makes it very easy to add an evictor to an already existing code base with little disturbance of the source code.

Evictors can provide substantial performance improvements over [default servants](#): especially if initialization of servants is expensive (for example, because servant state must be initialized by reading from a network), an evictor performs much better than a default servant, while keeping memory requirements low.

## Understanding Object Life Cycle

*Object life cycle* generally refers to how an object-oriented application (whether distributed or not) creates and destroys objects. For distributed applications, life cycle management presents particular challenges. For example, destruction of objects often can be surprisingly complex, especially in threaded applications. Before we go into the details of object creation and destruction, we need to have a closer look what we mean by the terms "life cycle" and "object" in this context.

Object life cycle refers to the act of creation and destruction of objects. For example, with our [file system](#) application, we may start out with an empty file system that only contains a root directory. Over time, clients (by as yet unspecified means) add new directories and files to the file system. For example, a client might create a new directory called `MyPoems` underneath the root directory. Some time later, the same or a different client might decide to remove this directory again, returning the file system to its previous empty state. This pattern of creation and destruction is known as object life cycle.

The life cycle of distributed objects raises a number of interesting and challenging questions. For example, what should happen if a client destroys a file while another client is reading or writing that file? And how do we prevent two files with the same name from existing in the same directory? Another interesting scenario is illustrated by the following sequence of events:

1. Client A creates a file called `DraftPoem` in the root directory and uses it for a while.
2. Some time later, client B destroys the `DraftPoem` file so it no longer exists.
3. Some time later still, client C creates a new `DraftPoem` file in the root directory, with different contents.
4. Finally, client A attempts to access the `DraftPoem` file it created earlier.

What should happen when, in the final step, client A tries to use the `DraftPoem` file? Should the client's attempt succeed and simply operate on the new contents of the file that were placed there by client C? Or should client A's attempt fail because, after all, the new `DraftPoem` file is, in a sense, a completely different file from the original one, even though it has the same name?

The answers to such questions cannot be made in general. Instead, meaningful answers depend on the semantics that each individual application attaches to object life cycle. In this chapter, we will explore the various possible interpretations and how to implement them correctly, particularly for threaded applications.

## Object Existence and Non-Existence

Before we talk about how to create and destroy objects, we need to look at a more basic concept, namely that of object existence. What does it mean for an object to "exist" and, more fundamentally, what do we mean by the term "object"?

As mentioned in [Ice Objects](#), an *Ice object* is a conceptual entity, or abstraction that does not really exist. On the client side, the concrete representation of an Ice object is a proxy and, on the server side, the concrete representation of an Ice object is a servant. Proxies and servants are the concrete programming-language artifacts that represent Ice objects.

Because Ice objects are abstract, conceptual entities, they are invisible to the Ice run time and to the application code — only proxies and servants are real and visible. It follows that, to determine whether an *Ice object* exists, any determination must rely on proxies and servants, because they are the only tangible entities in the system.

On this page:

- [Object Non-Existence](#)
- [Object Existence](#)
- [Indeterminate Object State](#)
- [Authoritative Object Existence Semantics](#)

## Object Non-Existence

Here is the definitive statement of what it means for an Ice object to *not* exist:

*An Ice object does not exist if an invocation on the object raises an `ObjectNotExistException`.*

This may seem self-evident but, on closer examination, is a little more subtle than you might expect. In particular, Ice object existence has meaning *only within the context of a particular invocation*. If that invocation raises `ObjectNotExistException`, the object is known to not exist. Note that this says nothing about whether concurrent or future requests to that object will also raise `ObjectNotExistException` — they may or may not, depending on the semantics that are implemented by the application.

Also note that, because all the Ice run time knows about are servants, an `ObjectNotExistException` really indicates that a *servant* for the request could not be found at the time the request was made. This means that, ultimately, it is the application that attaches the meaning "the Ice object does not exist" to this exception.

In theory, the application can attach any meaning it likes to `ObjectNotExistException` and a server can throw this exception for whatever reason it sees fit; in practice, however, we recommend that you do not do this because it breaks with existing convention and is potentially confusing. You should reserve this exception for its intended meaning and not abuse it for other purposes.

## Object Existence

The preceding definition does not say anything about object existence if something other than `ObjectNotExistException` is returned in response to a particular request. So, here is the definitive statement of what it means for an Ice object to exist:

*An Ice object exists if a twoway invocation on the object either succeeds, raises a user exception, or raises `FacetNotExistException` or `OperationNotExistException`.*

It is self-evident that an Ice object exists if a twoway invocation on it succeeds: obviously, the object received the invocation, processed it, and returned a result. However, note the qualification: this is true only for *twoway* invocations; for *oneway* and *datagram* invocations, nothing can be inferred about the existence of the corresponding Ice object by invoking an operation on it: because there is no reply from the server, the client-side Ice run time has no idea whether the request was dispatched successfully in the server or not. This includes user exceptions, `ObjectNotExistException`, `FacetNotExistException`, and `OperationNotExistException` — these exceptions are never raised by oneway and datagram invocations, regardless of the actual state of the target object.

If a twoway invocation raises a user exception, the Ice object obviously exists: the Ice run time never raises user exceptions so, for an invocation to raise a user exception, the invocation was dispatched successfully in the server, and the operation implementation in the servant raised the exception.

If a twoway invocation raises `FacetNotExistException`, we do know that the corresponding Ice object indeed exists: the Ice run time raises `FacetNotExistException` only if it can find the identity of the target object in the [Active Servant Map](#) (ASM), but cannot find the *facet* that was specified by the client.

Note that, if you use [servant locators](#), for these semantics to hold, your servant locator must correctly raise `FacetNotExistException` in the `locate` operation (instead of returning null or raising `ObjectNotExistException`) if an Ice object exists, but the particular target facet does not exist.

As a corollary to the preceding two definitions, we can state:

*A facet does not exist if a twoway invocation on the object raises `ObjectNotExistException` Or `FacetNotExistException`.*

*A facet exists if a twoway invocation on the object either succeeds, or raises `OperationNotExistException`.*

These definitions simply capture the fact that a facet is a "sub-object" of an Ice object: if an invocation raises `ObjectNotExistException`, we know that the facet does not exist either because, for a facet to exist, its Ice object must exist.

If an operation raises `OperationNotExistException`, we know that both the target Ice object and the target facet exist. However, the operation that the client attempted to invoke does not. (This is possible only if you use [dynamic invocation](#) or if you have mis-matched Slice definitions for client and server.)

## Indeterminate Object State

The preceding definitions clearly state under what circumstances we can conclude that an Ice object (or its facet) does or does not exist. However, the preceding definitions are incomplete because operation invocations can have outcomes other than success or failure with `ObjectNotExistException`, `FacetNotExistException`, or `OperationNotExistException`. For example, a client might receive a `MarshalException`, `UnknownLocalException`, `UnknownException`, or `TimeoutException`. In that case, the client cannot draw any conclusions about whether the Ice object on which it invoked a twoway operation exists or not — the exceptions simply indicate that something went wrong while the invocation was processed. So, to complete our definitions, we can state:

*If a twoway invocation raises a run-time exception other than `ObjectNotExistException`, `FacetNotExistException`, or `OperationNotExistException`, nothing is known about the existence or non-existence of the Ice object that was the target of the invocation. Furthermore, it is impossible to determine the state of existence of an Ice object with a oneway or datagram invocation.*

## Authoritative Object Existence Semantics

The preceding definitions capture the fact that, to make a determination of object existence or non-existence, the client-side Ice run time must be able to contact the server and, moreover, receive a reply from the server:

- If the server can be contacted and returns a successful reply for an invocation, the Ice object exists.
- If the server can be contacted and returns an `ObjectNotExistException` (or `FacetNotExistException`), the Ice object (or facet) does not exist. If the server returns an `OperationNotExistException`, the Ice object (and its facet) exists, but does not provide the requested operation, which indicates a type mismatch due to client and server using out-of-sync Slice definitions or due to incorrect use of dynamic invocation.
- If the server cannot be contacted, does not return a reply (as for oneway and datagram invocations), or if anything at all goes wrong with the process of sending an invocation, processing it in the server, and returning the reply, nothing is known about the state of the Ice object, including its existence or non-existence.

Another way of looking at this is that a decision as to whether an object exists or not is *never* made by the Ice run time and, instead, is *always* made by the server-side *application* code:

- If an invocation completes successfully, the server-side application code was involved because it processed the invocation.
- If an invocation returns `ObjectNotExistException` or `FacetNotExistException`, the server-side application code was also involved:
  - either the Ice run time could not find a servant for the invocation in the ASM, in which case the application code was involved by virtue of not having added a servant to the ASM in the first place, or
  - the Ice run time consulted a servant locator that explicitly returned null or raised `ObjectNotExistException` or `FacetNotExistException`.

This means that `ObjectNotExistException` and `FacetNotExistException` are *authoritative*: when you receive these exceptions, you can always believe what they tell you — the Ice run time never raises these exceptions without consulting your code, either implicitly (via an ASM lookup) or explicitly (by calling a servant locator's `locate` operation).

These semantics are motivated by the need to keep the Ice run time stateless with respect to object existence. For example, it would be nice to have stronger semantics, such as a promise that "once an Ice object has existed and been destroyed, all future requests to that Ice object also raise `ObjectNotExistException`". However, to implement these semantics, the Ice run time would have to remember all object identities that were used in the past, and prevent their reuse for new Ice objects. Of course, this would be inherently non-scalable. In addition, it would prevent applications from controlling object identity; allowing such control for applications is important however, for example, to link the identity of an Ice object to its [persistent state](#) in a database.

Note that, if the implementation of an operation calls another operation, dealing with `ObjectNotExistException` may require some care. For example, suppose that the client holds a proxy to an object of type `Service` and invokes an operation `provideService` on it:

**C++**

```
ServicePrx service = ...;

try {
 service->provideService();
} catch (const ObjectNotExistException&) {
 // Service does not exist.
}
```

Here is the implementation of `provideService` in the server, which makes a call on a helper object to implement the operation:

**C++**

```
void
ServiceI::provideService(const Ice::Current&)
{
 // ...
 proxyToHelper->someOp();
 // ...
}
```

If `proxyToHelper` happens to point at an object that was destroyed previously, the call to `someOp` will throw `ObjectNotExistException`. If the implementation of `provideService` does not intercept this exception, the exception will propagate all the way back to the client, who will conclude that the service has been destroyed when, in fact, the service still exists but the helper object used to implement `provideService` no longer exists.

Usually, this scenario is not a serious problem. Most often, the helper object cannot be destroyed while it is needed by `provideService` due to the way the application is structured. In that case, no special action is necessary because `someOp` will never throw `ObjectNotExistException`. On the other hand, if it is possible for the helper object to be destroyed, `provideService` can wrap a try-catch block for `ObjectNotExistException` around the call to `someOp` and throw an appropriate user exception from the exception handler (such as `ResourceUnavailable` or similar).

## Life Cycle of Proxies, Servants, and Ice Objects

It is important to be aware of the different roles of proxies, servants, and Ice objects in a system. Proxies are the client-side representation of Ice objects and servants are the server-side representation of Ice objects. Proxies, servants, and Ice objects have completely independent life cycles. Clients can create and destroy proxies with or without a corresponding servant or Ice object in existence, servers can create and destroy servants with or without a corresponding proxy or Ice object in existence and, most importantly, Ice objects can exist or not exist regardless of whether corresponding proxies or servants exist. Here are a few examples to illustrate this:

```
C++
```

```
{
 Ice::ObjectPtr obj
= communicator->stringToProxy("hello:tcp -p 10000");
 // Proxy exists now.

} // Proxy ceases to exist.
```

This code creates a proxy to an Ice object with the identity `Hello`. The server for this Ice object is expected to listen for invocations on the same host as the client, on port 10000, using the TCP/IP protocol. The proxy exists as soon as the call to `stringToProxy` completes and, thereafter, can be used by the client to make invocations on the corresponding Ice object.

However, note that this code says nothing at all about whether or not the corresponding Ice object exists. In particular, there might not be any Ice object with the identity `Hello`. Or there might be such an object, but the server for it may be down or unreachable. It is only when the client makes an invocation on the proxy that we get to find out whether the object exists, does not exist, or cannot be reached.

Similarly, at the end of the scope enclosing the `obj` variable in the preceding code, the proxy goes out of scope and is destroyed. Again, this says nothing about the state of the corresponding Ice object or its servant. This shows that the life cycle of a proxy is completely independent of the life cycle of its Ice object and the servant for that Ice object: clients can create and destroy proxies whenever they feel like it, and doing so has no implications for Ice objects or servant creation or destruction.

Here is another code example, this time for the server side:

```
C++
```

```
{
 FileIPtr file = new FileI("DraftPoem", root);
 // Servant exists now.

} // Servant ceases to exist.
```

Here, the server instantiates a servant for a `File` object by creating a `FileI` instance. The servant comes into being as soon as the call to `new` completes and ceases to exist as soon as the scope enclosing the `file` variable closes. Note that, as for proxies, the life cycle of the servant is completely independent of the life cycle of proxies and Ice objects. Clearly, the server can create and destroy a servant regardless of whether there are any proxies in existence for the corresponding Ice object.

Similarly, an Ice object can exist even if no servants exist for it. For example, our Ice objects might be persistent and stored in a database; in that case, if we switch off the server for our Ice objects, no servants exist for these Ice objects, even though the Ice objects continue to exist — the Ice objects are temporarily inaccessible, but exist regardless and, once their server is restarted, will become accessible again.

Conversely, a servant can exist without its corresponding Ice object. The mere creation of a servant does nothing, as far as the Ice run time is concerned. It is only once a servant is added to the [Active Servant Map \(ASM\)](#) (or a [servant locator](#) returns the servant from `locate`) that the servant incarnates its Ice object.

Finally, an Ice object can exist independently of proxies and servants. For example, returning to the database example, we might have an Ice server that acts as a front end to an online telephone book: each entry in the phone book corresponds to a separate Ice object. When a client invokes an operation, the server uses the [identity](#) of the incoming request to determine which Ice object is the target of the request and then contacts the back-end database to, for example, return the street address of the entry. With such a design, entries can be added to and

removed from the back-end database quite independently of what happens to proxies and servants — the server finds out whether an Ice object exists only when it accesses the back-end database.

The only time that the life cycle of an Ice object and a servant are linked is during an invocation on that Ice object: for an invocation to complete successfully, a servant must exist for the *duration of the invocation*. What happens to the servant thereafter is irrelevant to clients and, in general, is irrelevant to the corresponding Ice object.

It is important to be clear about the independence of the life cycles of proxies, servants, and Ice objects because this independence has profound implications for how you need to implement object life cycle. In particular, to destroy an Ice object, a client cannot simply destroy its proxy for an object because the server is completely unaware when a client does this.

Distributed object systems such as DCOM implement these semantics. However, this design is inherently non-scalable because of the cost of globally tracking proxy creation and destruction.

## Object Creation

Now that we understand what it means for an Ice object to exist, we can look at what is involved in creating an Ice object. Fundamentally, there is only one way for an Ice object to come into being: the server must instantiate a servant for the object and add an entry for that servant to the [Active Servant Map \(ASM\)](#) (or, alternatively, arrange for a [servant locator](#) to return a servant from its `locate` operation).

For the remainder of this chapter, we will ignore the distinction between using the ASM and a servant locator and simply assume that the code uses the ASM. This is because servant locators do not alter the discussion: if `locate` returns a servant, that is the same as a successful lookup in the ASM; if `locate` returns null or throws `ObjectNotExistException`, that is the same as an unsuccessful lookup in the ASM.

One obvious way for a server to create a servant is to, well, simply instantiate it and add it to the ASM of its own accord. For example:

**C++**

```
DirectoryIPtr root = new DirectoryI("/", 0);
adapter->addWithUUID(root); // Ice object exists now
```

The servant exists as soon as the call to `new` completes, and the Ice object exists as soon as the code adds the servant to the ASM: at that point, the Ice object becomes reachable to clients who hold a proxy to it.

This is the way we created Ice objects for our file system application earlier in the manual. However, doing so is not all that interesting because the only files and directories that exist are those that the server decides to create when it starts up. What we really want is a way for *clients* to create and destroy directories and files.

On this page:

- [Creating an Object with a Factory](#)
- [Implementing a Factory Operation](#)

### Creating an Object with a Factory

The canonical way to create an object is to use the factory pattern [1]. The factory pattern, in a nutshell, says that objects are created by invoking an operation (usually called `create`) on an object factory:

### Slice

```

interface PhoneEntry {
 idempotent string name();
 idempotent string getNumber();
 idempotent void setNumber(string phNum);
};

exception PhoneEntryExists {
 string name;
 string phNum;
};

interface PhoneEntryFactory {
 PhoneEntry* create(string name, string phNum)
 throws PhoneEntryExists;
};

```

Rather than continue with the file system example, we will simplify the discussion for the time being by using the phone book example mentioned earlier; we will return to the file system application to explore [more complex issues](#).

The entries in the phone book consist of simple name-number pairs. The interface to each entry is called `PhoneEntry` and provides operations to read the name and to read and write the phone number. (For a real application, the objects would likely be more complex and encapsulate more state. However, these simple objects will do for the purposes of this discussion.)

To create a new entry, a client calls the `create` operation on a `PhoneEntryFactory` object. (The factory is a singleton object [1] — that is, only one instance of that interface exists in the server.) It is the job of `create` to create a new `PhoneEntry` object, using the supplied name as the [object identity](#).

An immediate consequence of using the name as the object identity is that `create` can raise a `PhoneEntryExists` exception: presumably, if a client attempts to create an entry with the same name as an already-existing entry, we need to let the client know about this. (Whether this is an appropriate design is something we examine more closely in [Object Identity and Uniqueness](#).)

`create` returns a proxy to the newly-created object, so the client can use that proxy to invoke operations. However, this is by convention only. For example, `create` could be a `void` operation if the client has some other way to eventually get a proxy to the new object (such as creating the proxy from a string, or locating the proxy via a search operation). Alternatively, you could define "bulk" creation operations that allow clients to create several new objects with a single RPC. As far as the Ice run time is concerned, there is nothing special about a factory operation: a factory operation is just like any other operation; it just so happens that a factory operation creates a new Ice object as a side effect of being called, that is, the *implementation* of the operation is what creates the object, not the Ice run time.

Also note that `create` accepts a `name` and a `phNum` parameter, so it can initialize the new object. This is not compulsory, but generally a good idea. An alternate factory operation could be:

### Slice

```

interface PhoneEntryFactory {
 PhoneEntry* create(string name)
 throws PhoneEntryExists;
};

```

With this design, the assumption is that the client will call `setNumber` after it has created the object. However, in general, allowing objects

that are not fully initialized is a bad idea: it all too easily happens that a client either forgets to complete the initialization, or happens to crash or get disconnected before it can complete the initialization. Either way, we end up with a partially-initialized object in the system that can cause surprises later.

This is the approach taken by COM's `CoCreateObject`, which suffers from just that problem.

Similarly, so-called generic factories are also something to be avoided:

### Slice

```
dictionary<string, string> Params;

exception CannotCreateException {
 string reason;
};

interface GenericFactory {
 Object* create(Params p)
 throws CannotCreateException;
};
```

The intent here is that a `GenericFactory` can be used to create any kind of object; the `Params` dictionary allows an arbitrary number of parameters to be passed to the `create` operation in the form of name — value pairs, for example:

### C++

```
GenericFactoryPrx factory = ...;

Ice::ObjectPrx obj;
Params p;

// Make a car.
//
p["Make"] = "Ford";
p["Model"] = "Falcon";
obj = factory->create(p);
CarPrx car = CarPrx::checkedCast(obj);

// Make a horse.
//
p.clear();
p["Breed"] = "Clydesdale";
p["Sex"] = "Male";
obj = factory->create(p);
HorsePrx horse = HorsePrx::checkedCast(obj);
```

We strongly discourage you from creating factory interfaces such as this, unless you have a good overriding reason: generic factories undermine type safety and are much more error-prone than strongly-typed factories.

## Implementing a Factory Operation

The implementation of an object factory is simplicity itself. Here is how we could implement the `create` operation for our `PhoneEntryFactory`:

```

C++

PhoneEntryPrx
PhoneEntryFactory::create(const string& name, const string& phNum,
const Current& c)
{
 try {
 CommunicatorPtr comm = c.adapter->getCommunicator();
 PhoneEntryPtr servant = new PhoneEntryI(name, phNum);
 return PhoneEntryPrx::uncheckedCast(c.adapter->add(servant,
comm->stringToIdentity(name)));
 } catch (const Ice::AlreadyRegisteredException&) {
 throw PhoneEntryExists(name, phNum);
 }
}

```

The `create` function instantiates a new `PhoneEntryI` object (which is the servant for the new `PhoneEntry` object), adds the servant to the ASM, and returns the proxy for the new object. Adding the servant to the ASM is what creates the new Ice object, and client requests are dispatched to the new object as soon as that entry appears in the ASM (assuming the [object adapter is active](#)).

Note that, even though this code contains no explicit lock, it is thread-safe. The `add` operation on the object adapter is atomic: if two clients concurrently add a servant with the same identity, exactly one thread succeeds in adding the entry to the ASM; the other thread receives an `AlreadyRegisteredException`. Similarly, if two clients concurrently call `create` for different entries, the two calls execute concurrently in the server (if the server is multi-threaded); the implementation of `add` in the Ice run time uses appropriate locks to ensure that concurrent updates to the ASM cannot corrupt anything.

## Object Destruction

Now that clients can [create `PhoneEntry` objects](#), let us consider how to allow clients to destroy them again. One obvious design is to add a `destroy` operation to the factory — after all, seeing that a factory knows how to create objects, it stands to reason that it also knows how to destroy them again:

```

Slice

```

exception PhoneEntryNotExists {
    string name;
    string phNum;
};

interface PhoneEntryFactory {
    PhoneEntry* create(string name, string phNum)
        throws PhoneEntryExists;
    void destroy(PhoneEntry* pe)           // Bad idea!
        throws PhoneEntryNotExists;
};

```

```

While this works (and certainly can be implemented without problems), it is generally a bad idea. For one, an immediate problem we need to deal with is what should happen if a client passes a proxy to an already-destroyed object to `destroy`. We could raise an `ObjectNotExistException` to indicate this, but that is not a good idea because it makes it ambiguous as to which object does not exist: the factory, or the entry. (By convention, if a client receives an `ObjectNotExistException` for an invocation, what does not exist is the object the operation was targeted at, not some other object that in turn might be contacted by the operation.) This forces us to add a separate `PhoneEntryNotExists` exception to deal with the error condition, which makes the interface a little more complex.

A second and more serious problem with this design is that, in order to destroy an entry, the client must not only know which entry to destroy, but must also know *which factory created the entry*. For our example, with only a single factory, this is not a real concern. However, for more complex systems with dozens of factories (possibly in multiple server processes), it rapidly becomes a problem: for each object, the application code somehow has to keep track of which factory created what object; if any part of the code ever loses track of where an object originally came from, it can no longer destroy that object.

Of course, we could mitigate the problem by adding an operation to the `PhoneEntry` interface that returns a proxy to its factory. That way, clients could ask each object to provide the factory that created the object. However, that needlessly complicates the `Slice` definitions and really is just a band-aid on a fundamentally flawed design. A much better choice is to add the `destroy` operation to the `PhoneEntry` interface instead:

```

Slice

```

interface PhoneEntry {
    idempotent string name();
    idempotent string getNumber();
    idempotent void setNumber(string phNum);
    void destroy();
};

```

```

With this approach, there is no need for clients to somehow keep track of which factory created what object. Instead, given a proxy to a `PhoneEntry` object, a client simply invokes the `destroy` operation on the object and the `PhoneEntry` obligingly commits suicide. Note that we also no longer need a separate exception to indicate the "object does not exist" condition because we can raise `ObjectNotExistException` instead — the exception exists precisely to indicate this condition and, because `destroy` is now an operation on the phone entry itself, there is no ambiguity about which object it is that does not exist.

## Idempotency and Life Cycle Operations

You may be tempted to write the life cycle operations as follows:

Slice
<pre> interface PhoneEntry {     // ...     idempotent void destroy(); // Wrong! };  interface PhoneEntryFactory {     idempotent PhoneEntry* create(string name, string phNum)         throws PhoneEntryExists; }; </pre>

The idea is that `create` and `destroy` can be [idempotent operations](#) because it is safe to let the Ice run time retry the operation in the event of a temporary network failure. However, this assumption is not true. To see why, consider the following scenario:

1. A client invokes `destroy` on a phone entry.
2. The Ice run time sends the request to the server on the wire.
3. The connection goes down just after the request was sent, but before the reply for the request arrives in the client. It so happens that the request was received by the server and acted upon, and the reply from the server back to the client is lost because the connection is still down.
4. The Ice run time tries to read the reply for the request and realizes that the connection has gone down. Because the operation is marked idempotent, the run time attempts an [automatic retry](#) by re-establishing the connection and sending the request a second time, which happens to work.
5. The server receives the request to destroy the entry but, because the entry is destroyed already, the server returns an `ObjectNotExistException` to the client, which the Ice run time passes to the application code.
6. The application receives an `ObjectNotExistException` and falsely concludes that it tried to destroy a non-existent object when, in fact, the object did exist and was destroyed as intended.

A similar scenario can be constructed for `create`: in that case, the application will receive a `PhoneEntryExists` exception when, in fact, the entry did not exist and was created successfully.

These scenarios illustrate that `create` and `destroy` are *never* idempotent: sending one `create` or `destroy` invocation for a particular object is not the same as sending two invocations: the outcome depends on whether the first invocation succeeded or not, so `create` and `destroy` are not idempotent.

See Also

- [Idempotent Operations](#)
- [Automatic Retries](#)

## Implementing a destroy Operation

As far as the Ice run time is concerned, the act of destroying an Ice object is to remove the mapping between its proxy and its servant. In other words, an Ice object is destroyed when we remove its entry from the [Active Servant Map \(ASM\)](#). Once the ASM entry is gone, incoming operations for the object raise `ObjectNotExistException`, as they should.

On this page:

- [Object Destruction and Concurrency](#)
- [Concurrent Execution of Life Cycle and Non-Life Cycle Operations](#)

### Object Destruction and Concurrency

Here is the simplest version of `destroy`:

```

C++

```

void
PhoneEntryI::destroy(const Current& c)
{
    try {
        c.adapter->remove(c.id);
    } catch (const Ice::NotRegisteredException&)
        throw Ice::ObjectNotExistException(__FILE__, __LINE__);
}

```

```

The implementation removes the ASM entry for the servant, thereby destroying the Ice object. If the entry does not exist (presumably, because the object was destroyed previously), `destroy` throws an `ObjectNotExistException`, as you would expect.

The ASM entry is removed as soon as `destroy` calls `remove` on the object adapter. Assuming that we implement `create` as we saw earlier, so no other part of the code retains a smart pointer to the servant, this means that the ASM holds the only smart pointer to the servant, so the servant's reference count is 1.

We use [smart pointers](#) in C++, which are analogous to object references in languages such as Java and C#.

Once the ASM entry is removed (and its smart pointer destroyed), the reference count of the servant drops to zero. In C++, this triggers a call to the destructor of the servant, and the heap-allocated servant is deleted just as it should be; in languages such as Java and C#, this makes the servant eligible for garbage collection, so it will be deleted eventually as well.

Things get more interesting if we consider concurrent scenarios. One such scenario involves concurrent calls to `create` and `destroy`. Suppose we have the following sequence of events:

1. Client A creates a phone entry.
2. Client A passes the proxy for the entry to client B.
3. Client A destroys the entry.
4. Client A calls `create` for the same entry (passing the same name, which serves as the [object identity](#)) and, concurrently, client B calls `destroy` on the entry.

Clearly, something is strange about this scenario, because it involves two clients asking for conflicting things, with one client trying to create an object that existed previously, while another client tries to destroy the object that — unbeknownst to that client — was destroyed earlier.

Exactly what is seen by client A and client B depends on how the operations are dispatched in the server. In particular, the outcome depends on the order in which the [calls on the object adapter](#) to add (in `create`) and `remove` (in `destroy`) on the servant are executed:

- If the thread processing client A's invocation executes `add` before the thread processing client B's invocation, client A's call to `add` succeeds. Internally, the calls to `add` and `remove` are serialized, and client B's call to `remove` blocks until client A's call to `add` has completed. The net effect is that both clients see their respective invocations complete successfully.

- If the thread processing client B's invocation executes `remove` before the thread processing client A's invocation executes `add`, client B's thread receives a `NotRegisteredException`, which results in an `ObjectNotExistException` in client B. Client A's thread then successfully calls `add`, creating the object and returning its proxy.

This example illustrates that, if life cycle operations interleave in this way, the outcome depends on thread scheduling. However, as far as the Ice run time is concerned, doing this is perfectly safe: concurrent access does not cause problems for memory management or the integrity of data structures.

The preceding scenario allows two clients to attempt to perform conflicting operations. This is possible because clients can control the object identity of each phone entry: if the object identity were hidden from clients and assigned by the server (the server could assign a UUID to each entry, for example), the above scenario would not be possible. We will return to a more detailed discussion of such object identity issues in [Object Identity and Uniqueness](#).

## Concurrent Execution of Life Cycle and Non-Life Cycle Operations

This section applies to C++ only.

Another scenario relates to concurrent execution of ordinary (non-life cycle) operations and `destroy`:

- Client A holds a proxy to an existing object and passes that proxy to client B.
- Client B calls the `setNumber` operation on the object.
- Client A calls `destroy` on the object *while Client B's call to `setNumber` is still executing*.

The immediate question is what this means with respect to memory management. In particular, client A's thread calls `remove` on the object adapter while client B's thread is still executing inside the object. If this call to `remove` were to delete the servant immediately, it would delete the servant while client B's thread is still executing inside the servant, with potentially disastrous results.

The answer is that this cannot happen. Whenever the Ice run time dispatches an incoming invocation to a servant, it increments the servant's reference count for the duration of the call, and decrements the reference count again once the call completes. Here is what happens to the servant's reference count for the preceding scenario:

1. Initially, the servant is idle, so its reference count is at least 1 because the ASM entry stores a smart pointer to the servant. (The remainder of these steps assumes that the ASM stores the *only* smart pointer to the servant, so the reference count is exactly 1.)
2. Client B's invocation of `setNumber` arrives and the Ice run time increments the reference count to 2 before dispatching the call.
3. While `setNumber` is still executing, client A's invocation of `destroy` arrives and the Ice run time increments the reference count to 3 before dispatching the call.
4. Client A's thread calls `remove` on the object adapter, which destroys the smart pointer in the ASM and so decrements the reference to 2.
5. Either `setNumber` or `destroy` may complete first. It does not matter which call completes — either way, the Ice run time decrements the reference count as the call completes, so after one of these calls completes, the reference count drops to 1.
6. Eventually, when the final call (`setNumber` or `destroy`) completes, the Ice run time decrements the reference count once again, which causes the count to drop to zero. In turn, this triggers the call to `delete` (which calls the servant's destructor).

The net effect is that, while operations are executing inside a servant, the servant's reference count is always greater than zero. As the invocations complete, the reference count drops until, eventually, it reaches zero. However, that can only happen once no operations are executing, that is, once the servant is idle. This means that the Ice run time guarantees that a servant's destructor runs only once the final operation invocation has drained out of the servant, so it is impossible to "pull memory out from underneath an executing invocation".

For garbage-collected languages, such as C# and Java, the language run time provides the same semantics: while the servant can be reached via any reference in the application or the Ice run time, the servant will not be reclaimed by the garbage collector.

## Cleaning Up a Destroyed Servant

Here is a very simple implementation of our `PhoneEntryI` servant. (Methods are inlined for convenience only. Also note that, for the time being, this code ignores concurrency issues, which we return to in [Life Cycle and Normal Operations](#).)

**C++**

```
class PhoneEntryI : public PhoneEntry {
public:
 PhoneEntryI(const string& name, const string& phNum)
 : _name(name), _phNum(phNum)
 {
 }

 virtual string
 name(const Current&) {
 return _name;
 }

 virtual string
 getNumber(const Current&) {
 return _phNum;
 }

 virtual void
 setNumber(const string& phNum, const Current&) {
 _phNum = phNum;
 }

 virtual void
 destroy(const Current& c) {
 try {
 c.adapter->remove(c.id);
 } catch (const Ice::NotRegisteredException&)
 throw Ice::ObjectNotExistException(__FILE__, __LINE__);
 }

private:
 const string _name;
 string _phNum;
};
```

With this servant, `destroy` does just the right thing: it calls `delete` on the servant once the servant is idle, which in turn calls the destructor, so the memory used by the `_name` and `_phNum` data members is reclaimed.

However, real servants are rarely this simple. In particular, destruction of an Ice object may involve non-trivial actions, such as flushing a file, committing a transaction, making a remote call on another object, or updating a hardware device. For example, instead of storing the details of a phone entry in member variables, the servant could be implemented to store the details in a file; in that case, destroying the Ice object would require closing the file. Seeing that the Ice run time calls the destructor of a servant only once the servant becomes idle, the destructor would appear to be an ideal place to perform such actions, for example:

**C++**

```

class PhoneEntryI : public PhoneEntry {
public:
 // ...

 ~PhoneEntryI()
 {
 _myStream.close(); // Bad idea
 }

private:
 fstream _myStream;
};

```

The problem with this code is that it can fail, for example, if the file system is full and buffered data cannot be written to the file. Such clean-up failure is a general issue for non-trivial servants: for example, a transaction can fail to commit, a remote call can fail if the network goes down, or a hardware device can be temporarily unresponsive.

If we encounter such a failure, we have a serious problem: we cannot inform the client of the error because, as far as the client is concerned, the `destroy` call completed just fine. The client will therefore assume that the Ice object was correctly destroyed. However, the system is now in an inconsistent state: the Ice object was destroyed (because its ASM entry was removed), but the object's state still exists (possibly with incorrect values), which can cause errors later.

Another reason for avoiding such state clean-up in C++ destructors is that destructors cannot throw exceptions: if they do, and do so in the process of being called during unwinding of the stack due to some other exception, the program goes directly to `terminate` and does not pass "Go". (There are a few exotic cases in which it is possible to throw from a destructor and get away with it but, in general, is an excellent idea to maintain the no-throw guarantee for destructors.) So, if anything goes wrong during destruction, we are in a tight spot: we are forced to swallow any exception that might be encountered by the destructor, and the best we can do is log the error, but not report it to the client.

Finally, using destructors to clean up servant state does not port well to languages such as Java and C#. For these languages, similar considerations apply to error reporting from a finalizer and, with Java, finalizers may not run at all. Therefore, we recommend that you perform any clean-up actions in the body of `destroy` instead of delaying clean-up until the servant's destructor runs.

Note that the foregoing does *not* mean that you cannot reclaim servant resources in destructors; after all, that is what destructors are for. But it *does* mean that you should not try to reclaim resources from a destructor if the attempt can fail (such as deleting records in an external system as opposed to, for example, deallocating memory or adjusting the value of variables in your program).

## Life Cycle and Collection Operations

On this page:

- [Factories and Collection Operations](#)
- [Cyclic Dependencies between Factories and Objects](#)

### Factories and Collection Operations

The factory we defined [earlier](#) is what is known as a *pure* object factory because `create` is the only operation it provides. However, it is common for factories to do double duty and also act as collection managers that provide additional operations, such as `list` and `find`:

```

Slice

```

// ...

sequence<PhoneEntry*> PhoneEntries;

interface PhoneEntryFactory {
    PhoneEntry* create(string name, string phNum)
        throws PhoneEntryExists;

    idempotent PhoneEntry find(string name);
    idempotent PhoneEntries list();
};

```

```

`find` returns a proxy for the phone entry with the given name, and a null proxy if no such entry exists. `list` returns a sequence that contains the proxies of all existing entries.

Here is a simple implementation of `find`:

```

C++

```

PhoneEntryPrx
PhoneEntryFactory::find(const string& name, const Current& c)
{
    CommunicatorPtr comm = c.adapter->getCommunicator();

    PhoneEntryPrx pe;
    Identity id = comm->stringToIdentity(name);
    if (c.adapter->find(id)) {
        pe = PhoneEntryPrx::uncheckedCast(c.adapter->createProxy(id));
    }
    return pe;
}

```

```

If an entry exists in the [Active Servant Map](#) (ASM) for the given name, the code creates a proxy for the corresponding Ice object and returns it. This code works correctly even for threaded servers: because the look-up of the identity in the ASM is atomic, there is no problem with other threads concurrently modifying the ASM (for example, while servicing calls from other clients to `create` or `destroy`).

## Cyclic Dependencies between Factories and Objects

Unfortunately, implementing `list` is not as simple because it needs to iterate over the collection of entries, but the object adapter does not provide any iterator for ASM entries.

The reason for this is that, during iteration, the ASM would have to be locked to protect it against concurrent access, but locking the ASM would prevent call dispatch during iteration and easily cause deadlocks.

Therefore, we must maintain our own list of entries inside the factory:

```

C++

class PhoneEntryFactoryI : public PhoneEntryFactory
{
public:
 // ...

 void remove(const string&, const ObjectAdapterPtr&) {
 IceUtil::Mutex::Lock lock(_namesMutex);

 set<string>::iterator i = _names.find(name);
 if (i != _names.end())
 _names.erase(i);
 }

private:
 IceUtil::Mutex _namesMutex;
 set<string> _names;
};
```

The idea is to have a set of names of existing entries, and to update that set in `create` and `destroy` as appropriate. However, for threaded servers, that raises a concurrency issue: if we have clients that can concurrently call `create`, `destroy`, and `list`, we need to interlock these operations to avoid corrupting the `_names` set (because STL containers are not thread-safe). This is the purpose of the mutex `_namesMutex` in the factory: `create`, `destroy`, and `list` can each lock this mutex to ensure exclusive access to the `_names` set.

Another issue is that our implementation of `destroy` must update the set of entries that is maintained by the factory. This is the purpose of the `remove` member function: it removes the specified name from the `_names` set (of course, under protection of the `_namesMutex` lock). However, `destroy` is a method on the `PhoneEntryI` servant, whereas `remove` is a method on the factory, so the servant must know how to reach the factory. Because the factory is a singleton, we can fix this by adding a static `_factory` member to the `PhoneEntryI` class:

**C++**

```

class PhoneEntryI : public PhoneEntry {
public:
 // ...

 static PhoneEntryFactoryIPtr _factory;

private:
 const string _name;
 string _phNum;
};

```

The code in `main` then creates the factory and initializes the static member variable, for example:

**C++**

```

PersonI::_factory = new PersonFactoryI;

// Add factory to ASM and activate object
// adapter here...

```

This works, but it leaves a bad taste in our mouth because it sets up a cyclic dependency between the phone entry servants and the factory: the factory knows about the servants, and each servant knows about the factory so it can call `remove` on the factory. In general, such cyclic dependencies are a bad idea: if nothing else, they make a design harder to understand.

We could remove the cyclic dependency by moving the `_names` set and its associated mutex into a separate class instance that is referenced from both `PhoneEntryFactoryI` and `PhoneEntryI`. That would get rid of the cyclic dependency as far as the C++ type system is concerned but, as we will see later, it would not really help because the factory and its servants turn out to be mutually dependent regardless (because of concurrency issues). So, for the moment, we'll stay with this design and examine better alternatives after we have explored the concurrency issues in more detail.

With this design, we can implement `list` as follows:

## C++

```

PhoneEntries
PhoneEntryFactoryI::list(const Current& c)
{
 Mutex::Lock lock(_namesMutex);

 CommunicatorPtr comm = c.adapter->getCommunicator();

 PhoneEntries pe;
 set<string>::const_iterator i;
 for (i = _names.begin(); i != _names.end(); ++i) {
 ObjectPrx o = c.adapter->createProxy(comm->stringToIdentity(name));
 pe.push_back(PhoneEntryPrx::uncheckedCast(o));
 }

 return pe;
}

```

Note that `list` acquires a lock on the mutex, to prevent concurrent modification of the `_names` set by `create` and `destroy`. In turn, our `create` implementation now also locks the mutex:

```

PhoneEntryPrx
PhoneEntryFactory::create(const string& name, const string& phNum,
const Current& c)
{
 Mutex::Lock lock(_namesMutex);

 PhoneEntryPrx pe;
 try {
 CommunicatorPtr comm = c.adapter->getCommunicator();
 PhoneEntryPtr servant = new PhoneEntryI(name, phNum);
 pe = PhoneEntryPrx::uncheckedCast(c.adapter->add(servant,
comm->stringToIdentity(name)));
 } catch (const Ice::AlreadyRegisteredException&) {
 throw PhoneEntryExists(name, phNum);
 }
 _names.insert(name);

 return pe;
}

```

With this implementation, we are safe if `create` and `list` run concurrently: only one of the two operations can acquire the lock at a time, so there is no danger of corrupting the `_names` set.

`destroy` is now trivial to implement: it simply removes the ASM entry and calls `remove` on the factory:

**C++**

```
void
PhoneEntryI::destroy(const Current& c)
{
 // Note: not quite correct yet.
 c.adapter->remove(_name);
 _factory->remove(_name, c.adapter);
}
```

Note that this is not quite correct because we have not yet considered concurrency issues for `destroy`. We will consider this issue next.

## Life Cycle and Normal Operations

So far, we have mostly ignored the implementations of the `getNumber` and `setNumber` operations we defined in our discussion of [object creation](#). Obviously, `getNumber` and `setNumber` must be interlocked against concurrent access — without this interlock, concurrent requests from clients could result in one thread writing to the `_phNum` member while another thread is reading it, with unpredictable results. (Conversely, the `name` operation need not have an interlock because the name of a phone entry is immutable.) To interlock `getNumber` and `setNumber`, we can add a mutex `_m` to `PhoneEntryI`:

**C++**

```
class PhoneEntryI : public PhoneEntry {
public:
 // ...

 static PhoneEntryFactoryIPtr _factory;

private:
 const string _name;
 string _phNum;
 Mutex _m;
};
```

The `getNumber` and `setNumber` implementations then lock `_m` to protect `_phNum` from concurrent access:

## C++

```

string
PhoneEntryI::name(const Current&)
{
 return _name;
}

string
PhoneEntryI::getNumber(const Current&)
{
 // Incorrect implementation!

 Mutex::Lock lock(_m);

 return _phNum;
}

void
PhoneEntryI::setNumber(const string& phNum, const Current&)
{
 // Incorrect implementation!

 Mutex::Lock lock(_m);

 _phNum = phNum;
}

```

This looks good but, as it turns out, `destroy` throws a spanner in the works: as shown, this code suffers from a rare, but real, race condition. Consider the situation where a client calls `destroy` at the same time as another client calls `setNumber`. In a server with a [thread pool](#) with more than one thread, the calls can be dispatched in separate threads and can therefore execute concurrently.

The following sequence of events can occur:

- The thread dispatching the `setNumber` call locates the servant, enters the operation implementation, and is suspended by the scheduler immediately on entry to the operation, before it can lock `_m`.
- The thread dispatching the `destroy` call locates the servant, enters `destroy`, successfully removes the servant from the [Active Servant Map](#) (ASM) and the `_names` set, and returns.
- The thread that was suspended in `setNumber` is scheduled again, locks `_m`, and now operates on a conceptually already-destroyed Ice object.

Note that, even if we lock `_m` in `destroy`, the problem persists:

**C++**

```

void
PhoneEntryI::destroy(const Current& c)
{
 // Note: still not correct.

 IceUtil::Mutex::Lock lock(_m);

 c.adapter->remove(_name);
 _factory->remove(_name, c.adapter);
}

```

Even though `destroy` now locks `_m` and so cannot run concurrently with `getNumber` and `setNumber`, the preceding scenario can still arise. The problem here is that a thread can enter the servant and be suspended before it gets a chance to acquire a lock. With the code as it stands, this is not a problem: `setNumber` will simply update the `_phNum` member variable in a servant that no longer has an ASM entry. In other words, the Ice object is already destroyed — it just so happens that the servant for that Ice object is still hanging around because there is still an operation executing inside it. Any updates to the servant will succeed (even though they are useless because the servant's `destruct` or `will run` as soon as the last invocation leaves the servant.)

Note that this scenario is not unique to C++ and can arise even with Java synchronized operations: in that case, a thread can be suspended just after the Ice run time has identified the target servant, but before it actually calls the operation on the target servant. While the thread is suspended, another thread can execute `destroy`.

While this race condition does not affect our implementation, it does affect more complex applications, particularly if the servant modifies external state, such as a file system or database. For example, `setNumber` could modify a file in the file system; in that case, `destroy` would delete that file and probably close a file descriptor or stream. If we were to allow `setNumber` to continue executing after `destroy` has already done its job, we would likely encounter problems: `setNumber` might not find the file where it expects it to be or try to use the closed file descriptor and return an error; or worse, `setNumber` might end up re-creating the file in the process of updating the already-destroyed entry's phone number. (What exactly happens depends on how we write the code for each operation.)

Of course, we can try to anticipate these scenarios and handle the error conditions appropriately, but doing this for complex systems with complex servants rapidly gets out of hand: in each operation, we would have to ask ourselves what might happen if the servant is destroyed concurrently and, if so, take appropriate recovery action.

It is preferable to instead deal with interleaved invocations of `destroy` and other operations in a systematic fashion. We can do this by adding a `_destroyed` member to the `PhoneEntryI` servant. This member is initialized to false by the constructor and set to true by `destroy`. On entry to every operation (including `destroy`), we lock the mutex, test the `_destroyed` flag, and throw `ObjectNotExistException` if the flag is set:

**C++**

```

class PhoneEntryI : public PhoneEntry {
public:
 // ...

 static PhoneEntryFactoryIPtr _factory;

private:
 const string _name;
 string _phNum;
 bool _destroyed;
 Mutex _m;
}

```

```

};

PhoneEntryI::PhoneEntryI(const string& name, const string& phNum)
 : _name(name), _phNum(phNum), _destroyed(false)
{
}

string
PhoneEntryI::name(const Current&)
{
 Mutex::Lock lock(_m);

 if (_destroyed)
 throw ObjectNotExistException(__FILE__, __LINE__);

 return _name;
}

string
PhoneEntryI::getNumber(const Current&)
{
 Mutex::Lock lock(_m);

 if (_destroyed)
 throw ObjectNotExistException(__FILE__, __LINE__);

 return _phNum;
}

void
PhoneEntryI::setNumber(const string& phNum, const Current&)
{
 Mutex::Lock lock(_m);

 if (_destroyed)
 throw ObjectNotExistException(__FILE__, __LINE__);

 _phNum = phNum;
}

void
PhoneEntryI::destroy(const Current& c)
{
 Mutex::Lock lock(_m);

 if (_destroyed)
 throw ObjectNotExistException(__FILE__, __LINE__);

 _destroyed = true;
 c.adapter->remove(_name);
}

```

```
 _factory->remove(_name, c.adapter); // Dubious!
 }
```

If you are concerned about the repeated code on entry to every operation, you can put that code into a member function or base class to make it reusable (although the benefits of doing so are probably too minor to make this worthwhile).

Using the `_destroyed` flag, if an operation is dispatched and suspended before it can lock the mutex and, meanwhile, `destroy` runs to completion in another thread, it becomes impossible for an operation to operate on the state of such a "zombie" servant: the test on entry to each operation ensures that any operation that runs after `destroy` immediately raises `ObjectNotExistException`.

Also note the "dubious" comment in `destroy`: the operation first locks `_m` and, while holding that lock, calls `remove` on the factory, which in turn locks its own `_namesMutex`. This is not wrong as such, but as we will see shortly, it can easily lead to deadlocks if we modify the application later.

- [The Ice Threading Model](#)

## Removing Cyclic Dependencies

We mentioned [earlier](#) that factoring the `_names` set and its mutex into a separate class instance does not really solve the cyclic dependency problem, at least not in general. To see why, suppose that we want to extend our factory with a new `getDetails` operation:

**Slice**

```

// ...

struct Details {
 PhoneEntry* proxy;
 string name;
 string phNum;
};

sequence<Details> DetailsSeq;

interface PhoneEntryFactory {
 // ...

 DetailsSeq getDetails();
};

```

This type of operation is common in collection managers: instead of returning a simple list of proxies, `getDetails` returns a sequence of structures, each of which contains not only the object's proxy, but also some of the state of the corresponding object. The motivation for this is performance: with a plain list of proxies, the client, once it has obtained the list, is likely to immediately follow up with one or more remote calls for each object in the list in order to retrieve their state (for example, to display the list of objects to the user). Making all these additional remote procedure calls is inefficient, and an operation such as `getDetails` gets the job done with a single RPC instead.

To implement `getDetails` in the factory, we need to iterate over the set of entries and invoke the `getNumber` operation on each object. (These calls are collocated and therefore very efficient, so they do not suffer the performance problem that a client calling the same operations would suffer.) However, this is potentially dangerous because the following sequence of events is possible:

- Client A calls `getDetails`.
- The implementation of `getDetails` must lock `_namesMutex` to prevent concurrent modification of the `_names` set during iteration.
- Client B calls `destroy` on a phone entry.
- The implementation of `destroy` locks the entry's mutex `_m`, sets the `_destroyed` flag, and then calls `remove`, which attempts to lock `_namesMutex` in the factory. However, `_namesMutex` is already locked by `getDetails`, so `remove` blocks until `_m` is unlocked again.
- `getDetails`, while iterating over its set of entries, happens to call `getNumber` on the entry that is currently being destroyed by client B. `getNumber`, in turn, tries to lock its mutex `_m`, which is already locked by `destroy`.

At this point, the server deadlocks: `getDetails` holds a lock on `_namesMutex` and waits for `_m` to become available, and `destroy` holds a lock on `_m` and waits for `_namesMutex` to become available, so neither thread can make progress.

To get rid of the deadlock, we have two options:

- Rearrange the locking such that deadlock becomes impossible.
- Abandon the idea of calling back from the servants into the factory and use *reaping* instead.

We will explore both options in the following pages.

### Topics

- [Acquiring Locks without Deadlocks](#)
- [Reaping Objects](#)

### See Also

- [Life Cycle and Collection Operations](#)

## Acquiring Locks without Deadlocks

For our example, it is fairly easy to avoid the deadlock caused by [cyclic dependencies](#): instead of holding the lock for the duration of `destroy`, we set the `_destroyed` flag under protection of the lock and unlock `_m` again before calling `remove` on the factory:

```

C++

void
PhoneEntryI::destroy(const Current& c)
{
 {
 Mutex::Lock lock(_m);

 if (_destroyed)
 throw ObjectNotExistException(__FILE__, __LINE__);

 _destroyed = true;

 } // _m is unlocked here.

 _factory->remove(_name, c.adapter);
}

```

Now deadlock is impossible because no function holds more than one lock, and no function calls another function while it holds a lock. However, rearranging locks in this fashion can be quite difficult for complex applications. In particular, if an application uses callbacks that do complex things involving several objects, it can be next to impossible to prove that the code is free of deadlocks. The same is true for applications that use condition variables and suspend threads until a condition becomes true.

At the core of the problem is that concurrency can create circular locking dependencies: an operation on the factory (such as `getDetails`) can require the same locks as a concurrent call to `destroy`. This is one reason why threaded code is harder to write than sequential code — the interactions among operations require locks, but dependencies among these locks are not obvious. In effect, locks set up an entirely separate and largely invisible set of dependencies. For example, it was easy to spot the mutual dependency between the factory and the servants due to the presence of `remove`; in contrast, it was much harder to spot the lurking deadlock in `destroy`. Worse, deadlocks may not be found during testing and discovered only after deployment, when it is much more expensive to rectify the problem. See Also

- [Removing Cyclic Dependencies](#)

## Reaping Objects

Instead of trying to arrange code such that it is deadlock-free in the presence of callbacks and [cyclic dependencies](#), it is often easier to change the code to avoid the callbacks entirely and to use an approach known as *reaping*:

- `destroy` marks the servant as destroyed and removes the [Active Servant Map](#) (ASM) entry as usual, but it does not call back into the factory to update the `_names` set.
- Whenever a collection manager operation, such as `list`, `getDetails`, or `find` is called, the factory checks for destroyed servants and, if it finds any, removes them from the `_names` set.

Reaping can make for a much cleaner design because it avoids both the cyclic type dependency and the cyclic locking dependency.

On this page:

- [A Simple Reaping Implementation](#)
- [Alternative Reaping Implementations](#)

### A Simple Reaping Implementation

To implement reaping, we need to change our `PhoneEntryI` definition a little. It no longer has a static `_factory` smart pointer back to the factory (because it no longer calls `remove`). Instead, the servant now provides a member function `_isZombie` that the factory calls to check whether the servant was destroyed some time in the past:

```

C++

```

class PhoneEntryI : public PhoneEntry {
public:
    // ...

    bool _isZombie() const;

private:
    const string _name;
    string _phNum;
    bool _destroyed;
    Mutex _m;
};

```

```

The implementation of `_isZombie` is trivial: it returns the `_destroyed` flag under protection of the lock:

```

C++

```

bool
PhoneEntryI::_isZombie() const
{
    Mutex::Lock lock(_m);

    return _destroyed;
}

```

```

The `destroy` operation no longer calls back into the factory to update the `_names` set; instead, it simply sets the `_destroyed` flag and removes the ASM entry:

**C++**

```

void
PhoneEntryI::destroy(const Current& c)
{
 Mutex::Lock lock(_m);

 if (_destroyed)
 throw ObjectNotExistException(__FILE__, __LINE__);

 _destroyed = true;
 c.adapter->remove(c.id);
}

```

The factory now, instead of storing just the names of existing servants, maintains a map that maps the name of each servant to its smart pointer:

**C++**

```

class PhoneEntryFactoryI : public PhoneEntryFactory
{
public:
 // Constructor and Slice operations here...

private:
 typedef map<string, PhoneEntryIPtr> PMap;
 PMap _entries;
 Mutex _entriesMutex;
};

```

During `create` (and other operations, such as `list`, `getDetails`, and `find`), we scan for zombie servants and remove them from the `_entries` map:

## C++

```

PhoneEntryPrx
PhoneEntryFactory::create(const string& name, const string& phNum,
const Current& c)
{
 Mutex::Lock lock(_entriesMutex);

 PhoneEntryPrx pe;
 PhoneEntryIPtr servant = new PhoneEntryI(name, phNum);

 // Try to create new object.
 //
 try {
 CommunicatorPtr comm = c.adapter->getCommunicator();
 pe = PhoneEntryPrx::uncheckedCast(
 c.adapter->add(servant, comm->stringToIdentity(name)));
 } catch (const Ice::AlreadyRegisteredException&) {
 throw PhoneEntryExists(name, phNum);
 }

 // Scan for zombies.
 //
 PMap::iterator i = _entries.begin();
 while (i != _entries.end())
 {
 if (i->second->_isZombie())
 _entries.erase(i++);
 else
 ++i;
 }
 _entries[name] = servant;

 return pe;
}

```

The implementations of `list`, `getDetails`, and `find` scan for zombies as well. Because they need to iterate over the existing entries anyway, reaping incurs essentially no extra cost:

## C++

```

PhoneEntries
PhoneEntryFactoryI::list(const Current& c)
{
 Mutex::Lock lock(_entriesMutex);

 CommunicatorPtr comm = c.adapter->getCommunicator();

 PhoneEntries pe;
 PMap::iterator i = _entries.begin();
 for (i = _entries.begin(); i != _entries.end(); ++i) {
 if (i->second->_isZombie()) {
 _entries.erase(i++);
 } else {
 ObjectPrx o = c.adapter->createProxy(comm->stringToIdentity
(i->first));
 pe.push_back(PhoneEntryPrx::uncheckedCast(o));
 ++i;
 }
 }

 return pe;
}

// Similar for getDetails and find...

```

This is a much cleaner design: there is no cyclic dependency between the factory and the servants, either implicit (in the type system) or explicit (as a locking dependency). Moreover, the implementation is easier to understand once you get used to the idea of reaping: there is no need to follow complex callbacks and to carefully analyze the order of lock acquisition. (Note that, depending on how state is maintained for servants, you may also need to reap during start-up and shutdown.)

In general, we recommend that you use a reaping approach in preference to callbacks for all but the most trivial applications: it simply is a better approach that is easier to maintain and understand.

### Alternative Reaping Implementations

You may be concerned that reaping increases the cost of `create` from  $O(\log n)$  to  $O(n)$  because `create` now iterates over all existing entries and locks and unlocks a mutex in each servant (whereas, previously, it simply added each new servant to the `_names` set). Often, this is not an issue because life cycle operations are called infrequently compared to normal operations. However, you will notice the additional cost if you have a large number of servants (in the thousands or more) and life cycle operations are called frequently.

If you find that `create` is a bottleneck (by profiling, not by guessing!), you can change to a more efficient implementation by adding zombie servants to a separate zombie list. Reaping then iterates over the zombie list and removes each servant in the zombie list from the `_entries` map before clearing the zombie list. This reduces the cost of reaping to be proportional to the number of zombie servants instead of the total number of servants. In addition, it allows us to remove the `_isZombie` member function and to lock and unlock `_entriesMutex` only once instead of locking a mutex in each servant as part of `_isZombie`. We will see such an implementation when we revisit the [file system application](#).

You may also be concerned about the number of zombie servants that can accumulate in the server if `create` is not called for some time. For most applications, this is not a problem: the servants occupy memory, but no other resources because `destroy` can clean up scarce resources, such as file descriptors or network connections before it turns the servant into a zombie. If you really need to prevent accumulation of zombie servants, you can reap from a background thread that runs periodically, or you can count the number of zombies and trigger a reaping pass once that number exceeds some threshold.

## Object Identity and Uniqueness

When [creating an object with a factory](#), it may not be a good idea to allow clients to control the [object identity](#) of the Ice objects they create. Here is the scenario from our [previous discussion](#), re-cast in terms of our phone book application:

1. Client A creates a new phone entry for Fred.
2. Client A passes the proxy for the Fred entry as a parameter of a remote call to another part of the system, say, server B.
3. Server B remembers Fred's proxy.
4. Client A decides that the entry for Fred is no longer needed and calls Fred's destroy operation.
5. Some time later, client C creates a new phone entry for a different person whose name also happens to be Fred.
6. Server B decides to get Fred's phone number by calling `getNumber` on the proxy it originally obtained from client A.

At this point, things are likely to go wrong: server B thinks that it has obtained the phone number of the original Fred, but that entry no longer exists and has since been replaced by a new entry for a different person (who presumably has a different phone number).

What has happened here is that Fred has been reincarnated because the same object identity was used for two different objects. In general, such reused object identities are a bad idea. For example, consider the following interfaces:

**Slice**

```
interface Process {
 void launch(); // Start process.
};

interface Missile {
 void launch(); // Kill lots of people.
};
```

Replaying the preceding scenario, if client A creates a `Process` object called "Thunderbird" and destroys that object again, and client C creates a `Missile` object called "Thunderbird", when server B calls `launch`, it will launch a missile instead of a process.

To be fair, in reality, this scenario is unlikely because it tacitly assumes that both objects are implemented by the same object adapter but, in a realistic scenario, the same server would be unlikely to implement both launching of processes and missiles. However, if you have objects that derive from common base interfaces, so objects of different types share the same operation names, this problem is real: operation invocations can easily end up in a destroyed and later recreated object.

Specifically, the preceding scenario illustrates that, when the Ice run time dispatches a request, exactly three items determine where the request ends up being processed:

- the endpoint at which the server listens for incoming requests
- the identity of the Ice object that is the target of the request
- the name of the operation that is to be invoked on the Ice object

If object identities are insufficiently unique, a request intended for one object can end up being sent to a completely different object, provided that the original object used the same identity, that both provide an operation with the same name, and that the parameters passed to one operation happen to decode correctly when interpreted as the parameters to the other operation. (This is rare, but not impossible, depending on the type and number of parameters.)

The crucial question is, what do we mean by "insufficiently unique"? As far as the call dispatch is concerned, identities must be unique only per object adapter. This is because the ASM does not allow you to add two entries with the same object identity; by enforcing this, the [Active Servant Map](#) (ASM) ensures that each object identity belongs to exactly one servant. (Note that the converse, namely, that servants in ASM entries must be unique, is *not* the case: the ASM allows you to map different object identities to the same servant, which is useful to, for example, implement stateless facade objects — [default servants](#) are used for this purpose.) So, as far as the Ice run time is concerned, it is perfectly OK to reuse object identities for different Ice objects.

Note that the Ice run time cannot prevent reuse of object identities either. Doing so would require the run time to remember every object identity that has ever been used, which does not scale. Instead, the Ice run time makes the application responsible for ensuring that object identities are "sufficiently unique".

You can deal with the identity reuse problem in several ways. One option is to do nothing and simply ignore the problem. While this sounds facetious, it is a viable option for many applications because, due to their nature, identity reuse is simply impossible. For example, if you use a social security number as a person's identity, the problem cannot arise because the social security number of a deceased person is not given to another person.

Another option is to allow identity reuse and to write your application such that it can deal with such identities: if nothing bad happens when an identity is reused, there is no problem. (This is the case if you know that the life cycles of the proxies for two different objects with the same identity can never overlap.)

The third option is to ensure that object identities are guaranteed unique, for example, by establishing naming conventions that make reuse impossible, or by using a [UUID as the object identity](#). This can be useful even for applications for which identity reuse does not pose a problem. For example, if you use [well-known objects](#), globally-unique object identities allow you to move a server to a different machine without invalidating proxies to these objects that are held by clients.

In general, we recommend that if an Ice object naturally contains a unique item of state (such as a social security number), you should use that item as the object identity. On the other hand, if the natural object identity is insufficiently unique (as is the case with names of phone book entries), you should use a UUID as the identity. (This is particularly useful for anonymous transient objects, such as session objects, that may not have a natural identity.)

## Object Life Cycle for the File System Application

Now that we have had a look at the issues around object life cycle, let us return to our [file system application](#) and add life cycle operations to it, so clients can create and destroy files and directories.

To destroy a file or directory, the obvious choice is to add a `destroy` operation to the `Node` interface:

Slice
<pre> module Filesystem {      exception GenericError {         string reason;     };     exception PermissionDenied extends GenericError {};     exception NameInUse extends GenericError {};     exception NoSuchName extends GenericError {};      interface Node {         idempotent string name();         void destroy() throws PermissionDenied;     };      // ... }; </pre>

Note that `destroy` can throw a `PermissionDenied` exception. This is necessary because we must prevent attempts to destroy the root directory.

The `File` interface is unchanged:

Slice
<pre> module Filesystem {     // ...      sequence&lt;string&gt; Lines;      interface File extends Node {         idempotent Lines read();         idempotent void write(Lines text) throws GenericError;     };      // ... }; </pre>

Note that, because `File` derives from `Node`, it inherits the `destroy` operation we defined for `Node`.

The `Directory` interface now looks somewhat different from the previous version:

- The `list` operation returns a sequence of structures instead of a list of proxies: for each entry in a directory, the `NodeDesc` structure provides the name, type, and proxy of the corresponding file or directory.
- Directories provide a `find` operation that returns the description of the nominated node. If the nominated node does not exist, the operation throws a `NoSuchName` exception.
- The `createFile` and `createDirectory` operations create a file and directory, respectively. If a file or directory already exists, the operations throw a `NameInUse` exception.

Here are the corresponding definitions:

**Slice**

```

module Filesystem {
 // ...

 enum NodeType { DirType, FileType };

 struct NodeDesc {
 string name;
 NodeType type;
 Node* proxy;
 };

 sequence<NodeDesc> NodeDescSeq;

 interface Directory extends Node {
 idempotent NodeDescSeq list();
 idempotent NodeDesc find(string name) throws NoSuchName;
 File* createFile(string name) throws NameInUse;
 Directory* createDirectory(string name) throws NameInUse;
 };
};

```

Note that this design is somewhat different from the factory we designed for the [phone book application](#). In particular, we do not have a single object factory; instead, we have as many factories as there are directories, that is, each directory creates files and directories only in that directory.

The motivation for this design is twofold:

- Because all files and directories that can be created are immediate descendants of their parent directory, we avoid the complexities of parsing path names for a separator such as `"/`. This keeps our example code to manageable size. (A real-world implementation of a distributed file system would, of course, be able to deal with path names.)
- Having more than one object factory presents interesting implementation issues that we will explore in the following discussion.

Let's move on to the implementation of this design in C++ and Java. You can find the full code of the implementation (including languages other than C++ and Java) in the `Manual/lifecycle` directory of your Ice distribution.

## Implementing Object Life Cycle in C++

The implementation of our life cycle design has the following characteristics:

- It uses UUIDs as the object identities for nodes to avoid [object reincarnation problems](#).
- When `destroy` is called on a node, the node needs to destroy itself and inform its parent directory that it has been destroyed (because the parent directory is the node's factory and also acts as a collection manager for child nodes).

Note that, in contrast to the [initial version](#), the entire implementation resides in a `FilesystemI` namespace instead of being part of the `Filesystem` namespace. Doing this is not essential, but is a little cleaner because it keeps the implementation in a namespace that is separate from the Slice-generated namespace.

On this page:

- [Object Life Cycle Changes for the `NodeI` Class in C++](#)
- [Object Life Cycle Changes for the `DirectoryI` Class in C++](#)
- [Object Life Cycle Changes for the `FileI` Class in C++](#)
- [Object Life Cycle Concurrency Issues in C++](#)

### Object Life Cycle Changes for the `NodeI` Class in C++

To begin with, let us look at the definition of the `NodeI` class:

```

C++
namespace FilesystemI {

 class DirectoryI;
 typedef IceUtil::Handle<DirectoryI> DirectoryIPtr;

 class NodeI : public virtual Filesystem::Node {
 public:
 virtual std::string name(const Ice::Current&);
 Ice::Identity id() const;

 protected:
 NodeI(const std::string& name, const DirectoryIPtr& parent);

 const std::string _name;
 const DirectoryIPtr _parent;
 bool _destroyed;
 Ice::Identity _id;
 IceUtil::Mutex _m;
 };

 // ...
}

```

The purpose of the `NodeI` class is to provide the data and implementation that are common to both `FileI` and `DirectoryI`, which use implementation inheritance from `NodeI`.

As in the [initial version](#), `NodeI` provides the implementation of the `name` operation and stores the name of the node and its parent directory in the `_name` and `_parent` members. (The root directory's `_parent` member is null.) These members are immutable and initialized by the constructor and, therefore, `const`.

The `_destroyed` member, protected by the mutex `_m`, prevents the [race condition](#) we discussed earlier. The constructor initializes `_destr`

oyed to false and creates an identity for the node (stored in the `_id` member):

```

C++
FilesystemI::NodeI::NodeI(const string& name,
const DirectoryIPtr& parent)
 : _name(name), _parent(parent), _destroyed(false)
{
 _id.name = parent ? IceUtil::generateUUID() : "RootDir";
}

```

The `id` member function returns a node's identity, stored in the `_id` data member. The node must remember this identity because it is a UUID and is needed when we create a proxy to the node:

```

C++
Identity
FilesystemI::NodeI::id() const
{
 return _id;
}

```

The data members of `NodeI` are protected instead of private to keep them accessible to the derived `FileI` and `DirectoryI` classes. (Because the implementation of `NodeI` and its derived classes is quite tightly coupled, there is little point in making these members private and providing separate accessors and mutators for them.)

The implementation of the Slice `name` operation simply returns the name of the node, but also [checks whether the node has been destroyed](#):

```

C++
string
FilesystemI::NodeI::name(const Current&)
{
 IceUtil::Mutex::Lock lock(_m);

 if (_destroyed)
 throw ObjectNotExistException(__FILE__, __LINE__);

 return _name;
}

```

This completes the implementation of the `NodeI` base class.

### Object Life Cycle Changes for the `DirectoryI` Class in C++

Next, we need to look at the implementation of directories. The `DirectoryI` class derives from `NodeI` and the Slice-generated `Directory` skeleton class. Of course, it must implement the pure virtual member functions for its Slice operations, which leads to the following (not yet complete) definition:

**C++**

```

namespace FilesystemI {

 // ...

 class DirectoryI : virtual public NodeI,
 virtual public Filesystem::Directory {
 public:
 virtual Filesystem::NodeDescSeq list(const Ice::Current&);
 virtual Filesystem::NodeDesc find(const std::string&,
const Ice::Current&);
 Filesystem::FilePrx createFile(const std::string&,
const Ice::Current&);
 Filesystem::DirectoryPrx createDirectory(const std::string&,
const Ice::Current&);
 virtual void destroy(const Ice::Current&);
 // ...

 private:
 // ...
 };
}

```

Each directory stores its contents in a map that maps the name of a directory to its servant:

**C++**

```

namespace FilesystemI {

 // ...

 class DirectoryI : virtual public NodeI,
 virtual public Filesystem::Directory {
 public:
 // ...

 DirectoryI(const ObjectAdapterPtr& a,
 const std::string& name,
 const DirectoryIPtr& parent = 0);

 void removeEntry(const std::string& name);

 private:
 typedef std::map<std::string, NodeIPtr> Contents;
 Contents _contents;
 // ...
 };
}

```

Note that we use the inherited member `_m` to interlock operations.

The constructor simply initializes the `NodeI` base class:

**C++**

```

FilesystemI::DirectoryI::DirectoryI(const string& name,
const DirectoryIPtr& parent)
 : NodeI(name, parent)
{
}

```

The `removeEntry` member function is called by the child to remove itself from its parent's `_contents` map:

**C++**

```

void
FilesystemI::DirectoryI::removeEntry(const string& name)
{
 IceUtil::Mutex::Lock lock(_m);
 Contents::iterator i = _contents.find(name);
 if(i != _contents.end())
 {
 _contents.erase(i);
 }
}

```

Here is the `destroy` member function for directories:

**C++**

```

void
FilesystemI::DirectoryI::destroy(const Current& c)
{
 if (!_parent)
 throw PermissionDenied("Cannot destroy root directory");
 {
 IceUtil::Mutex::Lock lock(_m);

 if (_destroyed)
 throw ObjectNotExistException(__FILE__, __LINE__);

 if (!_contents.empty())
 throw PermissionDenied("Cannot destroy non-empty directory"
);
 c.adapter->remove(id());
 _destroyed = true;
 }

 _parent->removeEntry(_name);
}

```

The code first prevents destruction of the root directory and then checks whether this directory was destroyed previously. It then acquires the lock and checks that the directory is empty. Finally, `destroy` removes the [Active Servant Map \(ASM\)](#) entry for the destroyed directory and removes itself from its parent's `_contents` map. Note that we call `removeEntry` outside the synchronization to [avoid deadlocks](#).

The `createDirectory` implementation locks the mutex before checking whether the directory already contains a node with the given name (or an invalid empty name). If not, it creates a new servant, adds it to the ASM and the `_contents` map, and returns its proxy:

**C++**

```

DirectoryPrx
FilesystemI::DirectoryI::createDirectory(const string& name,
const Current& c)
{
 IceUtil::Mutex::Lock lock(_m);

 if (_destroyed)
 throw ObjectNotExistException(__FILE__, __LINE__);

 if (name.empty() || _contents.find(name) != _contents.end())
 throw NameInUse(name);

 DirectoryIPtr d = new DirectoryI(name, this);
 ObjectPrx node = c.adapter->add(d, d->id());
 _contents[name] = d;
 return DirectoryPrx::uncheckedCast(node);
}

```

The `createFile` implementation is identical, except that it creates a file instead of a directory:

**C++**

```

FilePrx
FilesystemI::DirectoryI::createFile(const string& name,
const Current& c)
{
 IceUtil::Mutex::Lock lock(_m);

 if (_destroyed)
 throw ObjectNotExistException(__FILE__, __LINE__);

 if (name.empty() || _contents.find(name) != _contents.end())
 throw NameInUse(name);

 FileIPtr f = new FileI(name, this);
 ObjectPrx node = c.adapter->add(f, f->id());
 _contents[name] = f;
 return FilePrx::uncheckedCast(node);
}

```

Here is the implementation of `list`:

**C++**

```

NodeDescSeq
FilesystemI::DirectoryI::list(const Current& c)
{
 IceUtil::Mutex::Lock lock(_m);

 if (_destroyed)
 throw ObjectNotExistException(__FILE__, __LINE__);

 NodeDescSeq ret;
 for (Contents::const_iterator i = _contents.begin();
i != _contents.end(); ++i)
 {
 NodeDesc d;
 d.name = i->first;
 d.type = FilePtr::dynamicCast(i->second) ? FileType : DirType;
 d.proxy = NodePrx::uncheckedCast(c.adapter->createProxy(i->second->id()));
 ret.push_back(d);
 }
 return ret;
}

```

After acquiring the lock, the code iterates over the directory's contents and adds a `NodeDesc` structure for each entry to the returned vector.

The `find` operation proceeds along similar lines:

**C++**

```

NodeDesc
FilesystemI::DirectoryI::find(const string& name, const Current& c)
{
 IceUtil::Mutex::Lock lock(_m);

 if (_destroyed)
 throw ObjectNotExistException(__FILE__, __LINE__);

 Contents::const_iterator pos = _contents.find(name);
 if (pos == _contents.end())
 throw NoSuchName(name);

 NodeIPtr p = pos->second;
 NodeDesc d;
 d.name = name;
 d.type = FilePtr::dynamicCast(p) ? FileType : DirType;
 d.proxy = NodePrx::uncheckedCast(c.adapter->createProxy(p->id()));
 return d;
}

```

**Object Life Cycle Changes for the FileI Class in C++**

The constructor of FileI is trivial: it simply initializes the data members of its base class::

**C++**

```

FilesystemI::FileI::FileI(const string& name,
const DirectoryIPtr& parent)
 : NodeI(name, parent)
{
}

```

The implementation of the three member functions of the FileI class is also trivial, so we present all three member functions here:

**C++**

```

Lines
FilesystemI::FileI::read(const Current&)
{
 IceUtil::Mutex::Lock lock(_m);

 if (_destroyed)
 throw ObjectNotExistException(__FILE__, __LINE__);

 return _lines;
}

// Slice File::write() operation.

void
FilesystemI::FileI::write(const Lines& text, const Current&)
{
 IceUtil::Mutex::Lock lock(_m);

 if (_destroyed)
 throw ObjectNotExistException(__FILE__, __LINE__);

 _lines = text;
}

void
FilesystemI::FileI::destroy(const Current& c)
{
 {
 IceUtil::Mutex::Lock lock(_m);

 if (_destroyed)
 throw ObjectNotExistException(__FILE__, __LINE__);

 c.adapter->remove(id());
 _destroyed = true;
 }

 _parent->removeEntry(_name);
}

```

**Object Life Cycle Concurrency Issues in C++**

The preceding implementation is provably deadlock free. All member functions hold only one lock at a time, so they cannot deadlock with each other or themselves. While the locks are held, the functions do not call other member functions that acquire locks, so any potential deadlock can only arise by concurrent calls to another mutating function, either on the same node or on different nodes. For concurrent calls

on the same node, deadlock is impossible because such calls are strictly serialized on the mutex `_m`; for concurrent calls to `destroy` on different nodes, each node locks its respective mutex `_m`, releases `_m` again, and then acquires and releases a lock on its parent (by calling `removeEntry`), also making deadlock impossible.

## Implementing Object Life Cycle in Java

The implementation of our life cycle design has the following characteristics:

- It uses UUIDs as the object identities for nodes to avoid [object reincarnation problems](#).
- When `destroy` is called on a node, the node needs to destroy itself and inform its parent directory that it has been destroyed (because the parent directory is the node's factory and also acts as a collection manager for child nodes).

Note that, in contrast to the [initial version](#), the entire implementation resides in a `FilesystemI` package instead of being part of the `Filesystem` package. Doing this is not essential, but is a little cleaner because it keeps the implementation in a package that is separate from the Slice-generated package.

On this page:

- [Object Life Cycle Changes for the NodeI Class in Java](#)
- [Object Life Cycle Changes for the DirectoryI Class in Java](#)
- [Object Life Cycle Changes for the FileI Class in Java](#)
- [Object Life Cycle Concurrency Issues in Java](#)

### Object Life Cycle Changes for the NodeI Class in Java

Our `DirectoryI` and `FileI` servants derive from a common `NodeI` base interface. This interface is not essential, but useful because it allows us to treat servants of type `DirectoryI` and `FileI` polymorphically:

```

Java

```

package FilesystemI;

public interface NodeI
{
    Ice.Identity id();
}

```

```

The only method is the `id` method, which returns the identity of the corresponding node.

### Object Life Cycle Changes for the DirectoryI Class in Java

As in the [initial version](#), the `DirectoryI` class derives from the generated base class `_DirectoryDisp`. In addition, the class implements the `NodeI` interface. `DirectoryI` must implement each of the Slice operations, leading to the following outline:

### Java

```

package FilesystemI;

import Ice.*;
import Filesystem.*;

public class DirectoryI extends _DirectoryDisp implements NodeI
{
 public Identity
 id();

 public synchronized String
 name(Current c);

 public synchronized NodeDesc[]
 list(Current c);

 public synchronized NodeDesc
 find(String name, Current c) throws NoSuchName;

 public synchronized FilePrx
 createFile(String name, Current c) throws NameInUse;

 public synchronized DirectoryPrx
 createDirectory(String name, Current c) throws NameInUse;

 public void
 destroy(Current c) throws PermissionDenied;

 // ...
}

```

To support the implementation, we also require a number of methods and data members:

## Java

```

package FilesystemI;

import Ice.*;
import Filesystem.*;

public class DirectoryI extends _DirectoryDisp implements NodeI
{
 // ...

 public DirectoryI();
 public DirectoryI(String name, DirectoryI parent);

 public synchronized void
 removeEntry(String name);

 private String _name; // Immutable
 private DirectoryI _parent; // Immutable
 private Identity _id; // Immutable
 private boolean _destroyed;
 private java.util.Map<String, NodeI> _contents;
}

```

The `_name` and `_parent` members store the name of this node and a reference to the node's parent directory. (The root directory's `_parent` member is null.) Similarly, the `_id` member stores the identity of this directory. The `_name`, `_parent`, and `_id` members are immutable once they have been initialized by the constructor. The `_destroyed` member prevents a [race condition](#); to interlock access to `_destroyed` (as well as the `_contents` member) we can use synchronized methods (as for the `name` method), or use a `synchronized(this)` block.

The `_contents` map records the contents of a directory: it stores the name of an entry, together with a reference to the child node.

Here are the two constructors for the class:

### Java

```

public DirectoryI()
{
 this("/", null);
}

public DirectoryI(String name, DirectoryI parent)
{
 _name = name;
 _parent = parent;
 _id = new Identity();
 _destroyed = false;
 _contents = new java.util.HashMap<String, NodeI>();

 _id.name = parent == null ? "RootDir" : java.util.UUID.randomUUID()
 .toString();
}

```

The first constructor is a convenience function to create the root directory with the fixed identity "RootDir" and a null parent.

The real constructor initializes the `_name`, `_parent`, `_id`, `_destroyed`, and `_contents` members. Note that nodes other than the root directory use a UUID as the object identity.

The `removeEntry` method is called by the child to remove itself from its parent's `_contents` map:

### Java

```

public synchronized void
removeEntry(String name)
{
 _contents.remove(name);
}

```

The implementation of the Slice name operation simply returns the name of the node, but also checks whether the node has been destroyed:

### Java

```

public synchronized String
name(Current c)
{
 if (_destroyed)
 throw new ObjectNotExistException();
 return _name;
}

```

Note that this method is synchronized, so the `_destroyed` member cannot be accessed concurrently.

Here is the `destroy` member function for directories:

### Java

```
public void
destroy(Current c) throws PermissionDenied
{
 if (_parent == null)
 throw new PermissionDenied("Cannot destroy root directory");

 synchronized(this) {
 if (_destroyed)
 throw new ObjectNotExistException();

 if (_contents.size() != 0)
 throw new PermissionDenied("Cannot destroy non?empty direct
ory");

 c.adapter.remove(id());
 _destroyed = true;
 }

 _parent.removeEntry(_name);
}
```

The code first prevents destruction of the root directory and then checks whether this directory was destroyed previously. It then acquires the lock and checks that the directory is empty. Finally, `destroy` removes the [Active Servant Map \(ASM\)](#) entry for the destroyed directory and removes itself from its parent's `_contents` map. Note that we call `removeEntry` outside the synchronization to [avoid deadlocks](#).

The `createDirectory` implementation acquires the lock before checking whether the directory already contains a node with the given name (or an invalid empty name). If not, it creates a new servant, adds it to the ASM and the `_contents` map, and returns its proxy:

### Java

```

public synchronized DirectoryPrx
createDirectory(String name, Current c) throws NameInUse
{
 if (_destroyed)
 throw new ObjectNotExistException();

 if (name.length() == 0 || !_contents.containsKey(name))
 throw new NameInUse(name);

 DirectoryI d = new DirectoryI(name, this);
 ObjectPrx node = c.adapter.add(d, d.id());
 _contents.put(name, d);
 return DirectoryPrxHelper.uncheckedCast(node);
}

```

The `createFile` implementation is identical, except that it creates a file instead of a directory:

### Java

```

public synchronized FilePrx
createFile(String name, Current c) throws NameInUse
{
 if (_destroyed)
 throw new ObjectNotExistException();

 if (name.length() == 0 || !_contents.containsKey(name))
 throw new NameInUse(name);

 FileI f = new FileI(name, this);
 ObjectPrx node = c.adapter.add(f, f.id());
 _contents.put(name, f);
 return FilePrxHelper.uncheckedCast(node);
}

```

Here is the implementation of `list`:

## Java

```

public synchronized NodeDesc[]
list(Current c)
{
 if(!_destroyed)
 throw new ObjectNotExistException();

 NodeDesc[] ret = new NodeDesc[_contents.size()];
 java.util.Iterator<java.util.Map.Entry<String, NodeI> > pos =
 _contents.entrySet().iterator();
 for(int i = 0; i < _contents.size(); ++i) {
 java.util.Map.Entry<String, NodeI> e = pos.next();
 NodeI p = e.getValue();
 ret[i] = new NodeDesc();
 ret[i].name = e.getKey();
 ret[i].type = p instanceof FileI
? NodeType.FileType : NodeType.DirType;
 ret[i].proxy = NodePrxHelper.uncheckedCast(c.adapter.createProx
y(p.id()));
 }
 return ret;
}

```

After acquiring the lock, the code iterates over the directory's contents and adds a `NodeDesc` structure for each entry to the returned array.

The `find` operation proceeds along similar lines:

### Java

```

public synchronized NodeDesc
find(String name, Current c) throws NoSuchName
{
 if (_destroyed)
 throw new ObjectNotExistException();

 NodeI p = _contents.get(name);
 if (p == null)
 throw new NoSuchName(name);

 NodeDesc d = new NodeDesc();
 d.name = name;
 d.type = p instanceof FileI ? NodeType.FileType : NodeType.DirType;
 d.proxy = NodePrxHelper.uncheckedCast(c.adapter.createProxy(p.id()))
);
 return d;
}

```

#### Object Life Cycle Changes for the `FileI` Class in Java

The `FileI` class is similar to the `DirectoryI` class. The data members store the name, parent, and identity of the file, as well as the `_destroyed` flag and the contents of the file (in the `_lines` member). The constructor initializes these members:

## Java

```
package FilesystemI;

import Ice.*;
import Filesystem.*;
import FilesystemI.*;

public class FileI extends _FileDisp implements NodeI
{
 // ...

 public FileI(String name, DirectoryI parent)
 {
 _name = name;
 _parent = parent;
 _destroyed = false;
 _id = new Identity();
 _id.name = Util.generateUUID();
 }

 private String _name;
 private DirectoryI _parent;
 private boolean _destroyed;
 private Identity _id;
 private String[] _lines;
}
```

The implementation of the remaining member functions of the `FileI` class is trivial, so we present all of them here:

## Java

```

public synchronized String
name(Current c)
{
 if (_destroyed)
 throw new ObjectNotExistException();
 return _name;
}

public Identity
id()
{
 return _id;
}

public synchronized String[]
read(Current c)
{
 if (_destroyed)
 throw new ObjectNotExistException();

 return _lines;
}

public synchronized void
write(String[] text, Current c)
{
 if (_destroyed)
 throw new ObjectNotExistException();

 _lines = (String[])text.clone();
}

public void
destroy(Current c)
{
 synchronized(this) {
 if (_destroyed)
 throw new ObjectNotExistException();

 c.adapter.remove(id());
 _destroyed = true;
 }

 _parent.removeEntry(_name);
}

```

## Object Life Cycle Concurrency Issues in Java

The preceding implementation is provably deadlock free. All methods hold only one lock at a time, so they cannot deadlock with each other or themselves. While the locks are held, the methods do not call other methods that acquire locks, so any potential deadlock can only arise by concurrent calls to another mutating method, either on the same node or on different nodes. For concurrent calls on the same node, deadlock is impossible because such calls are strictly serialized on the instance; for concurrent calls to `destroy` on different nodes, each node locks itself, releases itself again, and then acquires and releases a lock on its parent (by calling `removeEntry`), also making deadlock impossible.

### Creating Garbage

We have discussed the implementation of [object life cycle](#), that is, how to correctly provide clients with the means to create and destroy objects. However, throughout this discussion, we have tacitly assumed that clients actually call `destroy` once they no longer need an object. What if this is actually not the case? For example, a client might intend to call `destroy` on an object it no longer needs but crash before it can actually make the call.

To see why this is a realistic (and serious) scenario, consider an on-line retail application. Typically, such an application provides a shopping cart to the client, into which the client can place items. Naturally, the cart and the items it contains will be modelled as server-side objects. The expectation is that, eventually, the client will either finalize or cancel the purchase, at which point the shopping cart and its contents can be destroyed. However, the client may never do that, for example, because it crashes or simply loses interest.

The preceding scenario applies to many different applications and shows up in various disguises. For example, the objects might be session objects that encapsulate security credentials of a client, or might be iterator objects that allow a client to iterate over a collection of values. The key point is that the interactions between client and server are stateful: the server creates state on behalf of a client, holds that state for the duration of several client-server interactions, and expects the client to inform the server when it can clean up that state. If the client never informs the server, whatever resources are associated with that client's state are leaked; these resources are termed *garbage*.

The garbage might be memory, file descriptors, network connections, disk space, or any number of other things. Unless the server takes explicit action, eventually, the garbage will accumulate to the point where the server fails because it has run out of memory, file descriptors, network connections, or disk space.

In the context of Ice, the garbage are servants and their associated resources. In this section, we examine strategies that a server can use avoid drowning in that garbage.

### Garbage Collection Solutions

The server is presented with something of a dilemma by garbage objects. The difficulty is not in how to remove the garbage objects (after all, the server knows how to destroy each object), but how to identify whether a particular object is garbage or not. The server knows when a client uses an object (because the server receives an invocation for the object), but the server does not know when an object is no longer of interest to a client (because a dead client is indistinguishable from a slow one).

One approach to dealing with garbage is to avoid creating it in the first place: if all interactions between client and server are stateless, the garbage problem does not arise. Unfortunately, for many applications, implementing this approach is infeasible. The reason is that, in order to turn interactions that are inherently stateful (such as updating a database) into stateless ones, designers are typically forced to keep all the state on the client side, transmit whatever state is required by the server with each remote procedure call, and return the updated state back to the client. In many situations, this simply does not work: for one, the amount of state that needs to be transmitted with each call is often prohibitively large; second, replicating all the state on the client side creates other problems, such as different clients concurrently making conflicting updates to the same data.

The remainder of this section ignores stateless designs. This is not to say that stateless designs are undesirable: where suitable, they can be very effective. However, because many applications simply cannot use them, we focus instead on other ways to deal with garbage.

Mechanisms that identify and reclaim garbage objects are known as garbage collectors. Garbage collectors are well-understood for non-distributed systems. (For example, many programming languages, such as Java and C#, have built-in garbage collectors.)

Non-distributed garbage collectors keep track of all objects that are created, and perform some form of connectivity analysis to determine which objects are still reachable; any objects that are unreachable (that is, objects to which the application code no longer holds any reference) are garbage and are eventually reclaimed.

Unfortunately, for distributed systems, traditional approaches to garbage collection do not work because the cost of performing the connectivity analysis becomes prohibitively large. For example, DCOM provided a distributed garbage collector that turned out to be its Achilles' heel: the collector did not scale to large numbers of objects, particularly across WANs, and several attempts at making it scale failed.

An alternative to distributed garbage collection is to use timeouts to avoid the cost of doing a full connectivity analysis: if an object has not

been used for a certain amount of time, the server assumes that it is garbage and reclaims the object. The drawback of this idea is that it is possible for objects to be collected while they are still in use. For example, a customer may have placed a number of items in a shopping cart and gone out to lunch, only to find on return that the shopping cart has disappeared in the mean time.

Yet another alternative is to use the evictor pattern: the server puts a cap on the total number of objects it is willing to create on behalf of clients and, once the cap is reached, destroys the least-recently used object in order to make room for a new one. This puts an upper limit on the resources used by the server and eventually gets rid of all unwanted objects. But the drawback is the same as with timeouts: just because an object has not been used for a while does not necessarily mean that it truly is garbage.

Neither timeouts nor evictors are true garbage collectors because they can collect objects that are not really garbage, but they do have the advantage that they reap objects even if the client is alive, but forgets to call `destroy` on some of these objects.

## Simple Mechanisms for Garbage Collection

Traditional garbage collection fails in the distributed case for a number of reasons:

- Garbage collectors require connectivity analysis, which is prohibitively expensive. Furthermore, for distributed object systems that permit proxies to be externalized as strings, such as Ice, connectivity analysis is impossible because proxies can exist and travel by means that are invisible to the run time. For example, proxies can exist as records in a database and can travel as strings inside e-mail messages.
- Garbage collectors consider all objects in existence but, for the vast majority of applications, only a small subset of all objects actually ever needs collecting. The work spent in examining objects that can never become garbage is wasted.
- Garbage collectors examine connectivity at the granularity of a single object. However, for many distributed applications, objects are used in groups and, if one object in a group is garbage, all objects in the group are garbage. It would be useful to take advantage of this knowledge, but a garbage collector cannot do this because that knowledge is specific to each application.

In the remainder of this section, we examine a simple mechanism that allows you to get rid of garbage objects cheaply and effectively. The approach has the following characteristics:

- Only those objects that potentially can become garbage are considered for collection.
- Granularity of collection is under control of the application: you can have objects collected as groups of arbitrary size, down to a single object.
- Objects are guaranteed not to be collected prematurely.
- Objects are guaranteed to be collected if the client crashes or suffers loss of connectivity.
- The mechanism is simple to implement and has low run-time overhead.

It is equally important to be aware of the limitations of the approach:

- The approach collects objects if a client crashes, but offers no protection against clients that are still running, but have neglected to destroy objects that they no longer need. In other words, the server is protected against client-side hardware failure and catastrophic client crashes, but it is not protected against faulty programming logic of clients.
- The approach is not transparent at the interface level: it requires changes (albeit minor ones) to the interface definitions for an application.
- The approach requires the client to periodically call the server, thus consuming network resources even if the client is otherwise idle.

Despite the limitations, this approach to garbage collection is applicable to a wide variety of applications and meets the most pragmatic need: how to clean up in case something goes badly wrong (rather than how to clean up in case the client misbehaves).

## Using an Extra Level of Indirection to Collect Garbage

Object factories are typically singleton objects that create objects on behalf of various clients. It is important for our garbage collector to know which client created what objects, so the collector can reap the objects created by a specific client if that client crashes. We can easily deal with this requirement by adding the proverbial level of indirection: instead of making a factory a singleton object, we provide a singleton object that creates factories. Clients first create a factory and then create all other objects they need using that factory:

### Slice

```

interface Item { /* ...*/ };

interface Cart
{
 Item* create(/* ... */);
 idempotent string getName();
 void destroy();
 idempotent void refresh();
};

interface CartFactory // Singleton
{
 Cart* create(string name);
};

```

Clients obtain a proxy to the `CartFactory` singleton and call `create` to create a `Cart` object. In turn, the `Cart` object provides a `create` operation to place new objects of type `Item` into the cart. Note that the shopping cart name allows a client to distinguish different carts — the `name` parameter is *not* used to identify clients or to provide a unique identifier for carts. The `getName` operation on the `Cart` object returns the name that was used by the client to create it.

Each `Cart` object remembers which items it created. Because each client uses its own shopping cart, the server knows which objects were created by what client. In normal operation, a client first creates a shopping cart, and then uses the cart to create the items in the cart. Once the client has finished its job, it calls `destroy` on the cart. The implementation of `destroy` destroys both the cart and its items to reclaim resources.

To deal with crashed clients, the server needs to know when a cart is no longer in use. This is the purpose of the `refresh` operation: clients are expected to periodically call `refresh` on their cart objects. For example, the server might decide that, if a client's cart has not been refreshed for more than ten minutes, the cart is no longer in use and reclaim it. As long as the client calls `refresh` at least once every ten minutes, the cart (and the items it contains) remain alive; if more than ten minutes elapse, the server simply calls `destroy` on the cart. Of course, there is no need to hard-wire the timeout value — you can make it part of the application's configuration. However, to keep the implementation simple, it is useful to have the same timeout value for all carts, or to at least restrict the timeouts for different carts to a small number of fixed choices — this considerably simplifies the implementation in both client and server.

## Server-Side Changes for Garbage Collection

The implementation of the interfaces on the server side almost suggests itself:

- Whenever `refresh` is called on a cart, the cart records the time at which the call was made.
- The server runs a reaper thread that wakes up once every ten minutes. The reaper thread examines the timestamp of all carts and, if it finds a cart last time-stamped more than ten minutes ago, it calls `destroy` on that cart.
- Each cart remembers the items it contains and destroys them as part of its `destroy` implementation.

Here then is the reaper thread in outline. (Note that we have simplified the code to show the essentials. For example, we have omitted the code that is needed to make the reaper thread terminate cleanly when the server shuts down. See the code in `demo/Ice/session` for more detail.)

**C++**

```

class ReapThread : public IceUtil::Thread,
 public IceUtil::Monitor<IceUtil::Mutex>
{
public:
 ReapThread();
 virtual void run();
 void add(const CartPrx&, const CartIPtr&);

private:
 const IceUtil::Time _timeout;
 struct CartProxyPair
 {
 CartProxyPair(const CartPrx& p, const CartIPtr& c) :
 proxy(p), cart(c) { }
 const CartPrx proxy;
 const CartIPtr cart;
 };
 std::list<CartProxyPair> _carts;
};

typedef IceUtil::Handle<ReapThread> ReapThreadPtr;

```

Note that the reaper thread maintains a list of pairs. Each pair stores the proxy of a cart and its servant pointer. We need both the proxy and the pointer because we need to invoke methods on both the Slice interface and the implementation interface of the cart. Whenever a client creates a new cart, the server calls the `add` method on the reaper thread, passing it the new cart:

**C++**

```

void ReapThread::add(const CartPrx& proxy, const CartIPtr& cart)
{
 Lock sync(*this);
 _carts.push_back(CartProxyPair(proxy, cart));
}

```

The `run` method of the reaper thread is a loop that sleeps for ten minutes and calls `destroy` on any session that has not been refreshed within the preceding ten minutes:

**C++**

```

void ReaperThread::run()
{
 Lock sync(*this);
 while (true) {
 timedWait(_timeout);
 list<CartProxyPair>::iterator p = _carts.begin();
 while (p != _carts.end()) {
 try {
 //
 // Cart destruction may take some time.
 // Therefore the current time is computed
 // for each iteration.
 //
 if ((IceUtil::Time::now() - p->cart->timestamp()) >
 _timeout) {
 p->proxy->destroy();
 p = _carts.erase(p);
 } else {
 ++p;
 }
 } catch (const Ice::ObjectNotExistException&) {
 p = _carts.erase(p);
 }
 }
 }
}

```

Note that the reaper thread catches `ObjectNotExistException` from the call to `destroy`, and removes the cart from its list in that case. This is necessary because it is possible for a client to call `destroy` explicitly, so a cart may be destroyed already by the time the reaper thread examines it.

The `CartFactory` implementation is trivial:

**C++**

```

class CartFactoryI : CartFactory
{
public:
 CartFactoryI(const ReaperThreadPtr&);
 virtual CartPrx create(const std::string&, const Ice::Current&);

private:
 ReaperThreadPtr _reaper;
};

```

The constructor is passed the instantiated reaper thread and remembers that thread in the `_reaper` member.

The `create` method adds each new cart to the reaper thread's list of carts:

**C++**

```

CartPrx CartFactoryI::create(const string& name, const Ice::Current& c)
{
 CartIPtr cart = new CartI(name);
 CartPrx proxy = CartPrx::uncheckedCast(
 c.adapter->addWithUUID(cart));
 _reaper->add(proxy, cart);

 return proxy;
}

```

Note that each cart internally has a unique ID that is unrelated to its name — the name exists purely as a convenience for the application.

The server's `main` function starts the reaper thread and instantiates the cart factory:

**C++**

```

ReapThreadPtr reaper = new ReapThread();
CartFactory factory = new CartFactoryI(reaper);
reaper->start();
adapter->add(factory, Ice::stringToIdentity(CartFactory));
adapter->activate();

```

This completes the implementation on the server side. Note that there is very little code here, and that much of this code is essentially the same for each application. For example, we could easily turn the `ReapThread` class into a template class to permit the same code to be used for something other than shopping carts.

## Client-Side Changes for Garbage Collection

On the client side, the application code does what it would do with an ordinary factory, except for the extra level of indirection: the client first creates a cart, and then uses the cart as its factory.

As long as the client-side calls `refresh` at least once every ten minutes, the cart remains alive and, with it, all items the client created in that cart. Once the client misses a `refresh` call, the reaper thread in the server cleans up the cart and its items.

To keep the cart alive, you could sprinkle your application code with calls to `refresh` in the hope that at least one of these calls is made at least every ten minutes. However, that is not only error-prone, but also fails if the client blocks for some time. A much better approach is to run a thread in the client that automatically calls `refresh`. That way, the calls are guaranteed to happen even if the client's main thread blocks for some time, and the application code does not get polluted with `refresh` calls. Again, we show a simplified version of the refresh thread here that does not deal with issues such as clean shutdown and a few other irrelevant details:

**C++**

```

class CartRefreshThread : public IceUtil::Thread,
 public IceUtil::Monitor<IceUtil::Mutex>
{
public:
 CartRefreshThread(const IceUtil::Time& timeout, const CartPrx& cart)
 :
 _cart(cart),
 _timeout(timeout) {}

 virtual void run() {
 Lock sync(*this);
 while(true) {
 timedWait(_timeout);
 try {
 _cart->refresh();
 } catch(const Ice::Exception& ex) {
 return;
 }
 }
 }

private:
 const CartPrx _cart;
 const IceUtil::Time _timeout;
};

typedef IceUtil::Handle<CartRefreshThread> CartRefreshThreadPtr;

```

The client's `main` function instantiates the reaper thread after creating a cart. We assume that the client has a proxy to the cart factory in the `factory` variable:

**C++**

```

CartPrx cart = factory->create(name);
CartRefreshThreadPtr refresh = new
CartRefreshThread(IceUtil::Time::seconds(480), cart);
refresh->start();

```

Note that, to be on the safe side and also allow for some network delays, the client calls `refresh` every eight minutes; this is to ensure that at least one call to `refresh` arrives at the server within each ten-minute interval.

## Platform-Specific Features

This section describes Ice features that are available only on a specific platform, such as Microsoft Windows.

### Topics

- [Windows Services](#)
- [Windows Store Applications](#)

## Windows Services

A Windows service is a program that runs in the background and typically does not require user intervention. Similar to a daemon on Unix platforms, a Windows service is usually launched automatically when the operating system starts and runs until the system shuts down.

Ice includes the `Service` class that simplifies the task of writing an Ice-based Windows service in C++. Writing the service is only the first step, however, as it is also critically important that the service be installed and configured correctly for successful operation. Service installation and configuration is outside the scope of the `Service` class because these tasks are generally not performed by the service itself but rather as part of a larger administrative effort to deploy an application. Furthermore, there are security implications to consider when a service is able to install itself: such a service typically needs administrative rights to perform the installation, but does not necessarily need those rights while it is running. A better strategy is to grant administrative rights to a separate installer program and not to the service itself.

### Topics

- [Installing a Windows Service](#)
- [Using the Ice Service Installer](#)
- [Manually Installing a Service as a Windows Service](#)
- [Troubleshooting Windows Services](#)

## Installing a Windows Service

The installation of a Windows service varies in complexity with the needs of the application, but usually involves the following activities:

- Selecting the user account in which the service will run.
- Registering the service and establishing its activation mode and dependencies.
- Creating one or more file system directories to contain executables, libraries, and supporting files or databases.
- Configuring those directories with appropriate permissions so that they are accessible to the user account selected for the service.
- Creating keys in the Windows registry.
- Configuring the Windows Event Log so that the service can report status and error messages.

There are many ways to perform these tasks. For example, an administrator can [execute them manually](#). Another option is to write a script or program tailored to the needs of your application. Finally, you can build an installer using a developer tool such as InstallShield.

## Selecting a User Account for the Service

Before installing a service, you should give careful consideration to the user account that will run the service. Unless your service has special requirements, we recommend that you use the built-in account that Windows provides specifically for this purpose, `Local Service`.

### See Also

- [Manually Installing a Service as a Windows Service](#)

## Using the Ice Service Installer

Ice provides the command-line tool `iceserviceinstall` to assist you in installing and uninstalling the following Ice services as Windows services:

- [IceGrid registry](#)
- [IceGrid node](#)
- [Glacier2 router](#)

Ice includes other programs that can also be run as Windows services, such as the [IceBox](#) and [IcePatch2](#) servers. Typically it is not necessary to install these programs as Windows services because they can be launched by an IceGrid node service. However, if you wish to run an IceBox or IcePatch2 server as a Windows service without the use of IceGrid, you must [manually install](#) the service.

Here we describe how to use the Ice service installer and discuss its actions and prerequisites.

On this page:

- [iceserviceinstall Command Line Options](#)
- [Security Considerations for Ice Services](#)
- [iceserviceinstall Configuration File](#)
  - [Sample Configuration Files](#)
- [iceserviceinstall Properties](#)
- [Service Installation Process](#)
- [Uninstalling a Windows Service](#)

### `iceserviceinstall` Command Line Options

`iceserviceinstall` supports the following options and arguments:

```
iceserviceinstall [options] service config-file [property ...]

Options:
-h, --help Show this message.
-n, --nopause Do not call pause after displaying a message.
-v, --version Display the Ice version.
-u, --uninstall Uninstall the Windows service.
```

The *service* and *config-file* arguments are required during installation and uninstallation.

The *service* argument selects the type of service you are installing; use one of the following values:

- `icegridregistry`
- `icegridnode`
- `glacier2router`

Note that the Ice service installer currently does not support the installation of an IceGrid node with a collocated registry, therefore you must install the registry and node separately.

The *config-file* argument specifies the name of an Ice configuration file.

When installing a service, properties can be defined on the command line using the `--name=value` syntax, or they can be defined in the configuration file. The supported properties are described [below](#).

### Security Considerations for Ice Services

None of the Ice services require privileges beyond a normal user account. In the case of the IceGrid node service in particular, we do not recommend running it in a [user account](#) with elevated privileges because the service is responsible for launching server executables, and those servers would inherit the node's access rights.

## iceserviceinstall Configuration File

The Ice service installer requires that you specify the path name of the Ice configuration file for the service being installed or uninstalled. The tool needs this path name for several reasons:

- During installation, it verifies that the configuration file has sufficient access rights.
- It configures a newly-installed service to load the configuration file using its absolute path name, therefore you must decide in advance where the file will be located.
- It reads the configuration file and examines certain service-specific properties. For example, prior to installing an IceGrid registry service, the tool verifies that the directory specified by the property `IceGrid.Registry.Data` has sufficient access rights.
- The tool supports its own configuration parameters that may also be defined as [properties](#) in this file.

You may still modify a service's configuration file after installation, but you should uninstall and reinstall the service if you change any of the properties that influence the service installer's actions. The table below describes the service properties that affect the installer:

Property	Service	Description
<code>IceGrid.InstanceName</code>	IceGrid Registry	Value appears in the service name; also included in the default display name if one is not defined.
<code>IceGrid.Node.Data</code>	IceGrid Node	Directory is created if necessary; access rights are verified.
<code>IceGrid.Node.Name</code>	IceGrid Node	Value appears in the service name; also included in the default display name if one is not defined.
<code>IceGrid.Registry.Data</code>	IceGrid Registry	Directory is created if necessary; access rights are verified.
<code>Ice.Default.Locator</code>	IceGrid Node, Glacier2 Router	The IceGrid instance name is derived from the identity in this proxy.
<code>Ice.EventLog.Source</code>	All	Specifies the name of an event log source for the service.

The steps performed by the tool during an installation are described in detail [below](#).

## Sample Configuration Files

Ice includes sample configuration files for the IceGrid and Glacier2 services in the `config` subdirectory of your Ice installation. We recommend that you review the comments and settings in these files to familiarize yourself with a typical configuration of each service.

You can modify a configuration file to suit your needs or copy one to use as a starting point for your own configuration.

## iceserviceinstall Properties

The Ice service installer uses a set of optional properties that customize the installation process. These properties can be defined in the service's configuration file as discussed above, or they can be defined on the command line using the familiar `--name=value` syntax:

```
iceserviceinstall --DependOnRegistry=1 ...
```

The installer's properties are listed below:

- `AutoStart=num`  
If `num` is a value greater than zero, the service is configured to start automatically at system start up. Set this property to zero to configure the service to start on demand instead. If not specified, the default value is 1.
- `DependOnRegistry=num`  
If `num` is a value greater than zero, the service is configured to depend on the IceGrid registry, meaning Windows will start the registry prior to starting this service. Enabling this feature also requires that the property `Ice.Default.Locator` be defined in `config-file`. If not specified, the default value is zero.
- `Description=value`  
A brief description of the service. If not specified, a general description is used.

- `DisplayName=name`  
The friendly name that identifies the service to the user. If not specified, `iceserviceinstall` composes a default display name.
- `EventLog=name`  
The name of the event log used by the service. If not specified, the default value is `Application`.
- `ImagePath=path`  
The path name of the service executable. If not specified, `iceserviceinstall` assumes the service executable resides in the same directory as itself and fails if the executable is not found.
- `ObjectName=name`  
Specifies the account used to run the service. If not specified, the default value is `NT Authority\LocalService`.
- `Password=value`  
The password required by the account specified in `ObjectName`.

## Service Installation Process

The Ice service installer performs a number of steps to install a service. As discussed [earlier](#), you must specify the path name of the service's configuration file because the service installer uses certain properties during the installation process. The actions taken by the service installer are described below:

- Obtain the service's *instance name* from the configuration file. The instance name is specified by the property `IceGrid.InstanceName` or `Glacier2.InstanceName`. If an instance name is not specified, the default value is `IceGrid` or `Glacier2`, respectively. If the service being installed depends on the IceGrid registry, the IceGrid instance name is derived from the value of the `Ice.DefaultLocator` property.
- For an IceGrid node, obtain the node's name from the property `IceGrid.Node.Name`. This property must be defined when installing a node.
- Compose the service name from the service type, instance name, and node name (for an IceGrid node). For example, the default service name for an IceGrid registry is `icegridregistry.IceGrid`. Note that the service name is not the same as the display name.
- Resolve the user account specified by `ObjectName`.
- For an IceGrid registry, create the data directory specified by the property `IceGrid.Registry.Data` and ensure that the user account specified by `ObjectName` has read/write access to the directory.
- For an IceGrid node, create the data directory specified by the property `IceGrid.Node.Data` and ensure that the user account specified by `ObjectName` has read/write access to the directory.
- For an IceGrid node, ensure that the user account specified by `ObjectName` has read access to the following registry key:  
`HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Perflib`  
This key allows the node to access [CPU utilization statistics](#).
- Ensure that the user account specified by `ObjectName` has read/write access to the configuration file.
- Create a new Windows event log by adding the registry key specified by `EventLog`.
- Add an event log source under `EventLog` for the source name specified by `Ice.EventLog.Source`. If this property is not defined, the service name is used as the source name.
- Install the service, including command line arguments that specify the service name (`--service name`) and the absolute path name of the configuration file (`--Ice.Config=config-file`).

The Ice service installer currently does *not* perform these tasks:

- Modify access rights for the service's executable or its DLL dependencies
- Verify that the user account specified by `ObjectName` has the right to "Log on as a service"

## Uninstalling a Windows Service

When uninstalling an existing service, the Ice service installer first ensures that the service is stopped, then proceeds to remove the service. The service's event log source is removed and, if the service is not using the `Application` log, the event log registry key is also removed.

## Manually Installing a Service as a Windows Service

This page describes how to manually install and configure an Ice service as a Windows Service using the `IcePatch2` service as a case study. For the purposes of this discussion, we assume that Ice is installed in the directory `C:\Ice`. We also assume that you have administrative access to your system, which is required by many of the installation steps discussed below.

On this page:

- [Selecting a User Account for the IcePatch2 Service](#)
- [Preparing a Directory for the IcePatch2 Service](#)
  - [Selecting a Directory for the IcePatch2 Service](#)
  - [Creating the Directory for the IcePatch2 Service](#)
  - [Populating the Directory for the IcePatch2 Service](#)
- [Configuration File for the IcePatch2 Service](#)

  - [Using a Custom Log for the IcePatch2 Service](#)
  - [Registry Caching for the IcePatch2 Service](#)
- [Starting the IcePatch2 Service](#)
- [Testing the IcePatch2 Service](#)

### Selecting a User Account for the IcePatch2 Service

The `IcePatch2` service can run in a regular user account, therefore we will follow [our own recommendation](#) and use the Local Service account.

### Preparing a Directory for the IcePatch2 Service

The service needs a directory in which to store the files that it distributes to clients. A common mistake is assuming that a service will be able to access a file or directory that you created using your current account, which is likely to cause the service to fail in a way that is difficult to diagnose. To prevent such failures, we will ensure that the directory has the necessary permissions for the service to access it while running in the `Local Service` account.

### Selecting a Directory for the IcePatch2 Service

The directory tree for our `IcePatch2` service is shown below:

```
C:\Windows\
 ServiceProfiles\
 LocalService\
 AppData\
 Local\
 ZeroC\
 icepatch2\
 data\
```

### Creating the Directory for the IcePatch2 Service

Since `Local Service` is a built-in account, its user directory should already exist and have the proper access rights.

Opening the `LocalService` directory in Windows Explorer may require administrative permission. Once opened, the `AppData` subdirectory may not be visible without modifying the folder options to show hidden files and directories.

You can verify its access rights in a command window using the `icacls` utility:

```
> cd \Windows\ServiceProfiles
> icacls LocalService
LocalService NT AUTHORITY\SYSTEM:(OI)(CI)(F)
 BUILTIN\Administrators:(OI)(CI)(F)
 NT AUTHORITY\LOCAL SERVICE:(OI)(CI)(F)
```

The `AppData` subdirectory should inherit these same rights. Now we can create the remaining subdirectories:

```
> cd LocalService\AppData
> mkdir Local\ZeroC\icepatch2\data
```

If you want to further restrict access to files or subdirectories, you can modify them as necessary using the `icacls` utility. Note however that certain actions may cause a file to revert back to the access rights of its enclosing directory. For example, modifying a file using a text editor is often the equivalent of erasing the file and recreating it, which discards any access rights you may have previously set for the file.

You can also manage privilege settings interactively using Windows Explorer. For example, right click on the `LocalService` directory, select Properties, and select the Security tab. Click the Advanced button to modify the settings.

### Populating the Directory for the IcePatch2 Service

Now you can copy the files that will be distributed to clients into the `data` subdirectory. The new files should inherit the access rights of their enclosing directory. For the sake of discussion, let's copy some Slice files from the Ice distribution into the data directory:

```
> cd Local\ZeroC\icepatch2\data
> copy \Ice\slice\Ice*.ice
```

Next we need to run `icepatch2calc` to prepare the directory for use by the IcePatch2 service:

```
> cd Local\ZeroC\icepatch2\data
> icepatch2calc .
```

### Configuration File for the IcePatch2 Service

IcePatch2 requires a minimal set of configuration properties. We could specify them on the service's command line, but if we later want to modify those properties we would have to reinstall the service. Defining the properties in a file simplifies the task of modifying the service's configuration.

Our IcePatch2 configuration is quite simple:

```
IcePatch2.Directory=C:\Windows\ServiceProfiles\LocalService\AppData\Local\ZeroC\icepatch2\data
IcePatch2.Endpoints=tcp -p 10000
```

The `IcePatch2.Directory` property specifies the location of the server's data directory, which we created in the previous section.

We will save our configuration properties into the following file:

```
C:\Ice\config\icepatch2.cfg
```

We must also ensure that the service has permission to access its configuration file. The Ice run time never modifies a configuration file, therefore read access is sufficient. The configuration file likely already has the necessary access rights, which we can verify using the `icacls` utility that we described earlier:

```
> icacls C:\Ice\config\icepatch2.cfg
```

## Creating the IcePatch2 Service

We will use Microsoft's Service Control (`sc`) utility in a command window to create the service.

See <http://support.microsoft.com/kb/251192> for more information about the `sc` utility.

Our first `sc` command does the majority of the work (the command is formatted for readability but must be typed on a single line):

```
> sc create icepatch2 binPath= "C:\Ice\bin\icepatch2server.exe
--Ice.Config=C:\Ice\config\icepatch2.cfg --service icepatch2"
DisplayName= "IcePatch2 Server" start= auto
obj= "NT Authority\LocalService" password= ""
```

There are several important aspects of this command:

- The service name is `icepatch2`. You can use whatever name you like, as long as it does not conflict with an existing service. Note however that this name is used in other contexts, such as in the `--service` option discussed below, therefore you must use it consistently.
- Following the service are several options. Note that all of the option names end with an equals sign and are separated from their arguments with at least one space.
- The `binPath=` option is required. We supply the full path name of the IcePatch2 server executable, as well as command-line arguments that define the location of the configuration file and the name of the service, all enclosed in quotes.
- The `DisplayName=` option sets a friendly name for the service.
- The `start=` option configures the start up behavior for the service. We used the argument `auto` to indicate the service should be started automatically when Windows boots.
- The `obj=` option selects the user account in which this service runs. As we [explained](#), the `Local Service` account is appropriate for most services.
- The `password=` option supplies the password associated with the user account indicated by `obj=`. The `Local Service` account has an empty password.

The `sc` utility should report success if it was able to create the service as specified. You can verify that the new service was created with this command:

```
> sc qc icepatch2
```

Alternatively, you can start the Services administrative control panel and inspect the properties of the IcePatch2 service.

If you start the control panel, you will notice that the entry for IcePatch2 does not have a description. To add a description for the service, use the following command:

```
> sc description icepatch2 "IcePatch2 file server"
```

After refreshing the list of services, you should see the new description.

## Creating the Event Log for the IcePatch2 Service

By default, programs such as the IcePatch2 service that utilize the `Service` class log messages to the `Application` event log. Below we describe how to prepare the Windows registry for the service's default behavior, and we also show how to use a custom event log instead. We make use of Microsoft's Registry (`reg`) utility to modify the registry, although you could also use the interactive `regedit` tool. As always, caution is recommended whenever you modify the registry.

### Using the Application Log for the IcePatch2 Service

We must configure an event log source for events to display properly. The first step is to create a registry key with the name of the source. Since the `Service` class uses the service name as the source name by default, we add the key `icepatch2` as shown below:

```
> reg add
HKLM\SYSTEM\CurrentControlSet\Services\EventLog\Application\icepatch2
```

Inside this key we must add a value specifies the location of the Ice run time DLL:

```
> reg add
HKLM\SYSTEM\CurrentControlSet\Services\EventLog\Application\icepatch2 /v
EventMessageFile /t REG_EXPAND_SZ /d C:\Ice\bin\ice36.dll
```

We will also add a value indicating the types of events that the source supports:

```
> reg add
HKLM\SYSTEM\CurrentControlSet\Services\EventLog\Application\icepatch2 /v
TypesSupported /t REG_DWORD /d 7
```

The value 7 corresponds to the combination of the following event types:

- EVENTLOG\_ERROR\_TYPE
- EVENTLOG\_WARNING\_TYPE
- EVENTLOG\_INFORMATION\_TYPE

You can verify that the registry values have been defined correctly using the following command:

```
> reg query
HKLM\SYSTEM\CurrentControlSet\Services\EventLog\Application\icepatch2
```

Our configuration of the event log is now complete.

### Changing the Source Name for the IcePatch2 Service

Using the configuration described in the previous section, events logged by the IcePatch2 service are recorded in the event log using the source name `icepatch2`. If you prefer to use a source name that differs from the service name, you can replace `icepatch2` in the registry commands with the name of your choosing, but you must also add a matching definition for the property `Ice.EventLog.Source` to the service's configuration file.

For example, to use the source name `Ice File Patching Service`, you would add the registry key as shown below:

```
> reg add
"HKLM\SYSTEM\CurrentControlSet\Services\EventLog\Application\Ice File
Patching Service"
```

The commands to add the `EventMessageFile` and `TypesSupported` values must be modified in a similar fashion. Finally, add the following configuration property to `icepatch2.cfg`:

```
Ice.EventLog.Source=Ice File Patching Service
```

### Using a Custom Log for the IcePatch2 Service

You may decide that you want your services to record messages into an application-specific log instead of the `Application` log that is shared by other unrelated services. As an example, let us create a log named `MyApp`:

```
> reg add "HKLM\SYSTEM\CurrentControlSet\Services\EventLog\MyApp"
```

Next we add a subkey for the `IcePatch2` service. As described in the previous section, we will use a friendlier source name:

```
> reg add "HKLM\SYSTEM\CurrentControlSet\Services\EventLog\MyApp\Ice
File Patching Service"
```

Now we can define values for `EventMessageFile` and `TypesSupported`:

```
> reg add "HKLM\SYSTEM\CurrentControlSet\Services\EventLog\MyApp\Ice
File Patching Service" /v EventMessageFile /t REG_EXPAND_SZ /d
C:\Ice\bin\ice36.dll

> reg add "HKLM\SYSTEM\CurrentControlSet\Services\EventLog\MyApp\Ice
File Patching Service" /v TypesSupported /t REG_DWORD /d 7
```

Finally, we define `Ice.EventLog.Source` in the `IcePatch2` service's configuration file:

```
Ice.EventLog.Source=Ice File Patching Service
```

Note that you must restart the Event Viewer control panel after adding the `MyApp` registry key in order to see the new log.

### Registry Caching for the IcePatch2 Service

The first time a service logs an event, Windows' Event Log service caches the registry entries associated with the service's source. If you wish to modify a service's event log configuration, such as changing the service to use a custom log instead of the `Application` log, you should perform the following steps:

1. Stop the service.
2. Remove the unwanted event log registry key.
3. Add the new event log registry key(s).

4. Restart the system (or at least the Event Log service).
5. Start the service and verify that the log entries appear in the intended log.

After following these steps, open a log entry and ensure that it displays properly. If it does not, for example if the event properties indicate that the description of an event cannot be found, the problem is likely due to a misconfigured event source. Verify that the value of `EventMessageFile` refers to the correct location of the Ice run time DLL, and that the service is defining `Ice.EventLog.Source` in its configuration file (if necessary).

## Starting the IcePatch2 Service

We are at last ready to start the service. In a command window, you can use the `sc` utility:

```
> sc start icepatch2
```

The program usually responds with status information indicating that the start request is pending. You can query the service's status to verify that it started successfully:

```
> sc query icepatch2
```

The service should now be in the running state. If it is not in this state, open the Event Viewer control panel and inspect the relevant log for more information that should help you to locate the problem. Even if the service started successfully, you may still want to use the Event Viewer to confirm that the service is using the log you expected.

## Testing the IcePatch2 Service

Ice includes a graphical IcePatch2 client in the `demo/IcePatch2/MFC` directory of the Ice distribution. Once you have built the client, you can use it to test that the service is working properly.

## Troubleshooting Windows Services

This page describes how to troubleshoot Windows Services.

On this page:

- [Missing Libraries for a Windows Service](#)
- [Windows Firewall Interference](#)
- [IceGrid Node Performance Monitoring Issues](#)

### Missing Libraries for a Windows Service

One failure that commonly occurs when starting a Windows service is caused by missing DLLs, which usually results in an error window stating a particular DLL cannot be found. Fixing this problem can often be a trial-and-error process because the DLL mentioned in the error may depend on other DLLs that are also missing. It is important to understand that a Windows service is launched by the operating system and can be configured to execute as a different user, which means the service's environment (most importantly its `PATH`) may not match yours and therefore extra steps are necessary to ensure that the service can locate its required DLLs.

The command-line utility `dumpbin` can be used to discover the dependencies of an executable or DLL.

The simplest approach is to copy all of the necessary DLLs to the directory containing the service executable. If this solution is undesirable, another option is to modify the system `PATH` to include the directory or directories containing the required DLLs. (Note that modifying the system `PATH` requires restarting the system.) Finally, you can copy the necessary DLLs to `\WINDOWS\system32`, although we do not recommend this approach.

Copying DLLs to `\WINDOWS\system32` often results in subtle problems later when trying to develop using newer versions of the DLLs. Inevitably you will forget about the DLLs in `\WINDOWS\system32` and struggle to determine why your application is misbehaving or failing to start.

Assuming that DLL issues are resolved, a Windows service can fail to start for a number of other reasons, including

- invalid command-line arguments or configuration properties
- inability to access necessary resources such as file systems and databases, because either the resources do not exist or the service does not have sufficient access rights to them
- networking issues, such as attempting to open a port that is already in use, or DNS lookup failures

Failures encountered by the Ice run time prior to initialization of the communicator are reported to the Windows event log if no other logger implementation is defined, so that should be the first place you look. Typically you will find an entry in the `System` event log resembling the following message:

```
The IcePatch2 service terminated with service-specific error 1.
```

Error code 1 corresponds to `EXIT_FAILURE`, the value used by the `Service` class to indicate a failure during startup. Additional diagnostic messages may be available in the `Application` event log. See [Ice::Service Logging Considerations](#) for more information on configuring a logger for a Windows service.

As we mentioned earlier, insufficient access rights can also prevent a Windows service from starting successfully. By default, a Windows service is configured to run under a local system account, in which case the service may not be able to access resources owned by other users. It may be necessary for you to configure a service to run under a [different account](#), which you can do using the Services control panel. You should also review the [access rights](#) of files and directories required by the service.

### Windows Firewall Interference

Your choice of user account determines whether you receive any notification when the Windows Firewall blocks the ports that are used by your service. For example, if you use `Local Service` as we [recommended](#), you will not see any Windows Security Alert dialog (see this [Microsoft article](#) for details).

If you are not prompted to unblock your service, you will need to manually add an exception in Windows Firewall. For example, follow the

steps below to unblock the ports of a Glacier2 router service:

1. Open the Windows Firewall Settings panel and navigate to the Exceptions panel.
2. Select "Add program..."
3. Select "Browse," navigate to the Glacier2 router executable, and click "OK."

Note that adding an exception for a program unblocks all ports on which the program listens. Review the endpoint configurations of your services carefully to ensure that no unnecessary ports are opened.

For services listening on one or a few fixed ports, you could also create port exceptions in your Windows Firewall. Refer to the Windows Firewall documentation for details.

## IceGrid Node Performance Monitoring Issues

The IceGrid node uses Windows' `Perflib` facility to obtain statistics about the CPU utilization of its host for [load balancing](#) purposes. Occasionally, the IceGrid node may log the following warning message:

```
warning: Unable to lookup the performance counter name
```

This message is an indication that the node does not have sufficient privileges to access a key in the Windows registry:

```
HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Perflib
```

As part of its installation procedure, the `iceserviceinstall` utility modifies the permissions of this registry key to grant read access to the node's designated user account. If you are trying to change the node's user account, we recommend using the `iceserviceinstall` utility to uninstall and reinstall the node. If you wish to modify the permissions of this registry key manually, follow these steps:

1. Start `regedit` and navigate to the `Perflib` key.
2. Right click on `Perflib` and select `Permissions`.
3. If the desired user account is not already present, click `Add` to add the user account. Enter `LOCAL SERVICE` if you wish to run the node in the Local Service account, otherwise enter the name of the user account. Press `OK`.
4. Check the `Read` box in the `Allow` column to grant read access to the registry key and press `OK` to apply the changes.

Another way to grant the node's user account with the necessary access rights is to add it to the `Performance Monitor Users` group.

## Windows Store Applications

A Windows Store application that uses Ice must request certain capabilities in its manifest in order to access public and private networks. The image below shows the relevant settings in Visual Studio:

Neglecting to enable the proper capabilities can raise `Ice::SocketException` or, if you are debugging the application in Visual Studio at the time of the exception, it will likely break on `Platform::AccessDeniedException`.

If your client application uses SSL, you can bundle certificates with the application by including them in the application's declarations:

**Example**

The UWP sample programs in the Ice distribution use capabilities and declarations.

# Property Reference

This section provides a reference for all properties used by the Ice run time and its services.

Unless stated otherwise in the description of an individual property, its default value is the empty string. If a property takes a numeric value, the empty string is interpreted as zero.

Note that Ice reads properties that control the run time and its services only once on start-up, when you create a communicator. This means that you must set Ice-related properties to their correct values before you create a communicator. If you change the value of an Ice-related property after that point, it is likely that the new setting will simply be ignored.

## Object Adapter Properties

On this page:

- `adapter.ACM.Close`
- `adapter.ACM.Heartbeat`
- `adapter.ACM.Timeout`
- `adapter.AdapterId`
- `adapter.Endpoints`
- `adapter.Locator`
- `adapter.MessageSizeMax`
- `adapter.ProxyOptions`
- `adapter.PublishedEndpoints`
- `adapter.ReplicaGroupId`
- `adapter.Router`
- `adapter.ThreadPool.Serialize`
- `adapter.ThreadPool.Size`
- `adapter.ThreadPool.SizeMax`
- `adapter.ThreadPool.SizeWarn`
- `adapter.ThreadPool.StackSize`
- `adapter.ThreadPool.ThreadIdleTime`
- `adapter.ThreadPool.ThreadPriority`

### ***adapter.ACM.Close***

#### ***Synopsis***

`adapter.ACM.Close=num`

#### ***Description***

Overrides the value of `Ice.ACM.Server.Close` for incoming connections to the named object adapter.

Note that ACM can cause incoming oneway requests to be silently discarded.

### ***adapter.ACM.Heartbeat***

#### ***Synopsis***

`adapter.ACM.Heartbeat=num`

#### ***Description***

Overrides the value of `Ice.ACM.Server.Heartbeat` for incoming connections to the named object adapter.

### ***adapter.ACM.Timeout***

#### ***Synopsis***

`adapter.ACM.Timeout=num`

#### ***Description***

Overrides the value of `Ice.ACM.Server.Timeout` for incoming connections to the named object adapter.

### ***adapter.AdapterId***

**Synopsis**

```
adapter.AdapterId=id
```

**Description**

Specifies an identifier for the object adapter with the name *adapter*. This identifier must be unique among all object adapters using the same *locator* instance. If a locator proxy is defined using *adapter.Locator* or *Ice.Default.Locator*, this object adapter sets its endpoints with the locator registry upon activation.

***adapter*.Endpoints****Synopsis**

```
adapter.Endpoints=endpoints
```

**Description**

Sets the *endpoints* for the object adapter *adapter* to *endpoints*. These endpoints specify the network interfaces on which the object adapter receives requests. Proxies created by the object adapter contain these endpoints, unless the *adapter.PublishedEndpoints* property is also specified.

***adapter*.Locator****Synopsis**

```
adapter.Locator=locator
```

**Description**

Specifies a *locator* for the object adapter with the name *adapter*. The value is a stringified proxy to the Ice locator interface.

As a proxy property, you can configure additional [aspects of the proxy](#) using properties.

***adapter*.MessageSizeMax****Synopsis**

```
adapter.MessageSizeMax=num
```

**Description**

Overrides the setting of *Ice.MessageSizeMax* to limit the size of messages that can be received by this object adapter. If not defined, the adapter uses the value of *Ice.MessageSizeMax*.

***adapter*.ProxyOptions****Synopsis**

```
adapter.ProxyOptions=options
```

**Description**

Specifies the [proxy options](#) for proxies created by the object adapter. The value is a string representing the proxy options as they would be specified in a stringified proxy. The default value is "-t", that is, proxies created by the object adapter are configured to use twoway invocations by default.

## ***adapter.PublishedEndpoints***

### **Synopsis**

`adapter.PublishedEndpoints=endpoints`

### **Description**

When creating a proxy, the object adapter `adapter` normally includes the endpoints defined by `adapter.Endpoints`. If `adapter.PublishedEndpoints` is defined, the object adapter publishes these endpoints instead. This is useful in many situations, such as when a server resides behind a port-forwarding firewall, in which case the object adapter's public endpoints must specify the address and port of the firewall. The `adapter.ProxyOptions` property also influences the proxies created by an object adapter.

## ***adapter.ReplicaGroupId***

### **Synopsis**

`adapter.ReplicaGroupId=id`

### **Description**

Identifies the group of replicated object adapters to which this adapter belongs. The replica group is treated as a virtual object adapter, so that an indirect proxy of the form `identity@id` refers to the object adapters in the group. During binding, a client will attempt to establish a connection to an endpoint of one of the participating object adapters, and automatically try others until a connection is successfully established or all attempts have failed. Similarly, an outstanding request will, when permitted, automatically fail over to another object adapter of the replica group upon connection failure. The set of endpoints actually used by the client during binding is determined by the locator's configuration policies.

Defining a value for this property has no effect unless `adapter.AdapterId` is also defined. Furthermore, the locator registry may require replica groups to be defined in advance (see `IceGrid.Registry.DynamicRegistration`), otherwise `Ice.NotRegisteredException` is raised upon adapter activation. Regardless of whether an object adapter is replicated, it can always be addressed individually in an indirect proxy if it defines a value for `adapter.AdapterId`.

## ***adapter.Router***

### **Synopsis**

`adapter.Router=router`

### **Description**

Specifies a router for the object adapter with the name `adapter`. The value is a stringified proxy to the Ice router control interface. Defining a router allows the object adapter to receive callbacks from the router over a [bidirectional connection](#), thereby avoiding the need for the router to establish a connection back to the object adapter.

A router can only be assigned to one object adapter. Specifying the same router for more than one object adapter results in undefined behavior. The default value is no router.

As a proxy property, you can configure additional [aspects of the proxy](#) using properties.

## ***adapter.ThreadPool.Serialize***

### **Synopsis**

`adapter.ThreadPool.Serialize=num`

### **Description**

If *num* is a value greater than 0, the adapter's thread pool serializes all messages from each connection. It is not necessary to enable this feature in a thread pool whose maximum size is 1 thread. When a thread pool dispatches requests implemented with AMD, it serializes the dispatching of requests from each connection, but it does not wait for a request to complete before it dispatches the next request.

In a [multi-threaded pool](#), enabling serialization allows requests from different connections to be dispatched concurrently while preserving the order of messages on each connection. Note that serialization can have a significant impact on latency and throughput. If not defined, the default value is 0.

## ***adapter.ThreadPool.Size***

### **Synopsis**

```
adapter.ThreadPool.Size=num
```

### **Description**

A communicator creates a default server thread pool that dispatches requests to its object adapters. An object adapter can also be configured with its own [thread pool](#). This is useful in avoiding deadlocks due to thread starvation by ensuring that a minimum number of threads is available for dispatching requests to certain Ice objects.

*num* is the initial number of threads in the thread pool. The default value is 0, meaning that an object adapter by default uses the communicator's server thread pool. See [Ice.ThreadPool.name.Size](#) for more information.

## ***adapter.ThreadPool.SizeMax***

### **Synopsis**

```
adapter.ThreadPool.SizeMax=num
```

### **Description**

*num* is the maximum number of threads for the [thread pool](#). See [Ice.ThreadPool.name.SizeMax](#) for more information.

The default value is the value of [adapter.ThreadPool.Size](#), meaning the thread pool can never grow larger than its initial size.

## ***adapter.ThreadPool.SizeWarn***

### **Synopsis**

```
adapter.ThreadPool.SizeWarn=num
```

### **Description**

Whenever *num* threads are active in a [thread pool](#), a "low on threads" warning is printed. The default value is 0, which disables the warning.

## ***adapter.ThreadPool.StackSize***

### **Synopsis**

```
adapter.ThreadPool.StackSize=num
```

### **Description**

*num* is the stack size (in bytes) of threads in the [thread pool](#). The default value is 0, meaning the operating system's default is used.

## ***adapter.ThreadPool.ThreadIdleTime***

### ***Synopsis***

`adapter.ThreadPool.ThreadIdleTime=num`

### ***Description***

In a dynamically-sized [thread pool](#), Ice reaps a thread after it is idle for *num* seconds. Setting this property to 0 disables idle thread reaping. If not specified, the default value is 60 seconds. See [Ice.ThreadPool.name.ThreadIdleTime](#) for more information.

## ***adapter.ThreadPool.ThreadPriority***

### ***Synopsis***

`adapter.ThreadPool.ThreadPriority=num`

### ***Description***

*num* specifies a thread priority for the object adapter's [thread pool](#). The object adapter creates its threads with the specified priority. Leaving this property unset causes the adapter to create threads with the priority specified by [Ice.ThreadPool.Server.ThreadPriority](#) or, if that property is unset, the priority specified by [Ice.ThreadPriority](#).

## Proxy Properties

The communicator operation `propertyToProxy` creates a proxy from a group of configuration properties. The argument to `propertyToProxy` is a string representing the base name of the property group (shown as *name* in the property descriptions below). This name must correspond to a property that supplies the stringified form of the proxy. Subordinate properties can be defined to customize the proxy's local configuration.

The communicator operation `proxyToProperty` performs the inverse operation, that is, returns the property group for a proxy.

On this page:

- [name](#)
- [name.CollocationOptimized](#)
- [name.ConnectionCached](#)
- [name.Context.key](#)
- [name.EndpointSelection](#)
- [name.InvocationTimeout](#)
- [name.Locator](#)
- [name.LocatorCacheTimeout](#)
- [name.PreferSecure](#)
- [name.Router](#)

### ***name***

#### **Synopsis**

*name=proxy*

#### **Description**

The base property of the group with an application-specific *name* supplying the stringified representation of a proxy. Use the communicator operation `propertyToProxy` to retrieve the property and convert it into a proxy.

### ***name.CollocationOptimized***

#### **Synopsis**

*name.CollocationOptimized=num*

#### **Description**

If *num* is a value greater than zero, the proxy is configured to use `collocated invocations` when possible. Defining this property is equivalent to invoking the `ice_collocationOptimized proxy method`.

### ***name.ConnectionCached***

#### **Synopsis**

*name.ConnectionCached=num*

#### **Description**

If *num* is a value greater than zero, the proxy `caches` its chosen connection for use in subsequent requests. Defining this property is equivalent to invoking the `ice_connectionCached proxy method`.

### ***name.Context.key***

**Synopsis**

```
name.Context.key=value
```

**Description**

Adds the key/value pair to the proxy's [request context](#).

**name.EndpointSelection****Synopsis**

```
name.EndpointSelection=type
```

**Description**

Specifies the proxy's [endpoint selection](#) type. Legal values are `Random` and `Ordered`. Defining this property is equivalent to invoking the `ice_endpointSelection` proxy method.

**name.InvocationTimeout****Synopsis**

```
name.InvocationTimeout=num
```

**Description**

Specifies the [invocation timeout](#) to be used by this proxy. Defining this property is equivalent to invoking the `ice_invocationTimeout` proxy method.

**name Locator****Synopsis**

```
name.Locator=proxy
```

**Description**

Specifies the proxy of the [locator](#) to be used by this proxy. Defining this property is equivalent to invoking the `ice_locator` proxy method.

This is a proxy property, so you can configure additional local aspects of the proxy with subordinate properties. For example:

```
MyProxy.Locator=...
MyProxy.Locator.EndpointSelection=Ordered
```

**name.LocatorCacheTimeout****Synopsis**

```
name.LocatorCacheTimeout=num
```

**Description**

Specifies the [locator cache](#) timeout to be used by this proxy. Defining this property is equivalent to invoking the `ice_locatorCacheTimeout` proxy method.

## ***name.PreferSecure***

### ***Synopsis***

```
name.PreferSecure=num
```

### ***Description***

If *num* is a value greater than zero, the proxy gives [precedence](#) to secure endpoints. If not defined, the proxy uses the value of `Ice.Default.PreferSecure`.

Defining this property is equivalent to invoking the `ice_preferSecure` proxy method.

## ***name.Router***

### ***Synopsis***

```
name.Router=proxy
```

### ***Description***

Specifies the proxy of the [router](#) to be used by this proxy. Defining this property is equivalent to invoking the `ice_router` proxy method.

This is a proxy property, so you can configure additional local aspects of the proxy with subordinate properties. For example:

```
MyProxy.Router=...
MyProxy.Router.PreferSecure=1
```

## Miscellaneous Ice.\* Properties

On this page:

- `Ice.BackgroundLocatorCacheUpdates`
- `Ice.BatchAutoFlushSize`
- `Ice.CacheMessageBuffers`
- `Ice.ChangeUser`

- `Ice.CollectObjects`
- `Ice.Compression.Level`
- `Ice.ConsoleListener`
- `Ice.EventLog.Source`
- `Ice.HTTPProxyHost`
- `Ice.HTTPProxyPort`
- `Ice.ImplicitContext`
- `Ice.LogFile`
- `Ice.LogFile.SizeMax`
- `Ice.LogStdErr.Convert`
- `Ice.MessageSizeMax`
- `Ice.Nohup`
- `Ice.NullHandleAbort`
- `Ice.Package.module`
- `Ice.PrintAdapterReady`
- `Ice.PrintProcessId`
- `Ice.PrintStackTraces`
- `Ice.ProgramName`
- `Ice.RetryIntervals`
- `Ice.ServerIdleTime`
- `Ice.SOCKSProxyHost`
- `Ice.SOCKSProxyPort`
- `Ice.StdErr`
- `Ice.StdOut`
- `Ice.SyslogFacility`
- `Ice.ThreadInterruptSafe`
- `Ice.UseSyslog`
- `Ice.Voip`

### Ice.BackgroundLocatorCacheUpdates

#### Synopsis

`Ice.BackgroundLocatorCacheUpdates=num`

#### Description

If `num` is set to zero (the default), an invocation on an indirect proxy whose endpoints are older than the configured `locator cache` timeout triggers a locator cache update; the run time delays the invocation until the new endpoints are returned by the locator.

If `num` is set to a value larger than zero, an invocation on an indirect proxy with expired endpoints still triggers a locator cache update, but the update is performed in the background, and the run time uses the expired endpoints for the invocation. This avoids delaying the first invocation that follows expiry of a cache entry.

### Ice.BatchAutoFlushSize

#### Synopsis

`Ice.BatchAutoFlushSize=num`

#### Description

This property controls how the Ice run time deals with flushing of `batch messages`. If `num` is set to a value greater than zero, the run time automatically forces a flush of the current batch when a new message is added to a batch and that message would cause the batch to

exceed *num* kilobytes. If *num* is set to zero or a negative number, batches must be flushed explicitly by the application. If not defined, the default value is 1024.

When flushed, batch requests are sent as a single Ice message. The Ice run time in the receiver limits incoming messages to the maximum size specified by `Ice.MessageSizeMax`, therefore the sender must periodically flush batch requests (whether manually or automatically) to ensure they do not exceed the receiver's configured limit.

## Ice.CacheMessageBuffers

### Synopsis

`Ice.CacheMessageBuffers=num` (Java, .NET)

### Description

If *num* is a value greater than zero, the Ice run time caches message buffers for future reuse. This can improve performance and reduce the amount of garbage produced by Ice internals that the garbage collector would eventually spend time to reclaim. However, for applications that exchange very large messages, this cache may consume excessive amounts of memory and therefore should be disabled by setting this property to zero.

This property affects the caching of message buffers for synchronous invocation, asynchronous invocation, and synchronous dispatch. The Ice run time never caches message buffers for asynchronous dispatch.

### Platform Notes

- Java  
Ice allocates non-direct message buffers when this property is set to 1 and direct message buffers when set to 2. Use of direct message buffers minimizes copying and typically results in improved throughput. If not defined, the default value is 2.
- .NET  
If not defined, the default value is 1.

## Ice.ChangeUser

### Synopsis

`Ice.ChangeUser=user` (C++ & Unix only)

### Description

If set, Ice changes the user and group id to the respective ids of *user* in `/etc/passwd`. This only works if the Ice application is executed by the super-user.

## Ice.ClassGraphDepthMax

### Synopsis

`Ice.ClassGraphDepthMax=num`

### Description

Specifies the maximum depth for a graph of Slice class instances to unmarshal. If this maximum is reached, the Ice run time throws an `Ice::MarshalException`. Reading and destroying a Slice class graph are recursive operations. This property prevents stack overflows from occurring if a sender sends a very large graph and not enough space on the stack is available. To read larger graphs, you can increase the value of this property but you should also make sure the stack size is still large enough or increase it using the [thread pool StackSize](#) property.

Setting this property to 0 (or to a negative number) disables the depth limit altogether. If not specified, the default value is 0 (no limit). If you run your server in an insecure environment, you should set this property to a value small enough to not cause stack overflows.

## Ice.CollectObjects

### Synopsis

`Ice.CollectObjects=num` (C++)

### Description

Ice for C++ includes a [garbage collection facility](#) for reclaiming cyclic graphs of Slice class instances that are unmarshaled by the Ice run time. Setting this property to 1 causes the Ice run time to assume that all cyclic object graphs that a program receives are eligible for collection by default. If not specified, the default value is zero.

## Ice.Compression.Level

### Synopsis

`Ice.Compression.Level=num`

### Description

Specifies the bzip2 compression level to use when [compressing protocol messages](#). Legal values for `num` are 1 to 9, where 1 represents the fastest compression and 9 represents the best compression. Note that higher levels cause the bzip2 algorithm to devote more resources to the compression effort, and may not result in a significant improvement over lower levels. If not specified, the default value is 1.

## Ice.ConsoleListener

### Synopsis

`Ice.ConsoleListener=num` (.NET)

### Description

If `num` is non-zero, the Ice run time installs a `ConsoleTraceListener` that writes its messages to `stderr`. If `num` is zero, logging is disabled. Note that the setting of `#Ice.LogFile` overrides this property: if `Ice.LogFile` is set, messages are written to the log file regardless of the setting of `Ice.ConsoleListener`.

## Ice.EventLog.Source

### Synopsis

`Ice.EventLog.Source=name` (C++ & Windows only)

### Description

Specifies the name of an event log source to be used by a Windows service that subclasses `Ice::Service`. The value of `name` represents a subkey of the `Eventlog` registry key. An application (or administrator) typically prepares the registry key when the service is installed. If no matching registry key is found, Windows logs events in the `Application` log. Any backslashes in `name` are silently converted to forward slashes. If not defined, `Ice::Service` uses the service name as specified by the `--service` option.

## Ice.HTTPProxyHost

### Synopsis

`Ice.HTTPProxyHost=addr`

### Description

Specifies the host name or IP address of an HTTP proxy server. If *addr* is not empty, Ice uses the designated HTTP proxy server for all outgoing (client) connections.

## Ice.HTTPProxyPort

### Synopsis

```
Ice.HTTPProxyPort=num
```

### Description

The port number of the HTTP proxy server. If not specified, the default value is 1080.

## Ice.ImplicitContext

### Synopsis

```
Ice.ImplicitContext=type
```

### Description

Specifies whether a communicator has an [implicit request context](#) and, if so, at what scope the context applies. Legal values for this property are `None` (equivalent to the empty string), `PerThread`, and `Shared`. If not specified, the default value is `None`.

## Ice.LogFile

### Synopsis

```
Ice.LogFile=file
```

### Description

Replaces the communicator's [default logger](#) with a simple file-based logger implementation. This property does not affect the [per-process logger](#). The logger creates the specified file if necessary, otherwise it appends to the file. If the logger is unable to open the file, the application receives an `InitializationException` during [communicator initialization](#). If a logger object is supplied in the `InitializationData` argument during communicator initialization, it takes precedence over this property.

## Ice.LogFile.SizeMax

### Synopsis

```
Ice.LogFile.SizeMax=num (C++)
```

### Description

*num* is a positive integer that represents the maximum size of log files configured through `Ice.LogFile`, in bytes. When a log file's size reaches *num*, the Ice file-based logger renames this log file to `baselogfilename-datetimestamp.ext` and creates a new log file. The default value for *num* is 0, which means that the log file's size is unlimited. In this case, the Ice file-based logger opens and writes to a single log file.

## Ice.LogStdErr.Convert

### Synopsis

```
Ice.LogStdErr.Convert=num (C++)
```

### Description

If *num* is set to a value larger than zero, on Windows, the communicator's [default logger](#) converts log messages from the application's narrow string encoding (as defined by the installed narrow [string converter](#), if any) to the Windows console's code page. The default value for this property is 1 when `Ice.StdErr` is not set, and 0 otherwise. This property is read by the first communicator created in a process; it is ignored by other communicators.

## Ice.MessageSizeMax

### Synopsis

`Ice.MessageSizeMax=num`

### Description

This property controls the maximum size (in kilobytes) of an uncompressed protocol message that is accepted by the Ice run time. The size includes the size of the Ice protocol header. The default size is 1024 (1 megabyte).

The only purpose of this property is to prevent a malicious or defective sender from triggering a large memory allocation in a receiver. If this is not a concern, you can set `Ice.MessageSizeMax` to zero; as of Ice 3.6, setting this property to zero (or to a negative number) disables the message size limit altogether.

If the Ice run time in a receiver encounters an incoming message whose size exceeds the receiver's setting for `Ice.MessageSizeMax`, the run time raises a `MemoryLimitException` and closes the connection. For example, when a client receives an oversized reply message, the result of its invocation is a `MemoryLimitException`. When a server receives an oversized request message, the client receives a `ConnectionLostException` (because the server closed the connection) and the server logs a message if `Ice.Warn.Connections` is set.

## Ice.Nohup

### Synopsis

`Ice.Nohup=num`

### Description

If *num* is set to a value larger than zero, the `Application` convenience class (as well as the `Ice::Service` class in C++) ignore `SIGHUP` on Unix and `CTRL_LOGOFF_EVENT` on Windows. As a result, an application that sets `Ice.Nohup` continues to run if the user that started the application logs off. The default value for `Application` is 0, and the default value for `Ice::Service` is 1.

## Ice.NullHandleAbort

### Synopsis

`Ice.NullHandleAbort=num`

### Description

If *num* is set to a value larger than zero, invoking an operation using a null [smart pointer](#) causes the program to abort immediately instead of raising `IceUtil::NullHandleException`.

## Ice.Package.module

### Synopsis

`Ice.Package.module=package` (Java)

### Description

Ice for Java allows you to [customize](#) the packaging of generated code. If you use this feature, the Ice run time requires additional configuration in order to successfully unmarshal exceptions and concrete class types. This property associates a top-level Slice *module* with a Java *package*. If all top-level modules are generated into the same user-defined package, it is easier to use `Ice.Default.Package` inst

ead.

## Ice.PrintAdapterReady

### Synopsis

`Ice.PrintAdapterReady=num`

### Description

If *num* is set to a value larger than zero, an object adapter prints "*adapter\_name* ready" on standard output after activation is complete. This is useful for scripts that need to wait until an object adapter is ready to be used.

## Ice.PrintProcessId

### Synopsis

`Ice.PrintProcessId=num`

### Description

If *num* is set to a value larger than zero, the process ID is printed on standard output upon startup.

## Ice.PrintStackTraces

### Synopsis

`Ice.PrintStackTraces=num` (JavaScript, C++)

### Description

If *num* is set to a value larger than zero, inserting an exception that derives from `IceUtil::Exception` into a [logger helper class](#) (such as `Ice::Warning`) also displays the exception's stack trace. Likewise, the `ice_stackTrace` function on the base exception class, `IceUtil::Exception`, will return the stack trace or an empty string depending on the value *num*. If not set, the default value depends on how the Ice run time is compiled: 0 for an optimized build and 1 for a debug build.

On Windows, stack traces are available in debug builds and in release builds built with the environment variable `RELEASEPDBS=yes`. The release DLLs included in the standard Ice binary distribution are built with this setting enabled. The `.PDB` files for both the debug and release distribution builds are available in a separate Ice PDBs Windows installer.

When generating a stack trace, Windows will attempt to locate the `.PDB` files at the location stored in the associated DLLs; in case the `.PDB` file is not found at this location, Windows will attempt to locate this file using the following search path: current working directory, then the directory of the `IceUtil` DLL, and finally the search path specified by the environment variable `_NT_SYMBOL_PATH`. Therefore, if your `.PDB` files are no longer where you built them, you will need to copy them next to the `IceUtil` DLL or include their new directory in the `_NT_SYMBOL_PATH` environment variable.

This property is only supported in JavaScript, C++, and the scripting languages that use the Ice for C++ run time (Python, Ruby, PHP). Be aware that enabling this property in Python, Ruby or PHP will only display C/C++ stack traces.

## Ice.ProgramName

### Synopsis

`Ice.ProgramName=name`

### Description

*name* is the program name, which is [set automatically](#) from `argv[0]` (C++) and from `AppDomain.CurrentDomain.FriendlyName` (.NET

) during initialization. For Java, `Ice.ProgramName` is initialized to the empty string. The default name can be overridden by setting this property.

## Ice.RetryIntervals

### Synopsis

```
Ice.RetryIntervals=num [num ...]
```

### Description

This property defines the number of times an operation is [automatically retried](#) and the delay between each retry. For example, if the property is set to `0 100 500`, the operation is retried 3 times: immediately after the first failure, again after waiting 100ms after the second failure, and again after waiting 500ms after the third failure. The default value (0) means Ice retries once immediately. If set to `-1`, no retry occurs.

## Ice.ServerIdleTime

### Synopsis

```
Ice.ServerIdleTime=num
```

### Description

If `num` is set to a value larger than zero, Ice automatically calls `Communicator::shutdown` once the communicator has been idle for `num` seconds. This shuts down the communicator's server side and causes all threads waiting in `Communicator::waitForShutdown` to return. After that, a server will typically do some clean-up work before exiting. The default value is zero, meaning that the server will not shut down automatically. This property is often used for servers that are automatically [activated by IceGrid](#).

## Ice.SOCKSProxyHost

### Synopsis

```
Ice.SOCKSProxyHost=addr
```

### Description

Specifies the host name or IP address of a SOCKS proxy server. If `addr` is not empty, Ice uses the designated SOCKS proxy server for all outgoing (client) connections.

Ice currently only supports the SOCKS4 protocol, which means only IPv4 connections are allowed.

## Ice.SOCKSProxyPort

### Synopsis

```
Ice.SOCKSProxyPort=num
```

### Description

The port number of the SOCKS proxy server. If not specified, the default value is 1080.

## Ice.StdErr

## Synopsis

`Ice.StdErr=filename`

## Description

If `filename` is not empty, the standard error stream of this process is redirected to this file, in append mode. This property is checked only for the first communicator that is created in a process.

## Ice.StdOut

### Synopsis

`Ice.StdOut=filename`

### Description

If `filename` is not empty, the standard output stream of this process is redirected to this file, in append mode. This property is checked only for the first communicator created in a process.

## Ice.SyslogFacility

### Synopsis

`Ice.SyslogFacility=string` (Unix only)

### Description

This property sets the syslog facility to `string`. This property has no effect if `Ice.UseSyslog` is not set.

`string` can be any of syslog facilities: LOG\_AUTH, LOG\_AUTHPRIV, LOG\_CRON, LOG\_DAEMON, LOG\_FTP, LOG\_KERN, LOG\_LOCAL0, LOG\_LOCAL1, LOG\_LOCAL2, LOG\_LOCAL3, LOG\_LOCAL4, LOG\_LOCAL5, LOG\_LOCAL6, LOG\_LOCAL7, LOG\_LPR, LOG\_MAIL, LOG\_NEWS, LOG\_SYSLOG, LOG\_USER, LOG\_UUCP.

The default value is LOG\_USER.

## Ice.ThreadInterruptSafe

### Synopsis

`Ice.ThreadInterruptSafe=num` (Java)

### Description

If `num` is set to a value larger than zero, Ice for Java disables message caching by setting `Ice.CacheMessageBuffers` to 0 and takes other steps necessary to ensure that `Java interrupts` work correctly. If not defined, the default value is zero.

## Ice.UseSyslog

### Synopsis

`Ice.UseSyslog=num` (Unix only)

### Description

If `num` is set to a value larger than zero, a special `logger` is installed that logs to the `syslog` service instead of standard error. The identifier for `syslog` is the value of `#Ice.ProgramName`. Use `#Ice.SyslogFacility` to select a `syslog` facility.

## Ice.Voip

### Synopsis

`Ice.Voip=num` (Ice Touch only)

### Description

If `num` is set to a value larger than zero, the Ice run time sets the `kCFStreamNetworkServiceType` property to `kCFStreamNetworkServiceTypeVoIP` for all sockets created through the Ice communicator. Only voice over IP applications are allowed to use this setting. It ensures the sockets aren't closed and enables receiving data when the application is in the background. See the description from [Configuring Sockets for VoIP Usage](#) for information on this setting and when it's applicable.

The default value is zero.

## Freeze.\*

### Freeze.DbEnv.env-name.CheckpointPeriod

#### Synopsis

```
Freeze.DbEnv.env-name.CheckpointPeriod=num
```

#### Description

Every Berkeley DB environment created by Freeze has an associated thread that checkpoints this environment every *num* seconds. If *num* is less than 0, no checkpointing is performed. The default is 120 seconds.

### Freeze.DbEnv.env-name.DbHome

#### Synopsis

```
Freeze.DbEnv.env-name.DbHome=db-home
```

#### Description

Defines the home directory of this Freeze database environment. The default directory is *env-name*.

### Freeze.DbEnv.env-name.DbPrivate

#### Synopsis

```
Freeze.DbEnv.env-name.DbPrivate=num
```

#### Description

If *num* is set to a value larger than zero, Freeze instructs Berkeley DB to use process-private memory instead of shared memory. The default value is 1. Set this property to 0 in order to run a [FreezeScript](#) utility, or a Berkeley DB utility such as `db_archive`, on a running environment.

## Freeze.DbEnv.*env-name*.DbRecoverFatal

### Synopsis

```
Freeze.DbEnv.env-name.DbRecoverFatal=num
```

### Description

If *num* is set to a value larger than zero, fatal recovery is performed when the environment is opened. The default value is 0.

## Freeze.DbEnv.*env-name*.EncodingVersion

### Synopsis

```
Freeze.DbEnv.env-name.EncodingVersion=encoding
```

### Description

Defines the encoding used to decode keys and to encode keys and values. The default value is the value of `Ice.Default.EncodingVersion`.

## Freeze.DbEnv.*env-name*.LockFile

### Synopsis

```
Freeze.DbEnv.env-name.LockFile=num
```

### Description

If *num* is set to a value larger than zero, Freeze creates a lock file in the database environment to prevent other processes from opening the environment. The default value is 1.

Note that applications should not normally disable the lock file because simultaneous access to the same environment by multiple processes can lead to data corruption.

[FreezeScript](#) utilities automatically disable the lock file when `Freeze.DbEnv.env-name.DbPrivate` is set to zero.

## Freeze.DbEnv.*env-name*.OldLogsAutoDelete

```
Freeze.DbEnv.env-name.OldLogsAutoDelete=num
```

If *num* is set to a value larger than zero, old transactional logs no longer in use are deleted after each periodic checkpoint (see `Freeze.DbEnv.env-name.CheckpointPeriod`). The default value is 1.

## Freeze.DbEnv.*env-name*.PeriodicCheckpointMinSize

### Synopsis

```
Freeze.DbEnv.env-name.PeriodicCheckpointMinSize=num
```

**Description**

*num* is the minimum size in kilobytes for the periodic checkpoint (see `Freeze.DbEnv.env-name.CheckpointPeriod`). This value is passed to Berkeley DB's `checkpoint` function. The default is 0 (which means no minimum).

**Freeze.Evictor.env-name.filename.MaxTxSize****Synopsis**

```
Freeze.Evictor.env-name.filename.MaxTxSize=num
```

**Description**

Freeze can use a [background thread](#) to save updates to the database. Transactions are used to save many facets together. *num* defines the maximum number of facets saved per transaction. The default is `10 * SaveSizeTrigger` (see `Freeze.Evictor.env-name.filename.SaveSizeTrigger`); if this value is negative, the actual value is set to 100.

**Freeze.Evictor.env-name.filename.name.BtreeMinKey****Synopsis**

```
Freeze.Evictor.env-name.filename.name.BtreeMinKey=num
```

**Description**

*name* represents a database name or an index name. This property sets the B-tree minkey of the corresponding Berkeley DB database. *num* is ignored if it is less than 2. Please refer to the [Berkeley DB documentation](#) for details.

**Freeze.Evictor.env-name.filename.name.Checksum****Synopsis**

```
{{Freeze.Evictor.env-name.filename.Checksum=num
```

**Description**

If *num* is greater than 0, checksums on the corresponding Berkeley DB database(s) are enabled. Please refer to the [Berkeley DB documentation](#) for details.

**Freeze.Evictor.env-name.filename.PageSize****Synopsis**

```
Freeze.Evictor.env-name.filename.PageSize=num
```

**Description**

If *num* is greater than 0, it sets the page size of the corresponding Berkeley DB database(s). Please refer to the [Berkeley DB documentation](#) for details.

**Freeze.Evictor.env-name.filename.PopulateEmptyIndices****Synopsis**

```
Freeze.Evictor.env-name.filename.PopulateEmptyIndices=num
```

### Description

When *num* is not 0 and you create an evictor with one or more empty indexes, the `createBackgroundSaveEvictor` or `createTransactionalEvictor` call will populate these indexes by iterating over all the corresponding facets. This is particularly useful after transforming a Freeze evictor with `FreezeScript`, since `FreezeScript` does not transform indexes; however this can significantly slow down the creation of the evictor if you have an empty index because none of the facets currently in the database match the type of this index. The default value for this property is 0.

## Freeze.Evictor.env-name.filename.RollbackOnUserException

### Synopsis

```
Freeze.Evictor.env-name.filename.RollbackOnUserException=num
```

### Description

If *num* is set to a value larger than zero, a transactional evictor rolls back its transaction if the outcome of the dispatch is a user exception. If *num* is 0 (the default), the transactional evictor commits the transaction.

## Freeze.Evictor.env-name.filename.SavePeriod

### Synopsis

```
Freeze.Evictor.env-name.filename.SavePeriod=num
```

### Description

Freeze can use a [background thread](#) to save updates to the database. After *num* milliseconds without saving, if any facet is created, modified, or destroyed, this background thread wakes up to save these facets. When *num* is 0, there is no periodic saving. The default is 60 000.

## Freeze.Evictor.env-name.filename.SaveSizeTrigger

### Synopsis

```
Freeze.Evictor.env-name.filename.SaveSizeTrigger=num
```

### Description

Freeze can use a [background thread](#) to save updates to the database. When *num* is 0 or positive, as soon as *num* or more facets have been created, modified, or destroyed, this background thread wakes up to save them. When *num* is negative, there is no size trigger. The default is 10.

## Freeze.Evictor.env-name.filename.StreamTimeout

### Synopsis

```
Freeze.Evictor.env-name.filename.StreamTimeout=num
```

### Description

When the saving thread saves an object, it needs to lock this object in order to get a consistent copy of the object's state. If the lock cannot be acquired within *num* seconds, a fatal error is generated. If a [fatal error callback](#) was registered by the application, this callback is called; otherwise the program is terminated immediately. When *num* is 0 or negative, there is no timeout. The default value is 0.

## Freeze.Map.name.BtreeMinKey

### Synopsis

Freeze.Map.name.BtreeMinKey=num

### Description

*name* may represent a database name or an index name. This property sets the B-tree minkey of the corresponding Berkeley DB database. *num* is ignored if it is less than 2. Please refer to the [Berkeley DB documentation](#) for details.

## Freeze.Map.name.Checksum

### Synopsis

Freeze.Map.name.Checksum=num

### Description

*name* may represent a database name or an index name. If *num* is greater than 0, checksums for the corresponding Berkeley DB database are enabled. Please refer to the [Berkeley DB documentation](#) for details.

## Freeze.Map.name.PageSize

### Synopsis

Freeze.Map.name.PageSize=num

### Description

*name* may represent a database name or an index name. If *num* is greater than 0, it sets the page size of the corresponding Berkeley DB database. Please refer to the [Berkeley DB documentation](#) for details.

## Freeze.Trace.DbEnv

### Synopsis

Freeze.Trace.DbEnv=num

### Description

The Freeze database environment activity trace level:

0	No database environment activity trace (default).
1	Trace database open and close.
2	Also trace checkpoints and the removal of old log files.

## Freeze.Trace.Evictor

### Synopsis

Freeze.Trace.Evictor=num

**Description**

The Freeze evictor activity trace level:

0	No evictor activity trace (default).
1	Trace Ice object and facet creation and destruction, facet streaming time, facet saving time, object eviction (every 50 objects) and evictor deactivation.
2	Also trace object lookups, and all object evictions.
3	Also trace object retrieval from the database.

**Freeze.Trace.Map****Synopsis**

`Freeze.Trace.Map=num`

**Description**

The Freeze map activity trace level:

0	No map activity trace (default).
1	Trace database open and close.
2	Also trace iterator and transaction operations, and reference counting of the underlying database.

**Freeze.Trace.Transaction****Synopsis**

`Freeze.Trace.Transaction=num`

**Description**

The Freeze transaction activity trace level:

0	No transaction activity trace (default).
1	Trace transaction IDs and commit and rollback activity.

**Freeze.Warn.Deadlocks****Synopsis**

`Freeze.Warn.Deadlocks=num`

**Description**

If `num` is set to a value larger than zero, Freeze logs a warning message when a deadlock occur. The default value is 0.

**Freeze.Warn.Rollback****Synopsis**

`Freeze.Warn.Deadlocks=num`

**Description**

If *num* is set to a value larger than zero, Freeze logs a warning message when it rolls back a transaction that goes out of scope together with its associated connection. The default value is 1. (C++ only)

## Glacier2.AddConnectionContext

### Synopsis

`Glacier2.AddConnectionContext=num`

### Description

If `num` is set to 1 or 2, Glacier2 adds a number of key-value pairs to the [request context](#) that it sends with each request. If `num` is set to 1, these entries are added to the context for all forwarded requests. If `num` is set to 2, the contexts are added only to calls to `checkPermissions` and `authorize` on permission verifiers, and to calls to `create` on session managers.

If `num` is non-0, Glacier2 adds the following context entries:

<code>_con.type</code>	The type of the connection as returned by <code>Connection::type</code> .
<code>_con.localAddress</code>	The local address (TCP and SSL only).
<code>_con.localPort</code>	The local port (TCP and SSL only).
<code>_con.remoteAddress</code>	The remote address (TCP and SSL only).
<code>_con.remotePort</code>	The remote port (TCP and SSL only).

<code>_con.cipher</code>	The cipher (SSL only).
<code>_con.peerCert</code>	The first certificate of the client certificate chain (SSL only).

The default value is 0, meaning that no contexts are added.

## Glacier2.AddUserToAllowCategories

### Synopsis

`Glacier2.AddUserToAllowCategories=num`

### Description

Specifies whether to add an authenticated user ID to the `Glacier2.AllowCategories` property when creating a new session. The legal values are shown below:

0	Do not add the user ID (default).
1	Add the user ID.
2	Add the user ID with a leading underscore.

This property is deprecated and supported only for backward-compatibility. New applications should use `Glacier2.Filter.Category.AcceptUser`.

## Glacier2.Admin.AdapterProperty

### Synopsis

`Glacier2.Admin.AdapterProperty=value`

### Description

Glacier2 uses the adapter name `Glacier2.Admin` for its `administrative` object adapter. Therefore, `adapter properties` can be used to configure this adapter.

The `Glacier2.Admin.Endpoints` property must be defined to enable the administrative object adapter.

Glacier2's administrative interface allows a remote client to shut down the router; we generally recommend the use of endpoints that are accessible only from behind a firewall.

## Glacier2.AllowCategories

### Synopsis

`Glacier2.AllowCategories=list`

### Description

Specifies a white space-separated list of identity categories. If this property is defined, then the Glacier2 router only allows requests to Ice objects with an identity that matches one of the categories from this list. If `Glacier2.AddUserToAllowCategories` is defined with a non-0 value, the router automatically adds the user ID of each session to this list.

This property is deprecated and supported only for backward-compatibility. New applications should use `Glacier2.Filter.Category.Accept`.

## Glacier2.Client.AdapterProperty

### Synopsis

`Glacier2.Client.AdapterProperty=value`

### Description

Glacier2 uses the adapter name `Glacier2.Client` for the object adapter that it provides to clients. Therefore, [adapter properties](#) can be used to configure this adapter.

This adapter must be accessible to clients of Glacier2. Use of a secure transport for this adapter is highly recommended.

Note that `Glacier2.Registry.Client.Endpoints` controls the client endpoint for Glacier2. The port numbers 4063 (for TCP) and 4064 (for SSL) are reserved for Glacier2 by the [Internet Assigned Numbers Authority \(IANA\)](#).

## Glacier2.Client.AlwaysBatch

### Synopsis

`Glacier2.Client.AlwaysBatch=num`

### Description

If `num` is set to a value larger than 0, the Glacier2 router always batches queued oneway requests from clients to servers regardless of the value of their `_fwd` contexts. This property is only relevant when `Glacier2.Client.Buffered` is enabled. The default value is 0.

## Glacier2.Client.Buffered

### Synopsis

`Glacier2.Client.Buffered=num`

### Description

If `num` is set to a value larger than 0, the Glacier2 router operates in [buffered mode](#), in which incoming requests from clients are queued and processed in a separate thread. If `num` is set to 0, the router operates in unbuffered mode in which a request is forwarded in the same thread that received it. The default value is 1.

## Glacier2.Client.ForwardContext

### Synopsis

`Glacier2.Client.ForwardContext=num`

### Description

If `num` is set to a value larger than 0, the Glacier2 router includes the [request context](#) when forwarding requests from clients to servers. The default value is 0.

## Glacier2.Client.SleepTime

### Synopsis

`Glacier2.Client.SleepTime=num`

### Description

If `num` is set to a value larger than 0, the Glacier2 router sleeps for the specified number of milliseconds after forwarding all queued requests

from a client. This delay is useful for [batched delivery](#) because it makes it more likely for events to accumulate in a single batch. Similarly, if [overrides](#) are used, the delay makes it more likely for overrides to actually take effect. This property is only relevant when `Glacier2.Client.Trace.Buffered` is enabled. The default value is 0.

## Glacier2.Client.Trace.Override

### Synopsis

`Glacier2.Client.Trace.Override=num`

### Description

If `num` is set to a value larger than 0, the Glacier2 router logs a trace message whenever a request was [overridden](#). The default value is 0.

## Glacier2.Client.Trace.Reject

### Synopsis

`Glacier2.Client.Trace.Reject=num`

### Description

If `num` is set to a value larger than 0, the Glacier2 router logs a trace message whenever the router's configured [filters](#) reject a client's request. The default value is 0.

## Glacier2.Client.Trace.Request

### Synopsis

`Glacier2.Client.Trace.Request=num`

### Description

If `num` is set to a value larger than 0, the Glacier2 router logs a trace message for each request that is forwarded from a client. The default value is 0.

## Glacier2.CryptPasswords

### Synopsis

`Glacier2.CryptPasswords=file`

### Description

Specifies the file name of a Glacier2 [access control list](#). Each line of the file must contain a user name and an encrypted password, separated by white space, as described in [Writing a Password File](#). This property is ignored if `Glacier2.PermissionsVerifier` is defined.

## Glacier2.Filter.AdapterId.Accept

### Synopsis

`Glacier2.Filter.AdapterId.Accept=list`

### Description

Specifies a space-separated list of adapter identifiers. If defined, the Glacier2 router [filters requests](#) so that it only allows requests to Ice

objects with an adapter identifier that matches one of the entries in this list.

Identifiers that contain spaces must be enclosed in single or double quotes. Single or double quotes that appear within an identifier must be escaped with a leading backslash.

## Glacier2.Filter.Address.Accept

### Synopsis

```
Glacier2.Filter.Address.Accept=list
```

### Description

Specifies a space-separated list of address-port pairs. When defined, the Glacier2 router filters requests so that it only allows requests to Ice objects through proxies that contain network endpoint information that matches an address-port pair listed in this property. If not defined, the default value is `*`, which indicates that any network address is permitted. Requests accepted by this property may be rejected by the `Glacier2.Filter.Address.Reject` property.

Each pair is of the form `address:port`. The `address` or `port` number portion can include wildcards (`*`) or value ranges or groups. Ranges and groups have the form `[value1, value2, value3, ...]` and/or `[value1-value2]`. Wildcards, ranges, and groups may appear anywhere in the address-port pair string.

## Glacier2.Filter.Address.Reject

### Synopsis

```
Glacier2.Filter.Address.Reject=list
```

### Description

Specifies a space-separated list of address-port pairs. When defined, the Glacier2 router rejects requests to Ice objects through proxies that contain network endpoint information that matches an address-port pair listed in this property. If not set, the Glacier2 router allows requests to any network address unless the `Glacier2.Filter.Address.Accept` property is set, in which case requests will be accepted or rejected based on the `Glacier2.Filter.Address.Accept` property. If both the `Glacier2.Filter.Address.Accept` and `Glacier2.Filter.Address.Reject` properties are defined, the `Glacier2.Filter.Address.Reject` property takes precedence.

Each pair is of the form `address:port`. The `address` or `port` number portion can include wildcards (`*`) or value ranges or groups. Ranges and groups have the form `[value1, value2, value3, ...]` and/or `[value1-value2]`. Wildcards, ranges, and groups may appear anywhere in the address-port pair string.

## Glacier2.Filter.Category.Accept

### Synopsis

```
Glacier2.Filter.Category.Accept=list
```

### Description

Specifies a space-separated list of identity categories. If defined, the Glacier2 router filters requests so that it only allows requests to Ice objects with an identity that matches one of the categories in this list. If `Glacier2.Filter.Category.AcceptUser` is defined with a non-0 value, the router automatically adds the user name of each session to this list.

Categories that contain spaces must be enclosed in single or double quotes. Single or double quotes that appear within a category must be escaped with a leading backslash.

## Glacier2.Filter.Category.AcceptUser

### Synopsis

```
Glacier2.Filter.Category.AcceptUser=num
```

**Description**

Specifies whether to add an authenticated user ID to the `Glacier2.Filter.Category.Accept` property when creating a new session. The legal values are shown below:

0	Do not add the user ID (default).
1	Add the user ID.
2	Add the user ID with a leading underscore.

**Glacier2.Filter.Identity.Accept****Synopsis**

```
Glacier2.Filter.Identity.Accept=list
```

**Description**

Specifies a space-separated list of identities. If defined, the Glacier2 router [filters requests](#) so that it only allows requests to Ice objects with an identity that matches one of the entries in this list.

Identities that contain spaces must be enclosed in single or double quotes. Single or double quotes that appear within an identity must be escaped with a leading backslash.

**Glacier2.Filter.ProxySizeMax****Synopsis**

```
Glacier2.Filter.ProxySizeMax=num
```

**Description**

If set, the Glacier2 router [rejects requests](#) whose stringified proxies are longer than `num`. This helps secure the system against attack. If not set, Glacier2 will accept requests using proxies of any length.

**Glacier2.InstanceName****Synopsis**

```
Glacier2.InstanceName=name
```

**Description**

Specifies a default identity category for the [Glacier2 objects](#). If defined, the identity of the Glacier2 administrative interface becomes `name/admin` and the identity of the Glacier2 router interface becomes `name/router`.

If not defined, the default value is `Glacier2`.

**Glacier2.PermissionsVerifier****Synopsis**

```
Glacier2.PermissionsVerifier=proxy
```

**Description**

Specifies the proxy of an object that implements the `Glacier2::PermissionsVerifier` interface for [controlling access to Glacier2 sessions](#). The router invokes this proxy to validate the user name and password of each new session. Sessions created from a secure

connection are verified by the object specified in `Glacier2.SSLPermissionsVerifier`. For simple configurations, you can specify the name of a password file using `Glacier2.CryptPasswords`.

Glacier2 supplies a "null" permissions verifier object that accepts any username and password combination for situations in which no authentication is necessary. To enable this verifier, set the property value to `instance/NullPermissionsVerifier`, where `instance` is the value of `Glacier2.InstanceName`.

As a proxy property, you can configure additional [aspects of the proxy](#) using properties.

## Glacier2.ReturnClientProxy

### Synopsis

`Glacier2.ReturnClientProxy=num`

### Description

If `num` is a value greater than 0, Glacier2 maintains backward compatibility with clients using Ice versions prior to 3.2.0. In this case you should also define `Glacier2.Client.PublishedEndpoints` to specify the endpoints that clients should use to contact the router. For example, if the Glacier2 router resides behind a network firewall, the `Glacier2.Client.PublishedEndpoints` property should specify the firewall's external endpoints.

If not defined, the default value is 0.

## Glacier2.RoutingTable.MaxSize

### Synopsis

`Glacier2.RoutingTable.MaxSize=num`

### Description

This property sets the size of the router's [routing table](#) to `num` entries. If more proxies are added to the table than this value, proxies are evicted from the table on a least-recently used basis.

Clients based on Ice version 3.1 and later automatically retry operation calls on evicted proxies and transparently re-add such proxies to the table. Clients based on Ice versions earlier than 3.1 receive an `ObjectNotExistException` for invocations on evicted proxies. For such older clients, `num` must be set to a sufficiently large value to prevent these clients from failing.

The default size of the routing table is 1000.

## Glacier2.Server.AdapterProperty

### Synopsis

`Glacier2.Server.AdapterProperty=value`

### Description

Glacier2 uses the adapter name `Glacier2.Server` for the object adapter that it provides to servers. Therefore, [adapter properties](#) can be used to configure this adapter.

This adapter provides access to the `SessionControl` interface and must be accessible to servers that call back to router clients.

## Glacier2.Server.AlwaysBatch

### Synopsis

`Glacier2.Server.AlwaysBatch=num`

**Description**

If *num* is set to a value larger than 0, the Glacier2 router always batches queued oneway requests from servers to clients regardless of the value of their `_fwd` contexts. This property is only relevant when `Glacier2.Server.Buffered` is enabled. The default value is 0.

**Glacier2.Server.Buffered****Synopsis**

```
Glacier2.Server.Buffered=num
```

**Description**

If *num* is set to a value larger than 0, the Glacier2 router operates in `buffered mode`, in which incoming requests from servers are queued and processed in a separate thread. If *num* is set to 0, the router operates in unbuffered mode in which a request is forwarded in the same thread that received it. The default value is 1.

**Glacier2.Server.ForwardContext****Synopsis**

```
Glacier2.Server.ForwardContext=num
```

**Description**

If *num* is set to a value larger than 0, the Glacier2 router includes the `request context` when forwarding requests from servers to clients. The default value is 0.

**Glacier2.Server.SleepTime****Synopsis**

```
Glacier2.Server.SleepTime=num
```

**Description**

If *num* is set to a value larger than 0, the Glacier2 router sleeps for the specified number of milliseconds after forwarding all queued requests from a server. This delay is useful for `batched delivery` because it makes it more likely for events to accumulate in a single batch. Similarly, if overrides are used, the delay makes it more likely for overrides to actually take effect. This property is only relevant when `Glacier2.Server.Buffered` is enabled. The default value is 0.

**Glacier2.Server.Trace.Override****Synopsis**

```
Glacier2.Server.Trace.Override=num
```

**Description**

If *num* is set to a value larger than 0, the Glacier2 router logs a trace message whenever a request is `overridden`. The default value is 0.

**Glacier2.Server.Trace.Request****Synopsis**

```
Glacier2.Server.Trace.Request=num
```

**Description**

If *num* is set to a value larger than 0, the Glacier2 router logs a trace message for each request that is forwarded from a server. The default value is 0.

**Glacier2.SessionManager****Synopsis**

`Glacier2.SessionManager=proxy`

**Description**

Specifies the proxy of an object that implements the `Glacier2::SessionManager` interface. The router invokes this proxy to create a new session for a client, but only after the router validates the client's user name and password.

As a proxy property, you can configure additional [aspects of the proxy](#) using properties.

**Glacier2.SessionTimeout****Synopsis**

`Glacier2.SessionTimeout=num`

**Description**

If *num* is set to a value larger than 0, a client's session with the Glacier2 router [expires](#) after the specified *num* seconds of inactivity. The default value is 0, meaning sessions do not expire due to inactivity.

It is important to choose *num* such that client sessions do not expire prematurely.

The session timeout may also affect [Active Connection Management](#) (ACM) for client connections, which are connections to the router's object adapter named `Glacier2.Client`. If you have not explicitly configured the router with a value for `Glacier2.Client.ACM.Timeout`, the router uses the session timeout as the value for this property. If no session timeout is defined, the router's incoming client connections use its default ACM behavior.

**Glacier2.SSLPermissionsVerifier****Synopsis**

`Glacier2.SSLPermissionsVerifier=proxy`

**Description**

Specifies the proxy of an object that implements the `Glacier2::SSLPermissionsVerifier` interface for [controlling access to Glacier2 sessions](#). The router invokes this proxy to verify the credentials of clients that attempt to create a session from a secure connection. Sessions created with a user name and password are verified by the object specified in `Glacier2.PermissionsVerifier`.

Glacier2 supplies a "null" permissions verifier object that accepts the credentials of any client for situations in which no authentication is necessary. To enable this verifier, set the property value to `instance/NullSSLPermissionsVerifier`, where *instance* is the value of `Glacier2.InstanceName`.

As a proxy property, you can configure additional [aspects of the proxy](#) using properties.

**Glacier2.SSLSessionManager****Synopsis**

`Glacier2.SSLSessionManager=proxy`

**Description**

Specifies the proxy of an object that implements the `Glacier2::SSLSessionManager` interface for [managing sessions](#). The router invokes this proxy to create a new session for a client that has called `createSessionFromSecureConnection`.

As a proxy property, you can configure additional [aspects of the proxy](#) using properties.

**Glacier2.Trace.RoutingTable****Synopsis**

`Glacier2.Trace.RoutingTable=num`

**Description**

The routing table trace level:

0	No routing table trace (default).
1	Logs a message for each proxy that is added to the routing table.
2	Logs a message for each proxy that is evicted from the routing table (see <code>#Glacier2.RoutingTable.MaxSize</code> ).
3	Combines the output for trace levels 1 and 2.

**Glacier2.Trace.Session****Synopsis**

`Glacier2.Trace.Session=num`

**Description**

If `num` is set to a value larger than 0, the Glacier2 router logs trace messages about session-related activities. The default value is 0.

## Ice.ACM.\*

On this page:

- [Ice.ACM.Client.Close](#)
- [Ice.ACM.Client.Heartbeat](#)
- [Ice.ACM.Client.Timeout](#)
- [Ice.ACM.Close](#)
- [Ice.ACM.Heartbeat](#)
- [Ice.ACM.Timeout](#)
- [Ice.ACM.Server.Close](#)
- [Ice.ACM.Server.Heartbeat](#)
- [Ice.ACM.Server.Timeout](#)

### Ice.ACM.Client.Close

#### *Synopsis*

`Ice.ACM.Client.Close=num`

#### *Description*

Overrides the value of `Ice.ACM.Close` in a client context, meaning for outgoing connections.

### Ice.ACM.Client.Heartbeat

#### *Synopsis*

`Ice.ACM.Client.Heartbeat=num`

#### *Description*

Overrides the value of `Ice.ACM.Heartbeat` in a client context, meaning for outgoing connections.

### Ice.ACM.Client.Timeout

#### *Synopsis*

`Ice.ACM.Client.Timeout=num`

#### *Description*

Overrides the value of `Ice.ACM.Timeout` in a client context, meaning for outgoing connections.

### Ice.ACM.Close

#### *Synopsis*

`Ice.ACM.Close=num`

#### *Description*

This property determines when [Active Connection Management](#) (ACM) closes a connection. Legal values for `num` correspond directly to the `ACMClose` enumerators found in `Connection.ice`:

### Slice

```

local enum ACMClose {
 CloseOff,
 CloseOnIdle,
 CloseOnInvocation,
 CloseOnInvocationAndIdle,
 CloseOnIdleForceful
};

```

The table below describes the semantics of each value:

Enumerator	Property Value	Description
CloseOff	0	Disables automatic connection closure. A connection will be closed when the communicator is destroyed, when there's a network failure or when the peer closes it.
CloseOnIdle	1	Gracefully closes a connection that has been idle for the configured timeout period. A connection is idle if it has no pending outgoing or incoming requests.
CloseOnInvocation	2	Forcefully closes a connection that has been idle for the configured timeout period, but only if the connection has pending outgoing requests. This is useful when you don't want a connection to be closed when idle but still want the connection to be forcefully closed when invocations are in progress and no messages are received from the server (potentially indicating that the server is dead). This should be used with a heartbeat configuration where heartbeats are sent at regular intervals by a server while an invocation is being dispatched.
CloseOnInvocationAndIdle	3	Combines the behaviors of CloseOnIdle and CloseOnInvocation.
CloseOnIdleForceful	4	Forcefully closes a connection that has been idle for the configured timeout period, regardless of whether the connection has pending outgoing or incoming requests. This is typically used together with a heartbeat configuration that keeps idle connections alive.

You must set a non-zero value for `Ice.ACM.Timeout` for this property to have any effect. Use `Ice.ACM.Close` in conjunction with `Ice.ACM.Heartbeat` to tailor a connection management policy for your application. Use the corresponding `Ice.ACM.Client.Close` or `Ice.ACM.Server.Close` properties to override this setting in a client or server context, respectively. See [Connection Closure](#) for more information on closing connections.

If not defined, the default value is 3 in a client context and 2 in a server context.

## Ice.ACM.Heartbeat

### Synopsis

`Ice.ACM.Heartbeat=num`

### Description

This property determines whether heartbeats are enabled. You can use heartbeats in conjunction with the `Ice.ACM.Close` and `Ice.ACM.Timeout` properties to create a connection management policy as part of [Active Connection Management \(ACM\)](#). Legal values for `num` correspond directly to the `ACMHeartbeat` enumerators found in `Connection.ice`:

### Slice

```
local enum ACMHeartbeat {
 HeartbeatOff,
 HeartbeatOnInvocation,
 HeartbeatOnIdle,
 HeartbeatAlways
};
```

The table below describes the semantics of each value:

Enumerator	Property Value	Description
HeartbeatOff	0	Disables client-side heartbeats.
HeartbeatOnInvocation	1	Send a heartbeat at regular intervals if there are pending incoming requests.
HeartbeatOnIdle	2	Send a heartbeat at regular intervals when the connection is idle.
HeartbeatAlways	3	Send a heartbeat at regular intervals until the connection is closed.

You must set a non-zero value for `Ice.ACM.Timeout` for this property to have any effect. Use the corresponding `Ice.ACM.Client.Heartbeat` or `Ice.ACM.Server.Heartbeat` properties to override this setting in a client or server context, respectively.

To send a heartbeat, the Ice run time sends a `validate connection` message to the remote end. Heartbeats are not supported on datagram connections.

If not defined, the default value is 1.

## Ice.ACM.Timeout

### Synopsis

```
Ice.ACM.Timeout=num
```

### Description

The value for `num` represents a timeout in seconds for **Active Connection Management (ACM)**. The setting for `Ice.ACM.Close` determines when connections are automatically closed, and the setting for `Ice.ACM.Heartbeat` can be used to prevent connections from being closed prematurely. Use the corresponding `Ice.ACM.Client.Timeout` or `Ice.ACM.Server.Timeout` properties to override this setting in a client or server context, respectively.

If not defined, the default value is 60.

## Ice.ACM.Server.Close

### Synopsis

```
Ice.ACM.Server.Close=num
```

### Description

Overrides the value of `Ice.ACM.Close` in a server context, meaning for incoming connections.

## Ice.ACM.Server.Heartbeat

### **Synopsis**

`Ice.ACM.Server.Heartbeat=num`

### **Description**

Overrides the value of `Ice.ACM.Heartbeat` in a server context, meaning for incoming connections.

## **Ice.ACM.Server.Timeout**

### **Synopsis**

`Ice.ACM.Server.Timeout=num`

### **Description**

Overrides the value of `Ice.ACM.Timeout` in a server context, meaning for incoming connections.

## Ice.Admin.\*

On this page:

- [Ice.Admin.AdapterProperty](#)
- [Ice.Admin.DelayCreation](#)
- [Ice.Admin.Enabled](#)
- [Ice.Admin.Facets](#)
- [Ice.Admin.InstanceName](#)
- [Ice.Admin.Logger.KeepLogs](#)
- [Ice.Admin.Logger.KeepTraces](#)
- [Ice.Admin.Logger.Properties](#)
- [Ice.Admin.ServerId](#)

### Ice.Admin.AdapterProperty

#### Synopsis

```
Ice.Admin.AdapterProperty=value
```

#### Description

The Ice run time creates and activates an [administrative object adapter](#) named `Ice.Admin` if the [Administrative Facility](#) is enabled, `Ice.Admin.Endpoints` is defined and one of the following are true:

- `Ice.Admin.DelayCreation` is not enabled
- `Ice.Admin.DelayCreation` is enabled and the application calls `getAdmin` on the communicator after communicator initialization
- the application calls `createAdmin` with a null `adminAdapter` parameter

This object adapter is created to host the [admin object](#). [Adapter properties](#) can be used to configure the `Ice.Admin` object adapter.

Note that enabling the `Ice.Admin` object adapter is a security risk because a hostile client could use the administrative object to shut down the process. As a result, the [endpoints](#) for this object adapter should be carefully defined so that only trusted clients are allowed to use it.

### Ice.Admin.DelayCreation

#### Synopsis

```
Ice.Admin.DelayCreation=num
```

#### Description

If `num` is a value greater than zero, the Ice run time delays the creation of the `Ice.Admin` [administrative object adapter](#) until `getAdmin` is invoked on the communicator. If not specified, the default value is zero, meaning the `Ice.Admin` object adapter is created immediately after all plug-ins are initialized, provided `Ice.Admin.Endpoints` is defined.

### Ice.Admin.Enabled

#### Synopsis

```
Ice.Admin.Enabled=num
```

#### Description

If `num` is a value greater than zero, the [Administrative Facility](#) is enabled. If `num` is a zero or a negative value, the [Administrative Facility](#) is disabled. If this property is not set at all, the [Administrative Facility](#) is enabled when `Ice.Admin.Endpoints` is defined and not empty, and is disabled otherwise.

## Ice.Admin.Facets

### Synopsis

```
Ice.Admin.Facets=name [name ...]
```

### Description

Specifies the facets enabled by the [administrative object](#), allowing you to [filter](#) the facets that the administrative object enables by default. Facet names are delimited by commas or white space. A facet name that contains white space must be enclosed in single or double quotes. If not specified, all facets are enabled. While the Ice run time creates only the built-in facets (such as Process and Properties) that are enabled, you can create administrative facets without checking the value of this property. Ice ensures that only enabled administrative facets are available to clients.

## Ice.Admin.InstanceName

### Synopsis

```
Ice.Admin.InstanceName=name
```

### Description

Specifies an identity category for the [administrative object](#), when this object is created during communicator initialization or by a call to `getAdmin` on the communicator. If defined, the identity of the object becomes `name/admin`. If not specified, the default identity category is a UUID.

## Ice.Admin.Logger.KeepLogs

### Synopsis

```
Ice.Admin.Logger.KeepLogs=num
```

### Description

The [Logger admin facet](#), when enabled, caches up the `num` most recent log messages with a type other than `Ice::TraceMessage`. When `num` is 0 or less than 0, the Logger facet does not cache any of these log messages. The default value for `num` is 100.

## Ice.Admin.Logger.KeepTraces

### Synopsis

```
Ice.Admin.Logger.KeepTraces=num
```

### Description

The [Logger admin facet](#), when enabled, caches up the `num` most recent log messages with type `Ice::TraceMessage`. When `num` is 0 or less than 0, the Logger facet does not cache any of these trace messages. The default value for `num` is 100.

## Ice.Admin.Logger.Properties

### Synopsis

```
Ice.Admin.Logger.Properties=propertyList
```

### Description

The [Logger admin facet](#), when enabled, creates its own communicator to send log messages to attached remote loggers. Without this sub-communicator, sending log messages to remote loggers could trigger more local logging, which in turn would generate more logs sent to

remote loggers: a single genuine log could trigger an infinite number of log messages.

The properties of this sub-communicator are a few properties of the application's communicator (`Ice.Default.Locator`, `Ice.Plugin.IceSSL` and all `IceSSL` properties), plus the properties (if any) specified by `propertyList`. `propertyList` is a sequence of strings, that Ice reads using `getPropertyAsList`. Each of these strings uses the syntax `PropertyName=PropertyValue` to set a property. For example, you could turn on protocol tracing on the `Logger` facet's sub-communicator with:

```
Ice.Admin.Logger.Properties=Ice.Trace.Protocol=1
```

## Ice.Admin.ServerId

### Synopsis

```
Ice.Admin.ServerId=id
```

### Description

Specifies an identifier that uniquely identifies the process when the Ice run time registers the `Process` facet of its admin object with the locator registry.

## Ice.Config

### Ice.Config

#### Synopsis

```
--Ice.Config
--Ice.Config=1
--Ice.Config=config_file[,config_file,...]
```

#### Description

This property must be set from the command line with one of the options `--Ice.Config`, `--Ice.Config=1`, or `--Ice.Config=config_file`.

If the `Ice.Config` property is empty or set to 1, or not set at all, the Ice run time examines the contents of the `ICE_CONFIG` environment variable to retrieve the path names of one or more configuration files. Otherwise, `Ice.Config` must be set to the path names of one or more configuration files, separated by commas (path names can be relative or absolute). Property values are read from each of the configuration files listed.

In Java, Ice first attempts to open a configuration file as a [class loader resource](#). If that attempt fails, Ice opens the configuration file in the local file system.

Configuration files use a simple [syntax](#) consisting of `name=value` pairs with support for comments and escaping.

#### See Also

- [Using Configuration Files](#)

- [Alternate Property Stores](#)

## Ice.Default.\*

On this page:

- [Ice.Default.CollocationOptimized](#)
- [Ice.Default.EncodingVersion](#)
- [Ice.Default.EndpointSelection](#)
- [Ice.Default.Host](#)
- [Ice.Default.InvocationTimeout](#)
- [Ice.Default.Locator](#)
- [Ice.Default.LocatorCacheTimeout](#)
- [Ice.Default.Package](#)
- [Ice.Default.PreferSecure](#)
- [Ice.Default.Protocol](#)
- [Ice.Default.Router](#)
- [Ice.Default.SlicedFormat](#)
- [Ice.Default.SourceAddress](#)
- [Ice.Default.Timeout](#)

### Ice.Default.CollocationOptimized

#### Synopsis

```
Ice.Default.CollocationOptimized=num
```

#### Description

Specifies whether proxy invocations use [collocation optimization](#) by default. When enabled, proxy invocations on a collocated servant (i.e., a servant whose object adapter was created by the same communicator as the proxy) are made more efficiently by avoiding the network stack.

If not specified, the default value is 1. Set the property to 0 to disable collocation optimization by default.

### Ice.Default.EncodingVersion

#### Synopsis

```
Ice.Default.EncodingVersion=ver
```

#### Description

If this property is not defined, Ice 3.5 uses encoding version 1.1 by default. To force the Ice run time to use encoding version 1.0 as the default instead, set this property to 1.0:

```
Ice.Default.EncodingVersion=1.0
```

### Ice.Default.EndpointSelection

#### Synopsis

```
Ice.Default.EndpointSelection=policy
```

#### Description

This property controls the default [endpoint selection](#) policy for proxies with multiple endpoints. Permissible values are `Ordered` and `Random`. The default value of this property is `Random`.

### Ice.Default.Host

#### Synopsis

```
Ice.Default.Host=host
```

### Description

If an endpoint does not specify a host name (i.e., omits the `-h host` option), the `host` value from this property is used instead. The property has no default value.

## Ice.Default.InvocationTimeout

### Synopsis

```
Ice.Default.InvocationTimeout=num
```

### Description

Specifies the default [invocation timeout](#) in milliseconds to use for all proxies. If not defined, the default timeout is `-1`, which means an invocation never times out.

If set to `-2`, invocation timeouts are disabled and the Ice run time behaves like Ice versions `< 3.6`: it uses [connection timeouts](#) (defined on the endpoints) to wait for the response of the invocation. This setting is provided only for backward compatibility and might be deprecated in a future Ice major release.

## Ice.Default.Locator

### Synopsis

```
Ice.Default.Locator=locator
```

### Description

Specifies a default [locator](#) for all proxies and object adapters. The value is a stringified proxy for the `IceGrid` locator object. The default locator can be overridden on a proxy using the `ice_locator` [proxy method](#). The default value is no locator.

The default identity of the IceGrid locator object is `IceGrid/Locator`, but this identity is influenced by the `IceGrid.InstanceName` property. The locator object is available on the IceGrid client endpoints. For example, suppose `IceGrid.Registry.Client.Endpoints` is set as follows:

```
IceGrid.Registry.Client.Endpoints=tcp -p 12000 -h localhost
```

In this case, the stringified proxy for the IceGrid locator is:

```
Ice.Default.Locator=IceGrid/Locator:tcp -p 12000 -h localhost
```

As a proxy property, you can configure additional [aspects of the proxy](#) using properties.

## Ice.Default.LocatorCacheTimeout

### Synopsis

```
Ice.Default.LocatorCacheTimeout=num
```

### Description

Specifies the default [locator cache](#) timeout for indirect proxies. If `num` is set to a value larger than 0, locator cache entries older than `num` sec

onds are ignored. If set to 0, the locator cache is not used. If set to `-1`, locator cache entries do not expire.

Once a cache entry has expired, the Ice run time performs a new locate request to refresh the cache before sending the next invocation; therefore, the invocation is delayed until the run time has refreshed the entry. If you set `Ice.BackgroundLocatorCacheUpdates` to a non-0 value, the lookup to refresh the cache is still performed but happens in the background; this avoids the delay for the first invocation that follows expiry of a cache entry.

## Ice.Default.Package

### Synopsis

```
Ice.Default.Package=package
```

### Description

Ice for Java allows you to [customize](#) the packaging of generated code. If you use this feature, the Ice run time requires additional configuration in order to successfully unmarshal exceptions and concrete class types. This property specifies a default package to use if other attempts by the Ice run time to dynamically load a generated class have failed. Also see `Ice.Package.module`.

## Ice.Default.PreferSecure

### Synopsis

```
Ice.Default.PreferSecure=num
```

### Description

Specifies whether secure endpoints are given [precedence](#) in proxies by default. The default value of `num` is 0, meaning that insecure endpoints are given preference.

Setting this property to a non-0 value is the equivalent of invoking the [proxy method](#) `ice_preferSecure(true)` on proxies created by the Ice run time, such as those returned by `stringToProxy` or received as the result of an invocation. Proxies created by methods such as `ice_oneway` inherit the setting of the original proxy. If you want to force all proxies to use only secure endpoints, use `Ice.Override.Secure` instead.

See [Configuring Secure Proxies](#) for a discussion of secure proxies.

## Ice.Default.Protocol

### Synopsis

```
Ice.Default.Protocol=protocol
```

### Description

Sets the [protocol](#) that is being used if an endpoint uses default as the protocol specification. The default value is `tcp`.

## Ice.Default.Router

### Synopsis

```
Ice.Default.Router=router
```

### Description

Specifies the default [router](#) for all proxies. The value is a stringified proxy for the Glacier2 router control interface. The default router can be overridden on a proxy using the `ice_router` [proxy method](#). The default value is no router.

As a proxy property, you can configure additional [aspects of the proxy](#) using properties.

## Ice.Default.SlicedFormat

### Synopsis

```
Ice.Default.SlicedFormat=num
```

### Description

Specifies the encoding format of Slice classes and exceptions. The default value of *num* is 0, meaning that the encoding uses the compact format. Set this property to a non-0 value to use the sliced format by default. This setting is only relevant when using version 1.1 of the Ice encoding.

Note that you can also specify whether certain operations use the sliced format by annotating their definitions with [metadata](#).

## Ice.Default.SourceAddress

### Synopsis

```
Ice.Default.SourceAddress=addr
```

### Description

If specified, outgoing socket connections are bound to the network interface associated with the given address *addr*, which must be a numeric IP address. Proxy endpoints can override this setting with the `--sourceAddress` option. If no source address is configured, the Ice run time uses the operating system's default behavior for binding an outgoing socket connection.

This feature is not supported on WinRT.

## Ice.Default.Timeout

### Synopsis

```
Ice.Default.Timeout=num
```

### Description

Specifies the default timeout in milliseconds to use for an [endpoint](#) if no timeout is configured using the `-t` option. Use the value `-1` to configure an infinite default timeout. If not defined, the default timeout is 60000.

## Ice.InitPlugins

### Ice.InitPlugins

#### Synopsis

`Ice.InitPlugins=num`

#### Description

If `num` is a value greater than zero, the Ice run time automatically initializes the plug-ins it has loaded. The order in which plug-ins are loaded and initialized is determined by `Ice.PluginLoadOrder`. An application may need to set this property to zero in order to [interact directly with a plug-in](#) after it has been loaded but before it is initialized. In this case, the application must invoke `initializePlugins` on the plug-in manager to complete the initialization process. If not defined, the default value is 1.

When the [admin Object](#) is created, its `Process` facet is registered with the configured Locator registry if `Ice.Admin.ServerId` is set. This remote registration call may depend on plug-ins, such as the `IceSSL` plug-in. As a result, if you delay the initialization of the plug-ins by setting `Ice.InitPlugins` to 0, you may also want to delay the creation of the admin Object by setting `Ice.Admin.DelayCreation` to 1.

## Ice.IPv4

### Ice.IPv4

#### *Synopsis*

`Ice.IPv4=num`

#### *Description*

Specifies whether Ice uses IPv4. If *num* is a value greater than zero, IPv4 is enabled. If not specified, the default value is 1.

## Ice.IPv6

### Ice.IPv6

#### Synopsis

`Ice.IPv6=num`

#### Description

Specifies whether Ice uses IPv6. If *num* is a value greater than zero, IPv6 is enabled. If not specified, the default value is 1 if the system supports the creation of IPv6 sockets, and 0 otherwise.

#### Platform Notes

##### Java

Java's default network stack always accepts both IPv4 and IPv6 connections regardless of the settings of `Ice.IPv6`. You can configure the Java run time to use only IPv4 by starting your application with the following JVM option:

#### Java

```
java -Djava.net.preferIPv4Stack=true ...
```

## Ice.Override.\*

On this page:

- [Ice.Override.CloseTimeout](#)
- [Ice.Override.Compress](#)
- [Ice.Override.ConnectTimeout](#)
- [Ice.Override.Secure](#)
- [Ice.Override.Timeout](#)

### Ice.Override.CloseTimeout

#### Synopsis

```
Ice.Override.CloseTimeout=num
```

#### Description

This property overrides timeout settings used to [close connections](#). *num* is the timeout value in milliseconds, or `-1` for no timeout. If this property is not defined, then [Ice.Override.Timeout](#) is used. If [Ice.Override.Timeout](#) is not defined, the endpoint timeout is used.

### Ice.Override.Compress

#### Synopsis

```
Ice.Override.Compress=num
```

#### Description

If set, this property overrides [compression](#) settings in all proxies. If *num* is set to a value larger than zero, compression is enabled. If zero, compression is disabled.

The setting of this property is ignored in the server role.

Note that, if a client sets `Ice.Override.Compress=1` and sends a compressed request to a server that does not support compression, the server will close the connection and the client will receive `ConnectionLostException`.

If a client does not support compression and `Ice.Override.Compress=1`, the setting is ignored and a warning message is printed on `stderr`.

Regardless of the setting of this property, requests smaller than 100 bytes are never compressed.

### Ice.Override.ConnectTimeout

#### Synopsis

```
Ice.Override.ConnectTimeout=num
```

#### Description

This property overrides timeout settings used to [establish connections](#). *num* is the timeout value in milliseconds, or `-1` for no timeout. If this property is not defined, then [Ice.Override.Timeout](#) is used. If [Ice.Override.Timeout](#) is not defined, the endpoint timeout is used.

### Ice.Override.Secure

#### Synopsis

```
Ice.Override.Secure=num
```

#### Description

If set to a value larger than zero, this property overrides security settings in all proxies by allowing only secure endpoints. Defining this property is equivalent to invoking the `ice_secure(true)` [proxy method](#) on every proxy. If you wish to give priority to secure endpoints without precluding the use of non-secure endpoints, use `Ice.Default.PreferSecure`. Refer to [Configuring Secure Proxies](#) for more information on secure proxies.

## **Ice.Override.Timeout**

### ***Synopsis***

```
Ice.Override.Timeout=num
```

### ***Description***

If set, this property overrides timeout settings in all endpoints. *num* is the timeout value in milliseconds, or `-1` for no timeout.

## Ice.Plugin.\*

On this page:

- [Ice.Plugin.name](#)
- [Ice.Plugin.name.clr](#)
- [Ice.Plugin.name.cpp](#)
- [Ice.Plugin.name.java](#)

## Ice.Plugin.name

### Synopsis

```
Ice.Plugin.name=entry_point [args]
```

### Description

Defines a **plug-in** to be installed during communicator initialization. The format of *entry\_point* varies by Ice implementation language, therefore this property cannot be defined in a configuration file that is shared by programs in different languages. Ice provides an alternate syntax that facilitates such sharing:

- `Ice.Plugin.name.cpp` for C++
- `Ice.Plugin.name.java` for Java
- `Ice.Plugin.name.clr` for the .NET Common Language Runtime

Refer to the relevant property for your language mapping for details on the entry point syntax.

## Ice.Plugin.name.clr

### Synopsis

```
Ice.Plugin.name.clr=assembly:class [args]
```

### Description

Defines a .NET **plug-in** to be installed during communicator initialization. The *assembly* component can be a partially or fully qualified assembly name, such as `myplugin,Version=0.0.0.0,Culture=neutral`, or an assembly DLL name such as `myplugin.dll` that may optionally include a leading relative or absolute path name.

The locations that are searched for the assembly varies depending on how you define the *assembly* component:

Value for <i>assembly</i>	Example	Semantics
Fully-qualified assembly name (strong-named assembly)	<code>myplugin,Version=...,Culture=neutral,publicKeyToken=...</code>	<ol style="list-style-type: none"> <li>1. Checks assemblies that have already been loaded</li> <li>2. Searches the Global Assembly Cache (GAC)</li> <li>3. Searches the directory containing the <code>iceboxn</code> et executable</li> </ol>
Partially-qualified assembly name	<code>myplugin</code>	<ol style="list-style-type: none"> <li>1. Checks assemblies that have already been loaded</li> <li>2. Searches the directory containing the <code>iceboxn</code> et executable</li> </ol>

Relative path name	<code>plugins\MyPlugin.dll</code>	Path name is relative to the application's current working directory. Be sure to include the <code>.dll</code> extension in the path name.
Absolute path name	<code>C:\plugins\MyPlugin.dll</code>	Assembly must reside at the specified path name. Be sure to include the <code>.dll</code> extension in the path name.

See MSDN for more information on [how the CLR locates assemblies](#).

The specified *class* must implement the `Ice.PluginFactory` interface. Any arguments that follow the class name are passed to the factory's `create` method. For example:

```
Ice.Plugin.MyPlugin.clr=MyFactory,Version=1.2.3.4:MyFactory arg1 arg2
```

Whitespace separates the arguments, and any arguments that contain whitespace must be enclosed in quotes.

If you specify a relative path name in the entry point, the assembly is located relative to the program's current working directory:

```
Ice.Plugin.MyPlugin.clr=..\MyFactory.dll:MyFactory arg1 arg2
```

Enclose the assembly's path name in quotes if it contains spaces:

```
Ice.Plugin.MyPlugin.clr="C:\Program
Files\MyPlugin\MyFactory.dll:MyFactory" arg1 arg2
```

## Ice.Plugin.name.cpp

### Synopsis

```
Ice.Plugin.name.cpp=path[,version]:function [args]
```

### Description

Defines a C++ [plug-in](#) to be installed during communicator initialization. The *path* and optional *version* components are used to construct the path name of a DLL or shared library. If no version is supplied, the Ice version is used. The *function* component is the name of a function with C linkage. For example, the entry point `MyPlugin,36:create` would imply a shared library name of `libMyPlugin.so.36` on Unix and `MyPlugin36.dll` on Windows. Furthermore, if Ice is built on Windows with debugging, a `d` is automatically appended to the version (for example, `MyPlugin36d.dll`).

The function must be declared with external linkage and have the following signature:

**C++**

```
Ice::Plugin* function(const Ice::CommunicatorPtr& communicator,
 const std::string& name,
 const Ice::StringSeq& args);
```

Note that the function must return a pointer and not a smart pointer.

Any arguments that follow the entry point are passed to the entry point function. For example:

```
Ice.Plugin.MyPlugin.cpp=MyFactory,36:create arg1 arg2
```

Whitespace separates the arguments, and any arguments that contain whitespace must be enclosed in quotes.

The *path* component may optionally contain a relative or absolute path name, indicated by the presence of a path separator (/ or \). In this case, the last component of the path is used to construct the version-specific name of the shared library or DLL. Consider this example:

```
Ice.Plugin.MyPlugin.cpp=./MyFactory,36:create arg1 arg2
```

The use of a relative path means the Ice run time will look in the current working directory for `libMyPlugin.so.36` on Unix or `MyPlugin36.dll` on Windows.

If the *path* component contains spaces, the entire entry point must be enclosed in quotes:

```
Ice.Plugin.MyPlugin.cpp="C:\Program Files\MyPlugin\MyFactory,36:create"
arg1 arg2
```

If the *path* component does not include a leading path name, Ice delegates to the operating system to locate the shared library or DLL, which typically means that the plug-in can reside in any of the directories in your shared library or DLL search path.

When the plug-in is packaged in a static library and linked into the application through `Ice::registerPluginFactory`, the entry point (*path[,version]:function*) component of this property is ignored. The *args*, if any, are preserved, and are given to the registered plug-in factory function when the plug-in is created.

## Ice.Plugin.name.java

### Synopsis

```
Ice.Plugin.name.java=[path:]class [args]
```

### Description

Defines a Java [plug-in](#) to be installed during communicator initialization. The specified class must implement the `Ice.PluginFactory` inter

face. Any arguments that follow the class name are passed to the `create` method. For example:

```
Ice.Plugin.MyPlugin.java=MyFactory arg1 arg2
```

Whitespace separates the arguments, and any arguments that contain whitespace must be enclosed in quotes.

If *path* is specified, it may be the path name of a JAR file or class directory, as shown below:

```
Ice.Plugin.MyPlugin.java=MyFactory.jar:MyFactory
Ice.Plugin.MyOtherPlugin.java=/classes:MyOtherFactory
```

If *path* contains spaces, it must be enclosed in quotes:

```
Ice.Plugin.MyPlugin.java="factory classes.jar":MyFactory
```

If *class* is specified without a path, Ice attempts to load the class using [class loaders](#) in a well-defined order.

## Ice.PluginLoadOrder

### Ice.PluginLoadOrder

#### *Synopsis*

`Ice.PluginLoadOrder=names`

#### *Description*

Determines the order in which [plug-ins](#) are loaded (loaded is a synonym for created in this context). The Ice run time loads the plug-ins in the order they appear in `names`, where each plug-in name is separated by a comma or white space. Any plug-ins not mentioned in `names` are loaded afterward, in an undefined order.

C++ plug-ins for which factories were registered through `Ice::registerPluginFactory` with the last parameter set to `true` are always loaded first, in registration order, and are not affected by this property.

## Ice.PreferIPv6Address

### Ice.PreferIPv6Address

#### *Synopsis*

`Ice.PreferIPv6Address=num`

#### *Description*

If both IPv4 and IPv6 are enabled (the default), specifies whether Ice prefers IPv6 addresses over IPv4 addresses when resolving hostnames. If *num* is a value greater than zero, IPv6 addresses are preferred. If not specified, the default value is 0.

## Ice.TCP.\*

On this page:

- [Ice.TCP.Backlog](#)
- [Ice.TCP.RcvSize](#)
- [Ice.TCP.SndSize](#)

### Ice.TCP.Backlog

#### Synopsis

`Ice.TCP.Backlog=num`

#### Description

Specifies the size of the listen queue for each TCP or SSL server endpoint. If not defined, the default value for C++ programs uses the value of `SOMAXCONN` if present, or `511` otherwise. In Java and .NET, the default value is `511`.

### Ice.TCP.RcvSize

#### Synopsis

`Ice.TCP.RcvSize=num`

#### Description

This property sets the TCP receive buffer size to the specified value in bytes. The default value depends on the configuration of the local TCP stack. (A common default values is `65535` bytes.)

The OS may impose lower and upper limits on the receive buffer size or otherwise adjust the buffer size. If a limit is requested that is lower than the OS-imposed minimum, the value is silently adjusted to the OS-imposed minimum. If a limit is requested that is larger than the OS-imposed maximum, the value is adjusted to the OS-imposed maximum; in addition, Ice logs a warning showing the requested size and the adjusted size.

### Ice.TCP.SndSize

#### Synopsis

`Ice.TCP.SndSize=num`

#### Description

This property sets the TCP send buffer size to the specified value in bytes. The default value depends on the configuration of the local TCP stack. (A common default values is `65535` bytes.)

The OS may impose lower and upper limits on the send buffer size or otherwise adjust the buffer size. If a limit is requested that is lower than the OS-imposed minimum, the value is silently adjusted to the OS-imposed minimum. If a limit is requested that is larger than the OS-imposed maximum, the value is adjusted to the OS-imposed maximum; in addition, Ice logs a warning showing the requested size and the adjusted size.

## Ice.ThreadPool.\*

A communicator creates two [thread pools](#): the client thread pool dispatches AMI callbacks and incoming requests on [bidirectional connections](#), and the server thread pool dispatches requests to [object adapters](#).

This page describes configuration properties for the client and server thread pools. These thread pools are named `Client` and `Server`, respectively. In the property descriptions below, replace `name` with `Client` or `Server`.

On this page:

- [Ice.ThreadPool.name.Serialize](#)
- [Ice.ThreadPool.name.Size](#)
- [Ice.ThreadPool.name.SizeMax](#)
- [Ice.ThreadPool.name.SizeWarn](#)
- [Ice.ThreadPool.name.StackSize](#)
- [Ice.ThreadPool.name.ThreadIdleTime](#)
- [Ice.ThreadPool.name.ThreadPriority](#)

### Ice.ThreadPool.name.Serialize

#### Synopsis

```
Ice.ThreadPool.name.Serialize=num
```

#### Description

If `num` is a value greater than 0, the `Client` or `Server` [thread pool](#) serializes all messages from each connection. It is not necessary to enable this feature in a thread pool whose maximum size is 1 thread. When a thread pool dispatches requests implemented with AMD, it serializes the dispatching of requests from each connection, but it does not wait for a request to complete before it dispatches the next request.

In a multi-threaded pool, enabling serialization allows requests from different connections to be dispatched concurrently while preserving the order of messages on each connection. Note that serialization can have a significant impact on latency and throughput. If not defined, the default value is 0.

### Ice.ThreadPool.name.Size

#### Synopsis

```
Ice.ThreadPool.name.Size=num
```

#### Description

[Thread pools](#) in Ice can grow and shrink dynamically, based on an average load factor. A thread pool always has at least 1 thread and may grow as load increases up to the maximum size specified by `Ice.ThreadPool.name.SizeMax`. If `SizeMax` is not specified, Ice uses the value of `num` as the pool's maximum size. The `Client` or `Server` thread pool is initialized with `num` active threads, but the pool may shrink to only 1 thread during idle periods as determined by `Ice.ThreadPool.name.ThreadIdleTime`.

If not specified, the default value is 1 for both properties.

An object adapter can also be configured with its [own thread pool](#).

Note that multiple threads for the client thread pool are only required for [nested AMI invocations](#), or to allow multiple AMI callbacks to be dispatched concurrently.

To monitor the thread pool activities of the Ice run time, enable the `Ice.Trace.ThreadPool` property.

### Ice.ThreadPool.name.SizeMax

#### Synopsis

```
Ice.ThreadPool.name.SizeMax=num
```

### Description

*num* is the maximum number of threads for the Client or Server [thread pool](#). Refer to the [Ice.ThreadPool.name.Size](#) property for more information on configuring the size of a thread pool.

The default value for `SizeMax` is the value of `Size`, meaning the thread pool can never grow larger than its initial size.

To monitor the thread pool activities of the Ice run time, enable the [Ice.Trace.ThreadPool](#) property.

## Ice.ThreadPool.name.SizeWarn

### Synopsis

```
Ice.ThreadPool.name.SizeWarn=num
```

### Description

Whenever *num* threads are active in the Client or Server [thread pool](#), a "low on threads" warning is printed. The default value is 0, which disables the warning.

To monitor the thread pool activities of the Ice run time, enable the [Ice.Trace.ThreadPool](#) property.

## Ice.ThreadPool.name.StackSize

### Synopsis

```
Ice.ThreadPool.name.StackSize=num
```

### Description

*num* is the stack size (in bytes) of threads in the Client or Server [thread pool](#). The default value is 0, meaning the operating system's default is used.

## Ice.ThreadPool.name.ThreadIdleTime

### Synopsis

```
Ice.ThreadPool.name.ThreadIdleTime=num
```

### Description

Ice can automatically reap idle threads in the Client or Server [thread pool](#) to conserve resources. This property specifies the number of seconds a thread must be idle before it is reaped. If not specified, the default value is 60 seconds.

The threads in Ice thread pools are assigned jobs at random, and this randomness affects how quickly a thread in an under-utilized thread pool will get reaped.

To disable the reaping of idle threads, set `ThreadIdleTime` to 0. In this situation, the thread pool is initialized with [Ice.ThreadPool.name.Size](#) active threads and may grow to contain [Ice.ThreadPool.name.SizeMax](#) active threads, but the size of the pool never decreases.

To monitor the thread pool activities of the Ice run time, enable the [Ice.Trace.ThreadPool](#) property.

## Ice.ThreadPool.name.ThreadPriority

## **Synopsis**

`Ice.ThreadPool.name.ThreadPriority=num`

## **Description**

`num` specifies a thread priority for the threads in the `Client` or `Server` [thread pool](#). Leaving this property unset causes the run time to create threads with the default priority specified by `Ice.ThreadPriority`.

This property is unset by default.

You can also override the default priority for a specific object adapter using `adapter.ThreadPool.ThreadPriority`.

## Ice.ThreadPriority

### Ice.ThreadPriority

#### Synopsis

`Ice.ThreadPriority=num`

#### Description

`num` specifies a thread priority. Threads created by the Ice run time are created with the specified priority by default. Leaving this property unset causes the run time to create threads with the system default priority. This property is unset by default.

You can separately override the default priorities for the client and server thread pools using `Ice.ThreadPool.name.ThreadPriority` as well as for a specific object adapter using `adapter.ThreadPool.ThreadPriority`.

## Ice.Trace.\*

On this page:

- [Ice.Trace.Admin.Logger](#)
- [Ice.Trace.Admin.Properties](#)
- [Ice.Trace.Locator](#)
- [Ice.Trace.Network](#)
- [Ice.Trace.Protocol](#)
- [Ice.Trace.Retry](#)
- [Ice.Trace.Slicing](#)
- [Ice.Trace.ThreadPool](#)

### Ice.Trace.Admin.Logger

#### Synopsis

`Ice.Trace.Admin.Logger=num`

#### Description

Controls the trace level for the [Logger administrative facet](#).

0	No trace (default).
1	Trace when a remote logger is attached or detached.
2	Like 1, but also trace the sending of log messages to remote loggers.

### Ice.Trace.Admin.Properties

#### Synopsis

`Ice.Trace.Admin.Properties=num`

#### Description

Controls the trace level for property updates made via the [Properties facet](#):

0	No property trace (default).
1	Trace property addition, modification, and removal.

### Ice.Trace.Locator

#### Synopsis

`Ice.Trace.Locator=num`

#### Description

The Ice run time makes [locator](#) requests to resolve the endpoints of object adapters and well-known objects. Requests on the locator registry are used to update object adapter endpoints and set the server process proxy. This property controls the trace level for the Ice run time's interactions with the locator:

0	No locator trace (default).
1	Trace Ice locator and locator registry requests.
2	Like 1, but also trace the removal of endpoints from the cache.

## Ice.Trace.Network

### Synopsis

`Ice.Trace.Network=num`

### Description

Controls the trace level for low-level network activities such as connection establishment and read/write operations:

0	No network trace (default).
1	Trace successful connection establishment and closure.
2	Like 1, but also trace attempts to bind, connect, and disconnect sockets.
3	Like 2, but also trace data transfer, the <a href="#">published endpoints</a> for an object adapter, and the current list of local addresses for an endpoint that uses the wildcard address.

## Ice.Trace.Protocol

### Synopsis

`Ice.Trace.Protocol=num`

### Description

Controls the trace level for Ice [protocol](#) messages:

0	No protocol trace (default).
1	Trace Ice protocol messages.

## Ice.Trace.Retry

### Synopsis

`Ice.Trace.Retry=num`

### Description

Ice supports [automatic retries](#) in case of a request failure. This property controls the trace level for retry attempts:

0	No request retry trace (default).
1	Trace Ice operation call retries.
2	Also trace Ice endpoint usage.

## Ice.Trace.Slicing

### Synopsis

`Ice.Trace.Slicing=num`

### Description

The Ice data encoding for [exceptions](#) and [classes](#) enables a receiver to slice an unknown exception or class type to a known type. This

property controls the trace level for slicing activities:

0	No trace of slicing activity (default).
1	Trace all exception and class types that are unknown to the receiver and therefore sliced.

## Ice.Trace.ThreadPool

### **Synopsis**

`Ice.Trace.ThreadPool=num`

### **Description**

Controls the trace level for the Ice [thread pool](#):

0	No trace of thread pool activity (default).
1	Trace the creation, growing, and shrinking of thread pools.

## Ice.UDP.\*

On this page:

- [Ice.UDP.RcvSize](#)
- [Ice.UDP.SndSize](#)

### Ice.UDP.RcvSize

#### Synopsis

`Ice.UDP.RcvSize=num`

#### Description

This property sets the UDP receive buffer size to the specified value in bytes. Ice messages larger than `num - 28` bytes cause a `DatagramLimitException`. The default value depends on the configuration of the local UDP stack. (Common default values are 65535 and 8192 bytes.)

The OS may impose lower and upper limits on the receive buffer size or otherwise adjust the buffer size. If a limit is requested that is lower than the OS-imposed minimum, the value is silently adjusted to the OS-imposed minimum. If a limit is requested that is larger than the OS-imposed maximum, the value is adjusted to the OS-imposed maximum; in addition, Ice logs a warning showing the requested size and the adjusted size.

Values less than 28 are ignored.

Note that, on many operating systems, it is possible to set a buffer size greater than 65535. Such settings do not change the hard limit of 65507 bytes for the payload of a UDP packet, but merely affect how much data can be buffered by the kernel.

Settings less than 65535 limit the size of Ice datagrams as well as adjust the kernel buffer sizes.

### Ice.UDP.SndSize

#### Synopsis

`Ice.UDP.SndSize=num`

#### Description

This property sets the UDP send buffer size to the specified value in bytes. Ice messages larger than `num - 28` bytes cause a `DatagramLimitException`. The default value depends on the configuration of the local UDP stack. (Common default values are 65535 and 8192 bytes.)

The OS may impose lower and upper limits on the send buffer size or otherwise adjust the buffer size. If a limit is requested that is lower than the OS-imposed minimum, the value is silently adjusted to the OS-imposed minimum. If a limit is requested that is larger than the OS-imposed maximum, the value is adjusted to the OS-imposed maximum; in addition, Ice logs a warning showing the requested size and the adjusted size.

Values less than 28 are ignored.

Note that, on many operating systems, it is possible to set a buffer size greater than 65535. Such settings do not change the hard limit of 65507 bytes for the payload of a UDP packet, but merely affect how much data can be buffered by the kernel.

Settings less than 65535 limit the size of Ice datagrams as well as adjust the kernel buffer sizes.

## Ice.Warn.\*

On this page:

- [Ice.Warn.AMICallback](#)
- [Ice.Warn.Connections](#)
- [Ice.Warn.Datagrams](#)
- [Ice.Warn.Dispatch](#)
- [Ice.Warn.Endpoints](#)
- [Ice.Warn.UnknownProperties](#)
- [Ice.Warn.UnusedProperties](#)

### Ice.Warn.AMICallback

#### Synopsis

`Ice.Warn.AMICallback=num`

#### Description

If `num` is set to a value larger than zero, warnings are printed if an AMI callback raises an exception. The default value is 1.

### Ice.Warn.Connections

#### Synopsis

`Ice.Warn.Connections=num`

#### Description

If `num` is set to a value larger than zero, Ice applications print warning messages for certain exceptional conditions in connections. The default value is 0.

### Ice.Warn.Datagrams

#### Synopsis

`Ice.Warn.Datagrams=num`

#### Description

If `num` is set to a value larger than zero, a server prints a warning message if it receives a datagram that exceeds the server's receive buffer size. (Note that this condition is not detected by all UDP implementations — some implementations silently drop received datagrams that are too large.) The default value is 0.

### Ice.Warn.Dispatch

#### Synopsis

`Ice.Warn.Dispatch=num`

#### Description

If `num` is set to a value larger than zero, Ice applications print warning messages for certain exceptions that are raised while an incoming request is dispatched.

Warning levels:

0	No warnings.
---	--------------

1	Print warnings for unexpected <code>Ice::LocalException</code> , <code>Ice::UserException</code> , C++ exceptions, and Java run-time exceptions (default).
2	Like 1, but also issue warnings for <code>Ice::ObjectNotExistException</code> , <code>Ice::FacetNotExistException</code> , and <code>Ice::OperationNotExistException</code> .

## Ice.Warn.Endpoints

### Synopsis

`Ice.Warn.Endpoints=num`

### Description

If `num` is set to a value larger than zero, a warning is printed if a stringified proxy contains an endpoint that cannot be parsed. (For example, stringified proxies containing SSL endpoints cause this warning in versions of Ice that do not support SSL.) The default value is 1.

## Ice.Warn.UnknownProperties

### Synopsis

`Ice.Warn.UnknownProperties=num`

### Description

If `num` is set to a value larger than zero, the Ice run time prints a warning about unknown properties for [object adapters](#) and [proxies](#). The default value is 1.

## Ice.Warn.UnusedProperties

### Synopsis

`Ice.Warn.UnusedProperties=num`

### Description

If `num` is set to a value larger than zero, the Ice run time prints a warning during communicator destruction about properties that were set but not read. This warning is useful for detecting mis-spelled properties, such as `Filesystem.MaxFileSize`. The default value is 0.

## IceBox.\*

On this page:

- [IceBox.InheritProperties](#)
- [IceBox.LoadOrder](#)
- [IceBox.PrintServicesReady](#)
- [IceBox.Service.name](#)
- [IceBox.UseSharedCommunicator.name](#)

## IceBox.InheritProperties

### Synopsis

```
IceBox.InheritProperties=num
```

### Description

If *num* is set to a value larger than zero, each service inherits the configuration properties of the IceBox server's communicator. If not defined, the default value is zero.

## IceBox.LoadOrder

### Synopsis

```
IceBox.LoadOrder=names
```

### Description

Determines the [order](#) in which services are loaded. The service manager loads the services in the order they appear in *names*, where each service name is separated by a comma or white space. Any services not mentioned in *names* are loaded afterward, in an undefined order.

## IceBox.PrintServicesReady

### Synopsis

```
IceBox.PrintServicesReady=token
```

### Description

If this property is set to a value greater than zero, the service manager prints "*token* ready" on standard output once initialization of all the services is complete. This is useful for scripts that need to wait until all services are ready to be used.

## IceBox.Service.name

### Synopsis

```
IceBox.Service.name=entry_point [args]
```

### Description

Defines a [service](#) to be loaded during IceBox initialization. Any arguments that follow the entry point are examined; those matching the `--name.*=value` pattern are interpreted as property definitions and appear in the property set of the communicator that is passed to the service `start` method, and all remaining arguments are passed to the `start` method in the `args` parameter. Whitespace separates the arguments, and any arguments that contain whitespace must be enclosed in quotes.

### Platform Notes

**C++**

The value of *entry\_point* has the following form:

```
path[,version]:function
```

The *path* and optional *version* components are used to construct the name of a DLL or shared library. If no version is supplied, the version is the empty string. The *function* component is the name of a function with extern C linkage. For example, the entry point `IceStormService,35:createIceStorm` implies a shared library name of `libIceStormService.so.35` on Unix and `IceStormService35.dll` on Windows. Furthermore, if IceBox is built on Windows with debugging, a `d` is automatically appended to the version (e.g., `IceStormService35d.dll`).

The function must be declared with extern C linkage and have the following signature:

**C++**

```
IceBox::Service* function(Ice::CommunicatorPtr c);
```

Note that the function must return a pointer and not a smart pointer. The Ice core deallocates the object when it unloads the library. The communicator instance passed to this function is the server's communicator, which is not the same as the communicator passed to the service's `start` method.

The *path* component may optionally contain a relative or absolute path name, indicated by the presence of a path separator (`/` or `\`). In this case, the last component of the path is used to construct the name of the shared library or DLL. Consider this example:

```
IceBox.Service.IceStorm=./IceStormService,35:createIceStorm
```

The use of a relative path means the Ice run time will look in the current working directory for `libIceStormService.so.35` on Unix or `IceStormService35.dll` on Windows.

If the *path* component contains spaces, the entire entry point must be enclosed in quotes:

```
IceBox.Service.IceStorm="C:\Program
Files\ZeroC\Ice-3.5b\bin\IceStormService,35:createIceStorm"
```

If the *path* component does not include a leading path name, Ice delegates to the operating system to locate the shared library or DLL, which typically means that the plug-in can reside in any of the directories in your shared library or DLL search path.

**Java**

The value of *entry\_point* has the following form:

```
[path:]class
```

The *class* component must be the name of a class that implements the `IceBox.Service` interface and provides at least one of the constructors shown in the example below:

### Java

```
public class MyService implements IceBox.Service
{
 public MyService(Ice.Communicator serverCommunicator);
 public MyService();

 // ...
}
```

The constructor taking an `Ice.Communicator` argument is invoked if present, otherwise the default constructor is invoked.

If `path` is specified, it may be the path name of a JAR file or class directory, as shown below:

```
IceBox.Service.MyService=MyService.jar:MyServiceImpl
IceBox.Service.MyOtherService=/classes:MyOtherServiceImpl
```

If `path` contains spaces, it must be enclosed in quotes:

```
IceBox.Service.MyService="factory classes.jar":MyServiceImpl
```

IceBox uses a single class loader to load all services having the same value for `path`.

If `class` is specified without a path, IceBox attempts to load the class using [class loaders](#) in a well-defined order.

#### **.NET**

The value of `entry_point` has the form `assembly:class`. The `assembly` can be a partially or fully qualified assembly name, such as `myplugin,Version=0.0.0.0,Culture=neutral`, or an assembly DLL name such as `myplugin.dll`, and may optionally include a leading relative or absolute path name.

You *must* use a fully-qualified assembly name to load a service from an assembly in the Global Assembly Cache.

The specified class must implement the `IceBox.Service` interface and provide at least one of the constructors shown in the example below:

**C#**

```
public class MyService : IceBox.Service
{
 public MyService(Ice.Communicator serverCommunicator);
 public MyService();

 // ...
}
```

The constructor taking an `Ice.Communicator` argument is invoked if present, otherwise the default constructor is invoked.

If you specify a relative path name in the entry point, the assembly is located relative to the program's current working directory:

```
IceBox.Service.MyService=..\MyService.dll:MyServiceImpl
```

Enclose the assembly's path name in quotes if it contains spaces:

```
IceBox.Service.MyService="C:\Program
Files\MyService\MyService.dll:MyServiceImpl"
```

Finally, if the assembly uses a leading path name, be sure to include the `.dll` extension.

## IceBox.UseSharedCommunicator.*name*

### Synopsis

```
IceBox.UseSharedCommunicator.name=num
```

### Description

If *num* is set to a value larger than zero, the service manager supplies the service *name* with a communicator that might be [shared by other services](#). If the `IceBox.InheritProperties` property is also defined, the shared communicator inherits the properties of the IceBox server. If not defined, the default value is zero.

## IceBoxAdmin

### IceBoxAdmin.ServiceManager.Proxy

#### *Synopsis*

`IceBoxAdmin.ServiceManager.Proxy=proxy`

#### *Description*

This property configures the proxy that is used by the [iceboxadmin](#) utility to locate the service manager.

## IceDiscovery.\*

This page describes the properties supported by the `IceDiscovery` plug-in.

On this page:

- `IceDiscovery.Address`
- `IceDiscovery.DomainId`
- `IceDiscovery.Interface`
- `IceDiscovery.Locator.AdapterProperty`
- `IceDiscovery.Lookup`
- `IceDiscovery.Multicast.AdapterProperty`
- `IceDiscovery.Port`
- `IceDiscovery.Reply.AdapterProperty`
- `IceDiscovery.RetryCount`
- `IceDiscovery.Timeout`

### IceDiscovery.Address

#### Synopsis

`IceDiscovery.Address=addr`

#### Description

Specifies the multicast IP address to use for sending or receiving multicast requests. If not defined, the default value depends on other property settings:

- If `Ice.PreferIPv6Address` is enabled or `Ice.IPv4` is disabled, IceDiscovery uses the IPv6 address `ff15::1`
- Otherwise IceDiscovery uses `239.255.0.1`

### IceDiscovery.DomainId

#### Synopsis

`IceDiscovery.DomainId=id`

#### Description

Specifies the domain ID used to locate objects and object adapters. The IceDiscovery plug-in only responds to requests from clients with the same domain ID and ignores requests from clients with a different domain ID. If not defined, the default domain ID is an empty string.

### IceDiscovery.Interface

#### Synopsis

`IceDiscovery.Interface=intf`

#### Description

Specifies the IP address of the interface to use for sending or receiving multicast requests. If not defined, the operating system will select a default interface to send and receive the UDP multicast datagrams.

### IceDiscovery.Locator.AdapterProperty

#### Synopsis

`IceDiscovery.Locator.AdapterProperty=value`

**Description**

IceDiscovery creates an object adapter named `IceDiscovery.Locator`.

You don't normally need to set [other properties](#) for this object adapter.

**IceDiscovery.Lookup****Synopsis**

```
IceDiscovery.Lookup=endpoint
```

**Description**

Specifies the multicast endpoint that a client uses to send discovery requests. If not defined, the endpoint is composed as follows:

```
udp -h addr -p port --interface intf
```

where `addr` is the value of `IceDiscovery.Address`, `port` is the value of `IceDiscovery.Port`, and `intf` is the value of `IceDiscovery.Interface`.

**IceDiscovery.Multicast.AdapterProperty****Synopsis**

```
IceDiscovery.Multicast.AdapterProperty=value
```

**Description**

IceDiscovery creates an object adapter named `IceDiscovery.Multicast` for receiving discovery requests from clients. If not otherwise defined by `IceDiscovery.Multicast.Endpoints`, the endpoint for this object adapter is composed as follows:

```
udp -h addr -p port --interface intf
```

where `addr` is the value of `IceDiscovery.Address`, `port` is the value of `IceDiscovery.Port`, and `intf` is the value of `IceDiscovery.Interface`.

You don't normally need to set [other properties](#) for this object adapter.

**IceDiscovery.Port****Synopsis**

```
IceDiscovery.Port=port
```

**Description**

Specifies the multicast port to use for sending or receiving multicast requests. If not set, the default value is 4061.

**IceDiscovery.Reply.AdapterProperty****Synopsis**

```
IceDiscovery.Reply.AdapterProperty=value
```

**Description**

IceDiscovery creates an object adapter named `IceDiscovery.Reply` for receiving replies to [multicast requests](#). If not otherwise defined

by `IceDiscovery.Reply.Endpoints`, the endpoint for this object adapter is composed as follows:

```
udp --interface intf
```

where *intf* is the value of `IceDiscovery.Interface`. A fixed port is not necessary for this endpoint.

You don't normally need to set [other properties](#) for this object adapter.

## IceDiscovery.RetryCount

### Synopsis

```
IceDiscovery.RetryCount=num
```

### Description

Specifies the maximum number of times that the plug-in will retry sending UDP multicast requests before giving up. The `IceDiscovery.Timeout` property determines how long the plug-in waits for a reply before trying again. If not defined, the default retry count is 3.

## IceDiscovery.Timeout

### Synopsis

```
IceDiscovery.Timeout=num
```

### Description

Specifies the time interval in milliseconds to wait for replies to UDP multicast requests. If no server replies during this time interval, the client will retry the request the number of times specified by `IceDiscovery.RetryCount`. If not defined, the default timeout is 300.

## IceGrid.\*

On this page:

- IceGrid.InstanceName
- IceGrid.Node.AdapterProperty
- IceGrid.Node.AllowEndpointsOverride
- IceGrid.Node.AllowRunningServersAsRoot
- IceGrid.Node.CollocateRegistry
- IceGrid.Node.Data
- IceGrid.Node.DisableOnFailure
- IceGrid.Node.Name
- IceGrid.Node.Output
- IceGrid.Node.PrintServersReady
- IceGrid.Node.ProcessorSocketCount
- IceGrid.Node.PropertiesOverride
- IceGrid.Node.RedirectErrToOut
- IceGrid.Node.Trace.Activator
- IceGrid.Node.Trace.Adapter
- IceGrid.Node.Trace.Patch
- IceGrid.Node.Trace.Replica
- IceGrid.Node.Trace.Server
- IceGrid.Node.UserAccountMapper
- IceGrid.Node.UserAccounts
- IceGrid.Node.WaitTime
- IceGrid.Registry.AdminCryptPasswords
- IceGrid.Registry.AdminPermissionsVerifier
- IceGrid.Registry.AdminSessionFilters
- IceGrid.Registry.AdminSessionManager.AdapterProperty
- IceGrid.Registry.AdminSSLPermissionsVerifier
- IceGrid.Registry.Client.AdapterProperty
- IceGrid.Registry.CryptPasswords
- IceGrid.Registry.Data
- IceGrid.Registry.DefaultTemplates
- IceGrid.Registry.Discovery.AdapterProperty
- IceGrid.Registry.Discovery.Address
- IceGrid.Registry.Discovery.Enabled
- IceGrid.Registry.Discovery.Interface
- IceGrid.Registry.Discovery.Port
- IceGrid.Registry.DynamicRegistration
- IceGrid.Registry.Internal.AdapterProperty
- IceGrid.Registry.NodeSessionTimeout
- IceGrid.Registry.PermissionsVerifier
- IceGrid.Registry.ReplicaName
- IceGrid.Registry.ReplicaSessionTimeout
- IceGrid.Registry.Server.AdapterProperty
- IceGrid.Registry.SessionFilters
- IceGrid.Registry.SessionManager.AdapterProperty
- IceGrid.Registry.SessionTimeout
- IceGrid.Registry.SSLPermissionsVerifier
- IceGrid.Registry.Trace.Adapter
- IceGrid.Registry.Trace.Application
- IceGrid.Registry.Trace.Locator
- IceGrid.Registry.Trace.Node
- IceGrid.Registry.Trace.Object
- IceGrid.Registry.Trace.Patch
- IceGrid.Registry.Trace.Replica
- IceGrid.Registry.Trace.Server
- IceGrid.Registry.Trace.Session
- IceGrid.Registry.UserAccounts

### IceGrid.InstanceName

#### Synopsis

IceGrid.InstanceName=*name*

**Description**

Specifies an alternate identity category for the well-known IceGrid objects. If defined, the identities of the IceGrid objects become:

```
name/AdminSessionManager
name/AdminSessionManager-replica
name/AdminSSLSessionManager
name/AdminSSLSessionManager-replica
name/NullPermissionsVerifier
name/NullSSLPermissionsVerifier
name/Locator
name/Query
name/Registry
name/Registry-replica
name/RegistryUserAccountMapper
name/RegistryUserAccountMapper-replica
name/SessionManager
name/SSLSessionManager
```

If not specified, the default identity category is IceGrid.

**IceGrid.Node.AdapterProperty****Synopsis**

```
IceGrid.Node.AdapterProperty=value
```

**Description**

An IceGrid node uses the adapter name `IceGrid.Node` for the object adapter that the registry contacts to communicate with the node. Therefore, [adapter properties](#) can be used to configure this adapter.

**IceGrid.Node.AllowEndpointsOverride****Synopsis**

```
IceGrid.Node.AllowEndpointsOverride=num
```

If *num* is set to a non-zero value, an IceGrid node permits servers to override previously set endpoints even if the server is active. Setting this property to a non-zero value is necessary if the servers managed by the node use the object adapter operation `refreshPublishedEndpoints`. The default value of *num* is zero.

**IceGrid.Node.AllowRunningServersAsRoot****Synopsis**

```
IceGrid.Node.AllowRunningServersAsRoot=num
```

If *num* is set to a non-zero value, an IceGrid node will permit servers started by the node to run with super-user privileges. Note that you should not set this property unless the node uses a secure endpoint; otherwise, clients can start arbitrary processes with super-user privileges on the node's machine.

The default value of *num* is zero.

**IceGrid.Node.CollocateRegistry****Synopsis**

```
IceGrid.Node.CollocateRegistry=num
```

### **Description**

If *num* is set to a value larger than zero, the `node` collocates the IceGrid registry.

The collocated registry is configured with the same properties as the standalone IceGrid registry.

## **IceGrid.Node.Data**

### **Synopsis**

```
IceGrid.Node.Data=path
```

### **Description**

Defines the path of the IceGrid node `data directory`. The node creates `distrib`, `servers`, and `tmp` subdirectories in this directory if they do not already exist. The `distrib` directory contains `distribution` files downloaded by the node from an IcePatch2 server. The `servers` directory contains configuration data for each `deployed server`. The `tmp` directory holds temporary files.

## **IceGrid.Node.DisableOnFailure**

### **Synopsis**

```
IceGrid.Node.DisableOnFailure=num
```

### **Description**

The node considers a server to have terminated improperly if it has a non-zero exit code or if it exits due to one of the signals `SIGABRT`, `SIGBUS`, `SIGILL`, `SIGFPE`, or `SIGSEGV`. The node marks such a server as disabled if *num* is a non-zero value; a `disabled server` cannot be activated on demand. For values of *num* greater than zero, the server is disabled for *num* seconds. If *num* is a negative value, the server is disabled indefinitely, or until it is explicitly enabled or started via an administrative action. The default value is zero, meaning the node does not disable servers in this situation.

## **IceGrid.Node.Name**

### **Synopsis**

```
IceGrid.Node.Name=name
```

### **Description**

Defines the *name* of the IceGrid node. All nodes using the same registry must have unique names; a node refuses to start if there is a node with the same name running already. This property must be defined for each node.

## **IceGrid.Node.Output**

### **Synopsis**

```
IceGrid.Node.Output=path
```

### **Description**

Defines the path of the IceGrid node output directory. If set, the node redirects the `stdout` and `stderr` output of the started servers to files named `server.out` and `server.err` in this directory. Otherwise, the started servers share the `stdout` and `stderr` of the node's process.

## **IceGrid.Node.PrintServersReady**

**Synopsis**

```
IceGrid.Node.PrintServersReady=token
```

**Description**

The IceGrid node prints "*token* ready" on standard output after all the servers managed by the node are ready. This is useful for scripts that wish to wait until all servers have been started and are ready for use.

**IceGrid.Node.ProcessorSocketCount****Synopsis**

```
IceGrid.Node.ProcessorSocketCount=num
```

**Description**

This property sets the number of processor sockets. This value is reported by the `icegridadmin node sockets` command. On Windows Vista (or later), Windows Server 2008 (or later), and Linux systems, the number of processor sockets is set automatically by the Ice run time. On other systems, the run time cannot obtain the socket count from the operating system; you can use this property to set the number of processor sockets manually on such systems.

**IceGrid.Node.PropertiesOverride****Synopsis**

```
IceGrid.Node.PropertiesOverride=overrides
```

**Description**

Defines a list of properties that override the properties defined in server deployment descriptors. For example, in some cases it is desirable to set the property `Ice.Default.Host` for servers, but not in server deployment descriptors. The property definitions must be separated by white space.

**IceGrid.Node.RedirectErrToOut****Synopsis**

```
IceGrid.Node.RedirectErrToOut=num
```

**Description**

If *num* is set to a value larger than zero, the `stderr` of each started server is redirected to the server's `stdout`.

**IceGrid.Node.Trace.Activator****Synopsis**

```
IceGrid.Node.Trace.Activator=num
```

**Description**

The activator trace level:

0	No activator trace (default).
1	Trace process activation, termination.

2	Like 1, but more verbose, including process signaling and more diagnostic messages on process activation.
3	Like 2, but more verbose, including more diagnostic messages on process activation (e.g., path, working directory, and arguments of the activated process).

## IceGrid.Node.Trace.Adapter

### Synopsis

`IceGrid.Node.Trace.Adapter=num`

### Description

The object adapter trace level:

0	No object adapter trace (default).
1	Trace object adapter addition, removal.
2	Like 1, but more verbose, including object adapter activation and deactivation and more diagnostic messages.
3	Like 2, but more verbose, including object adapter transitional state change (for example, "waiting for activation").

## IceGrid.Node.Trace.Patch

### Synopsis

`IceGrid.Node.Trace.Patch=num`

### Description

The patch trace level:

0	No patching trace (default).
1	Show summary of patch progress.
2	Like 1, but more verbose, including download statistics.
3	Like 2, but more verbose, including checksum information.

## IceGrid.Node.Trace.Replica

### Synopsis

`IceGrid.Node.Trace.Replica=num`

### Description

The replica trace level:

0	No replica trace (default).
1	Trace session lifecycle between nodes and replicas.
2	Like 1, but more verbose, including session establishment attempts and failures.
3	Like 2, but more verbose, including keep alive messages sent to the replica.

## IceGrid.Node.Trace.Server

### Synopsis

`IceGrid.Node.Trace.Server=num`

### Description

The server trace level:

0	No server trace (default).
1	Trace server addition, removal.
2	Like 1, but more verbose, including server activation and deactivation, property updates, and more diagnostic messages.
3	Like 2, but more verbose, including server transitional state change (activating and deactivating).

## IceGrid.Node.UserAccountMapper

### Synopsis

`IceGrid.Node.UserAccountMapper=proxy`

### Description

Specifies the proxy of an object that implements the `IceGrid::UserAccountMapper` interface for [customizing](#) the user accounts under which servers are activated. The IceGrid node invokes this proxy to map session identifiers (the user ID for sessions created with a user ID and password, or the distinguished name for sessions created from a secure connection) to user accounts.

As a proxy property, you can configure additional [aspects of the proxy](#) using properties.

## IceGrid.Node.UserAccounts

### Synopsis

`IceGrid.Node.UserAccounts=file`

### Description

Specifies the file name of an IceGrid node user account map file. Each line of the file must contain an identifier and a user account, separated by white space. The identifier will be matched against the client session identifier (the user ID for sessions created with a user ID and password, or the distinguished name for sessions created from a secure connection). This user account map file is used by the node to [map session identifiers to user accounts](#). This property is ignored if `IceGrid.Node.UserAccountMapper` is defined.

## IceGrid.Node.WaitTime

### Synopsis

`IceGrid.Node.WaitTime=num`

### Description

Defines the interval in seconds that IceGrid waits for [server activation and deactivation](#).

If a server is automatically activated and does not register its object adapter endpoints within this time interval, the node assumes there is a problem with the server and returns an empty set of endpoints to the client.

If a server is being gracefully deactivated and IceGrid does not detect the server deactivation during this time interval, IceGrid kills the server.

The default value is 60 seconds.

## IceGrid.Registry.AdminCryptPasswords

### Synopsis

```
IceGrid.Registry.AdminCryptPasswords=file
```

### Description

Specifies the file name of an IceGrid registry [access control list for administrative clients](#). Each line of the file must contain a user name and a password, separated by white space. The password must be a MCF encoded string as described [here](#). If this property is not defined, the default value is `admin-passwords`. This property is ignored if `IceGrid.Registry.AdminPermissionsVerifier` is defined.

## IceGrid.Registry.AdminPermissionsVerifier

### Synopsis

```
IceGrid.Registry.AdminPermissionsVerifier=proxy
```

### Description

Specifies the proxy of an object that implements the `Glacier2::PermissionsVerifier` interface for [controlling access to IceGrid administrative sessions](#). The IceGrid registry invokes this proxy to validate each new administrative session created by a client with the `IceGrid::Registry` interface.

As a proxy property, you can configure additional [aspects of the proxy](#) using properties.

## IceGrid.Registry.AdminSessionFilters

### Synopsis

```
IceGrid.Registry.AdminSessionFilters=num
```

### Description

This property controls whether IceGrid establishes filters for sessions created with the [IceGrid session manager](#). If `num` is set to a value larger than zero, IceGrid establishes these filters, so [Glacier2](#) limits access to the `IceGrid::AdminSession` object and the `IceGrid::Admin` object that is returned by the `getAdmin` operation. If `num` is set to zero, IceGrid does not establish filters, so access to these objects is controlled solely by Glacier2's configuration.

The default value is 1.

## IceGrid.Registry.AdminSessionManager.AdapterProperty

### Synopsis

```
IceGrid.Registry.AdminSessionManager.AdapterProperty=value
```

### Description

The IceGrid registry uses the adapter name `IceGrid.Registry.AdminSessionManager` for the object adapter that processes incoming requests from [IceGrid administrative sessions](#). Therefore, [adapter properties](#) can be used to configure this adapter. (Note any setting of `IceGrid.Registry.AdminSessionManager.AdapterId` is ignored because the registry always provides a direct adapter.)

For security reasons, defining endpoints for this object adapter is optional. If you do define endpoints, they should only be accessible to Glacier2 routers used to create IceGrid administrative sessions.

## IceGrid.Registry.AdminSSLPermissionsVerifier

### Synopsis

```
IceGrid.Registry.AdminSSLPermissionsVerifier=proxy
```

### Description

Specifies the proxy of an object that implements the `Glacier2::SSLPermissionsVerifier` interface for [controlling access to IceGrid administrative sessions](#). The IceGrid registry invokes this proxy to validate each new administrative session created by a client from a secure connection with the `IceGrid::Registry` interface.

As a proxy property, you can configure additional [aspects of the proxy](#) using the properties.

## IceGrid.Registry.Client.AdapterProperty

### Synopsis

```
IceGrid.Registry.Client.AdapterProperty=value
```

### Description

IceGrid uses the adapter name `IceGrid.Registry.Client` for the object adapter that processes incoming requests from clients. Therefore, [adapter properties](#) can be used to configure this adapter. (Note any setting of `IceGrid.Registry.Client.AdapterId` is ignored because the registry always provides a direct adapter.)

Note that `IceGrid.Registry.Client.Endpoints` controls the client endpoint for the registry. The port numbers 4061 (for TCP) and 4062 (for SSL) are reserved for the registry by the [Internet Assigned Numbers Authority \(IANA\)](#).

## IceGrid.Registry.CryptPasswords

### Synopsis

```
IceGrid.Registry.CryptPasswords=file
```

### Description

Specifies the file name of an IceGrid registry [access control list](#). Each line of the file must contain a user name and a password, separated by white space. The password must a MCF encoded string as described [here](#). If this property is not defined, the default value is `passwords`. This property is ignored if `IceGrid.Registry.PermissionsVerifier` is defined.

## IceGrid.Registry.Data

### Synopsis

```
IceGrid.Registry.Data=path
```

### Description

Defines the path of the IceGrid registry [data directory](#). The directory specified in `path` must already exist.

## IceGrid.Registry.DefaultTemplates

### Synopsis

```
IceGrid.Registry.DefaultTemplates=path
```

### Description

Defines the path name of an XML file containing default [template descriptors](#). A sample file named `config/templates.xml` that contains convenient server templates for Ice services is provided in the Ice distribution.

## IceGrid.Registry.Discovery.AdapterProperty

### Synopsis

```
IceGrid.Registry.Discovery.AdapterProperty=value
```

### Description

The IceGrid registry creates an object adapter named `IceGrid.Registry.Discovery` for receiving [multicast discovery queries](#) from clients. If not otherwise defined by `IceGrid.Registry.Discovery.Endpoints`, the endpoint for this object adapter is composed as follows:

```
udp -h addr -p port [--interface intf]
```

where `addr` is the value of `IceGrid.Registry.Discovery.Address`, `port` is the value of `IceGrid.Registry.Discovery.Port`, and `intf` is the value of `IceGrid.Registry.Discovery.Interface`.

You don't normally need to set [other properties](#) for this object adapter.

## IceGrid.Registry.Discovery.Address

### Synopsis

```
IceGrid.Registry.Discovery.Address=addr
```

### Description

Specifies the multicast IP address to use for receiving multicast discovery queries. If not defined, the default value depends on the setting of `Ice.IPv4`: if enabled (the default), IceDiscovery uses the address `239.255.0.1`, otherwise IceDiscovery assumes the application wants to use IPv6 and defaults to the address `ff15::1` instead. This property is used to compose the endpoint of the `IceGrid.Registry.Discovery` object adapter.

## IceGrid.Registry.Discovery.Enabled

### Synopsis

```
IceDiscovery.Enabled=num
```

### Description

If `num` is a value larger than zero, the registry creates the `IceGrid.Registry.Discovery` object adapter and listens for [multicast discovery queries](#). If not defined, the default value is 1. Set this property to zero to disable multicast discovery.

## IceGrid.Registry.Discovery.Interface

### Synopsis

```
IceGrid.Registry.Discovery.Interface=intf
```

### Description

Specifies the IP address of the interface to use for receiving multicast discovery queries. If not defined, the operating system will select a default interface to send and receive the UDP multicast datagrams. This property is used to compose the endpoint of the `IceGrid.Registry.Discovery` object adapter.

## IceGrid.Registry.Discovery.Port

### Synopsis

`IceGrid.Registry.Discovery.Port=port`

### Description

Specifies the multicast port to use for receiving multicast discovery queries. If not set, the default value is 4061. This property is used to compose the endpoint of the `IceGrid.Registry.Discovery` object adapter.

## IceGrid.Registry.DynamicRegistration

### Synopsis

`IceGrid.Registry.DynamicRegistration=num`

### Description

If `num` is set to a value larger than zero, the locator registry does not require Ice servers to preregister object adapters and replica groups, but rather creates them automatically if they do not exist. If this property is not defined, or `num` is set to zero, an attempt to register an unknown object adapter or replica group causes adapter activation to fail with `Ice.NotRegisteredException`. An object adapter registers itself when the `adapter.AdapterId` property is defined. The `adapter.ReplicaGroupId` property identifies the replica group.

## IceGrid.Registry.Internal.AdapterProperty

### Synopsis

`IceGrid.Registry.Internal.AdapterProperty=value`

### Description

The IceGrid registry uses the adapter name `IceGrid.Registry.Internal` for the object adapter that processes incoming requests from nodes and slave replicas. Therefore, `adapter properties` can be used to configure this adapter. (Note any setting of `IceGrid.Registry.Internal.AdapterId` is ignored because the registry always provides a direct adapter.)

## IceGrid.Registry.NodeSessionTimeout

### Synopsis

`IceGrid.Registry.NodeSessionTimeout=num`

### Description

Each IceGrid node establishes a session with the registry that must be refreshed periodically. If a node does not refresh its session within `num` seconds, the node's session is destroyed and the servers deployed on that node become unavailable to new clients. If not specified, the default value is 30 seconds.

## IceGrid.Registry.PermissionsVerifier

### Synopsis

`IceGrid.Registry.PermissionsVerifier=proxy`

### Description

Specifies the proxy of an object that implements the `Glacier2::PermissionsVerifier` interface for [controlling access to IceGrid sessions](#). The IceGrid registry invokes this proxy to validate each new client session created by a client with the `IceGrid::Registry` interface.

As a proxy property, you can configure additional [aspects of the proxy](#) using properties.

## IceGrid.Registry.ReplicaName

### Synopsis

```
IceGrid.Registry.ReplicaName=name
```

### Description

Specifies the name of a [registry replica](#). If not defined, the default value is `Master`, which is the name reserved for the master replica. Each registry replica must have a unique name.

## IceGrid.Registry.ReplicaSessionTimeout

### Synopsis

```
IceGrid.Registry.ReplicaSessionTimeout=num
```

### Description

Each IceGrid [registry replica](#) establishes a session with the master registry that must be refreshed periodically. If a replica does not refresh its session within *num* seconds, the replica's session is destroyed and the replica no longer receives replication information from the master registry. If not specified, the default value is 30 seconds.

## IceGrid.Registry.Server.AdapterProperty

### Synopsis

```
IceGrid.Registry.Server.AdapterProperty=value
```

### Description

The IceGrid registry uses the adapter name `IceGrid.Registry.Server` for the object adapter that processes incoming requests from servers. Therefore, [adapter properties](#) can be used to configure this adapter. (Note any setting of `IceGrid.Registry.Server.AdapterId` is ignored because the registry always provides a direct adapter.)

## IceGrid.Registry.SessionFilters

### Synopsis

```
IceGrid.Registry.SessionFilters=num
```

### Description

This property controls whether IceGrid establishes filters for sessions created with the [IceGrid session manager](#). If *num* is set to a value larger than zero, IceGrid establishes these filters, so Glacier2 limits access to the `IceGrid::Query` and `IceGrid::Session` objects, and to objects and adapters allocated by the session. If *num* is set to zero, IceGrid does not establish filters, so access to objects is controlled solely by Glacier2's configuration.

The default value is 0.

## IceGrid.Registry.SessionManager.AdapterProperty

### Synopsis

`IceGrid.Registry.SessionManager.AdapterProperty=value`

### Description

The IceGrid registry uses the adapter name `IceGrid.Registry.SessionManager` for the object adapter that processes incoming requests from [client sessions](#). Therefore, [adapter properties](#) can be used to configure this adapter. (Note any setting of `IceGrid.Registry.SessionManager.AdapterId` is ignored because the registry always provides a direct adapter.)

For security reasons, defining endpoints for this object adapter is optional. If you do define endpoints, they should only be accessible to Glacier2 routers used to create IceGrid client sessions.

## IceGrid.Registry.SessionTimeout

### Synopsis

`IceGrid.Registry.SessionTimeout=num`

### Description

IceGrid [clients](#) or [administrative clients](#) might establish a session with the registry. This session must be refreshed periodically. If the client does not refresh its session within `num` seconds, the session is destroyed. If not specified, the default value is 30 seconds.

## IceGrid.Registry.SSLPermissionsVerifier

### Synopsis

`IceGrid.Registry.SSLPermissionsVerifier=proxy`

### Description

Specifies the proxy of an object that implements the `Glacier2::SSLPermissionsVerifier` interface for [controlling access to IceGrid sessions](#). The IceGrid registry invokes this proxy to validate each new client session created by a client from a secure connection with the `IceGrid::Registry` interface.

As a proxy property, you can configure additional [aspects of the proxy](#) using properties.

## IceGrid.Registry.Trace.Adapter

### Synopsis

`IceGrid.Registry.Trace.Adapter=num`

### Description

The object adapter trace level:

0	No object adapter trace (default).
1	Trace object adapter registration, removal, and replication.

## IceGrid.Registry.Trace.Application

### Synopsis

`IceGrid.Registry.Trace.Application=num`

**Description**

The application trace level:

0	No application trace (default).
1	Trace application addition, update, and removal.

**IceGrid.Registry.Trace.Locator****Synopsis**

`IceGrid.Registry.Trace.Locator=num`

**Description**

The locator and locator registry trace level:

0	No locator trace (default).
1	Trace failures to locate an adapter or object, and failures to register adapter endpoints.
2	Like 1, but more verbose, including registration of adapter endpoints.

**IceGrid.Registry.Trace.Node****Synopsis**

`IceGrid.Registry.Trace.Node=num`

**Description**

The node trace level:

0	No node trace (default).
1	Trace node registration, removal.
2	Like 1, but more verbose, including load statistics.

**IceGrid.Registry.Trace.Object****Synopsis**

`IceGrid.Registry.Trace.Object=num`

**Description**

The object trace level:

0	No object trace (default).
1	Trace object registration, removal.

**IceGrid.Registry.Trace.Patch****Synopsis**

`IceGrid.Registry.Trace.Patch=num`

### **Description**

The patch trace level:

0	No patching trace (default).
1	Show summary of patch progress.

## **IceGrid.Registry.Trace.Replica**

### **Synopsis**

`IceGrid.Registry.Trace.Replica=num`

### **Description**

The server trace level:

0	No server trace (default).
1	Trace session lifecycle between master replica and slaves.

## **IceGrid.Registry.Trace.Server**

### **Synopsis**

`IceGrid.Registry.Trace.Server=num`

### **Description**

The server trace level:

0	No server trace (default).
1	Trace the addition and removal of servers in the Registry database.

## **IceGrid.Registry.Trace.Session**

### **Synopsis**

`IceGrid.Registry.Trace.Session=num`

### **Description**

The session trace level:

0	No client or admin session trace (default).
1	Trace client or admin session registration, removal.
2	Like 1, but more verbose, includes keep alive messages.

## **IceGrid.Registry.UserAccounts**

### **Synopsis**

`IceGrid.Registry.UserAccounts=file`

**Description**

Specifies the file name of an IceGrid registry user account map file. Each line of the file must contain an identifier and a user account, separated by white space. The identifier will be matched against the client session identifier (the user ID for sessions created with a user ID and password, or the distinguished name for sessions created from a secure connection). This user account map file is used by IceGrid nodes to map session identifiers to user accounts if the nodes' `IceGrid.Node.UserAccountMapper` property is set to the proxy `IceGrid/RegistryUserAccountMapper`.

## IceGridAdmin.\*

On this page:

- `IceGridAdmin.AuthenticateUsingSSL`
- `IceGridAdmin.Discovery.Address`
- `IceGridAdmin.Discovery.Interface`
- `IceGridAdmin.Discovery.Lookup`
- `IceGridAdmin.Discovery.Reply.AdapterProperty`
- `IceGridAdmin.Host`
- `IceGridAdmin.InstanceName`
- `IceGridAdmin.Password`
- `IceGridAdmin.Port`
- `IceGridAdmin.Replica`
- `IceGridAdmin.Trace.Observers`
- `IceGridAdmin.Trace.SaveToRegistry`
- `IceGridAdmin.Username`

### IceGridAdmin.AuthenticateUsingSSL

#### Synopsis

`IceGridAdmin.AuthenticateUsingSSL=num`

#### Description

If `num` is a value greater than zero, `icegridadmin` uses SSL authentication when establishing its session with the IceGrid registry. If not defined or the value is zero, `icegridadmin` uses user name and password authentication.

### IceGridAdmin.Discovery.Address

#### Synopsis

`IceGridAdmin.Discovery.Address=addr`

#### Description

Specifies the multicast IP address to use for sending [multicast discovery queries](#). If not defined, the default value depends on the setting of `Ice.IPv4`: if enabled (the default), the client uses the address `239.255.0.1`, otherwise the client assumes it should use IPv6 and defaults to the address `ff15::1` instead. This property is used to compose the value of `IceGridAdmin.Discovery.Lookup`.

### IceGridAdmin.Discovery.Interface

#### Synopsis

`IceGridAdmin.Discovery.Interface=intf`

#### Description

Specifies the IP address of the interface to use for sending [multicast discovery queries](#). If not defined, the operating system will select a default interface to send the UDP multicast datagrams. This property is used to compose the value of `IceGridAdmin.Discovery.Lookup`.

### IceGridAdmin.Discovery.Lookup

#### Synopsis

`IceGridAdmin.Discovery.Lookup=endpoint`

**Description**

Specifies the endpoint that the client uses to send [multicast discovery queries](#). If not defined, the endpoint is composed as follows:

```
udp -h addr -p port [--interface intf]
```

where *addr* is the value of `IceGridAdmin.Discovery.Address`, *port* is the value of `IceGridAdmin.Port`, and *intf* is the value of `IceGridAdmin.Discovery.Interface`.

**IceGridAdmin.Discovery.Reply.AdapterProperty****Synopsis**

```
IceGridAdmin.Discovery.Reply.AdapterProperty=value
```

**Description**

The client creates an object adapter named `IceGridAdmin.Discovery.Reply` for receiving replies to [multicast discovery queries](#). If not otherwise defined by `IceGridAdmin.Discovery.Reply.Endpoints`, the endpoint for this object adapter is composed as follows:

```
udp [--interface intf]
```

where *intf* is the value of `IceGridAdmin.Discovery.Interface`. A fixed port is not necessary for this endpoint.

You don't normally need to set [other properties](#) for this object adapter.

**IceGridAdmin.Host****Synopsis**

```
IceGridAdmin.Host=host
```

**Description**

When used together with `IceGridAdmin.Port`, `icegridadmin` connects directly to the target registry at the specified host and port.

**IceGridAdmin.InstanceName****Synopsis**

```
IceGridAdmin.InstanceName=name
```

**Description**

Specifies the name of an IceGrid instance to which `icegridadmin` will connect.

When using [multicast discovery](#), you can define this property to limit your discovery results only to those locators deployed for the given instance, in case you have multiple unrelated IceGrid instances deployed that use the same multicast address and port.

**IceGridAdmin.Password****Synopsis**

```
IceGridAdmin.Password=password
```

**Description**

Specifies the password that `icegridadmin` should use when authenticating its session with the IceGrid registry. For security reasons you may prefer not to define a password in a plain-text configuration property, in which case you should omit this property and allow `icegridadmin` to prompt you for it interactively. This property is ignored when SSL authentication is enabled via `IceGridAdmin.AuthenticateUsi`

ngSSL.

## IceGridAdmin.Port

### Synopsis

`IceGridAdmin.Port=port`

### Description

When used together with `IceGridAdmin.Host`, `icegridadmin` connects directly to the target registry at the specified host and port.

When using [multicast discovery](#), this property specifies the port to use for sending multicast discovery queries. This property is also used to compose the value of `IceGridAdmin.Discovery.Lookup`.

If not set, the default value is 4061.

## IceGridAdmin.Replica

### Synopsis

`IceGridAdmin.Replica=name`

### Description

Specifies the name of the [registry replica](#) that `icegridadmin` should contact. If not defined, the default value is `Master`.

## IceGridAdmin.Trace.Observers

### Synopsis

`IceGridAdmin.Trace.Observers=num`

### Description

If `num` is a value greater than zero, the IceGrid graphical administrative client displays trace information about the observer callbacks it receives from the registry. If not defined, the default value is zero.

## IceGridAdmin.Trace.SaveToRegistry

### Synopsis

`IceGridAdmin.Trace.SaveToRegistry=num`

### Description

If `num` is a value greater than zero, the IceGrid graphical administrative client displays trace information about the modifications it commits to the registry. If not defined, the default value is zero.

## IceGridAdmin.Username

### Synopsis

`IceGridAdmin.Username=name`

### Description

Specifies the username that `icegridadmin` should use when authenticating its session with the IceGrid registry. This property is ignored when SSL authentication is enabled via `IceGridAdmin.AuthenticateUsingSSL`.

## IceLocatorDiscovery.\*

This page describes the properties supported by the IceLocatorDiscovery plug-in.

On this page:

- [IceLocatorDiscovery.Address](#)
- [IceLocatorDiscovery.InstanceName](#)
- [IceLocatorDiscovery.Interface](#)
- [IceLocatorDiscovery.Locator.AdapterProperty](#)
- [IceLocatorDiscovery.Lookup](#)
- [IceLocatorDiscovery.Port](#)
- [IceLocatorDiscovery.Reply.AdapterProperty](#)
- [IceLocatorDiscovery.RetryCount](#)
- [IceLocatorDiscovery.RetryDelay](#)
- [IceLocatorDiscovery.Timeout](#)

### IceLocatorDiscovery.Address

#### Synopsis

`IceLocatorDiscovery.Address=addr`

#### Description

Specifies the multicast IP address to use for sending multicast queries. If not defined, the default value depends on other property settings:

- If [Ice.PreferIPv6Address](#) is enabled or [Ice.IPv4](#) is disabled, IceLocatorDiscovery uses the IPv6 address `ff15::1`
- Otherwise IceLocatorDiscovery uses `239.255.0.1`

### IceLocatorDiscovery.InstanceName

#### Synopsis

`IceLocatorDiscovery.InstanceName=name`

#### Description

Specifies the name of a locator instance. If you have multiple unrelated locators deployed that use the same multicast address and port, you can define this property to limit your discovery results only to those locators deployed for the given instance. If not defined, the plug-in adopts the instance name of the first locator to respond to a query; if a subsequent query discovers a locator with a different instance name, the plug-in logs a message and ignores the result.

### IceLocatorDiscovery.Interface

#### Synopsis

`IceLocatorDiscovery.Interface=intf`

#### Description

Specifies the IP address of the interface to use for sending multicast queries. If not defined, the operating system will select a default interface to send the UDP multicast datagrams.

### IceLocatorDiscovery.Locator.AdapterProperty

#### Synopsis

`IceLocatorDiscovery.Locator.AdapterProperty=value`

**Description**

IceLocatorDiscovery creates an object adapter named `IceLocatorDiscovery.Locator`, therefore all of the [object adapter properties](#) can be set.

You don't normally need to set properties for this object adapter.

**IceLocatorDiscovery.Lookup****Synopsis**

```
IceLocatorDiscovery.Lookup=endpoint
```

**Description**

Specifies the multicast endpoint that a client uses to send discovery queries. If not defined, the endpoint is composed as follows:

```
udp -h addr -p port --interface intf
```

where *addr* is the value of `IceLocatorDiscovery.Address`, *port* is the value of `IceLocatorDiscovery.Port`, and *intf* is the value of `IceLocatorDiscovery.Interface`.

**IceLocatorDiscovery.Port****Synopsis**

```
IceLocatorDiscovery.Port=port
```

**Description**

Specifies the multicast port to use for sending multicast queries. If not set, the default value is 4061.

**IceLocatorDiscovery.Reply.AdapterProperty****Synopsis**

```
IceLocatorDiscovery.Reply.AdapterProperty=value
```

**Description**

IceLocatorDiscovery creates an object adapter named `IceLocatorDiscovery.Reply` for receiving replies to [multicast discovery queries](#). If not otherwise defined by `IceLocatorDiscovery.Reply.Endpoints`, the endpoint for this object adapter is composed as follows:

```
udp --interface intf
```

where *intf* is the value of `IceLocatorDiscovery.Interface`. A fixed port is not necessary for this endpoint.

You don't normally need to set [other properties](#) for this object adapter.

**IceLocatorDiscovery.RetryCount****Synopsis**

```
IceLocatorDiscovery.RetryCount=num
```

**Description**

Specifies the maximum number of times that the plug-in will retry sending UDP multicast queries before giving up. The `IceLocatorDiscovery.Timeout` property determines how long the plug-in waits for a reply before trying again. If not defined, the default retry count is 3.

## IceLocatorDiscovery.RetryDelay

### Synopsis

`IceLocatorDiscovery.RetryDelay=num`

### Description

If the plug-in fails to receive any responses to a query after retrying the number of times specified by `IceLocatorDiscovery.RetryCount`, the plug-in waits at least `num` milliseconds before starting another round of query attempts. If not defined, the default value is 2000.

## IceLocatorDiscovery.Timeout

### Synopsis

`IceLocatorDiscovery.Timeout=num`

### Description

Specifies the time interval in milliseconds to wait for replies to UDP multicast queries. If no server replies during this time interval, the client will retry the request the number of times specified by `IceLocatorDiscovery.RetryCount`. If not defined, the default timeout is 300.

## IceMX.Metrics.\*

On this page:

- [IceMX.Metrics.view.Accept.attribute](#)
- [IceMX.Metrics.view.Disabled](#)
- [IceMX.Metrics.view.GroupBy](#)
- [IceMX.Metrics.view.Reject.attribute](#)
- [IceMX.Metrics.view.RetainDetached](#)

Metrics view are configured with the properties described below. The *view* below can be replaced with one of the following:

- [IceMX.Metrics.view-name](#)
- [IceMX.Metrics.view-name.Map.map-name](#)
- [IceMX.Metrics.view-name.Map.map-name.Map.submap-name](#)

If a view is defined without Map properties, the view will contain all the metrics map known by the [Metrics facet](#). If a view defines one or more map properties it will only contain these maps.

For a list of supported maps see:

- [The Metrics Facet](#)
- [Glacier2 Metrics](#)
- [IceStorm Metrics](#)

### IceMX.Metrics.view.Accept.attribute

#### Synopsis

```
IceMX.Metrics.view.Accept.attribute=regex
```

#### Description

This property defines a rule to accept the monitoring of an instrumented object or operation based on the value of one of its attribute. If the *attribute* matches the specified *regex* and if it satisfies other *Accept* and *Reject* filters the instrumented object or operation will be monitored.

For example, to accept monitoring instrumented objects or operations which are from the object adapter named "MyAdapter", you can setup the following accept property:

- `IceMX.Metrics.MyView.Accept.parent=MyAdapter`

### IceMX.Metrics.view.Disabled

#### Synopsis

```
IceMX.Metrics.view.Disabled=num
```

#### Description

If *num* is set to a value larger than zero, the metrics view or the map is disabled. This property is useful to pre-configure a view or map. The view can be disabled initially to not incur overhead and enabled only when needed at runtime.

### IceMX.Metrics.view.GroupBy

#### Synopsis

```
IceMX.Metrics.view.GroupBy=delimited attributes
```

#### Description

This property defines how metrics are grouped and how the ID of each metrics object is created. The grouping is based on attributes specific

to the instrumented object or operation. For example, you can group the invocation metrics by operation name or proxy identity. All the invocations with the same operation name or proxy identity will record metrics using the same metrics object. You can specify several attributes to group metrics based on multiple attributes. You must delimit the attributes with delimiters when specify the value of the `GroupBy` property. A delimiter is any character which is not an alpha numeric or the dot character. Attributes which can be used to specify the value of this property are defined in relevant section of the Ice manual. Here are some examples of `GroupBy` properties.

- `IceMX.Metrics.MyView.GroupBy=operation`
- `IceMX.Metrics.MyView.GroupBy=identity [operation]`
- `IceMX.Metrics.MyView.GroupBy=remoteHost:remotePort`

## IceMX.Metrics.view.Reject.attribute

### Synopsis

`IceMX.Metrics.view.Reject.attribute=regex`

### Description

This property defines a rule to accept the monitoring of an instrumented object or operation based on the value of one of its attribute. If the `attribute` matches the specified `regex` and if it satisfies other `Accept` and `Reject` filters the instrumented object or operation will be monitored.

For example, to reject monitoring instrumented objects or operations which are from the object adapter named "Ice.Admin", you can setup the following reject property:

- `IceMX.Metrics.MyView.Reject.parent=Ice\.Admin`

## IceMX.Metrics.view.RetainDetached

### Synopsis

`IceMX.Metrics.view.RetainedDetached=num`

### Description

If `num` is set to a value larger than zero, up to `num` metrics object whose `current` value is 0 will be kept in memory by the metrics map. This is useful to prevent indefinite memory growth if the monitoring of an instrumented object or operation creates a unique metrics object, only the last `num` metrics object will be kept in memory. The default value is 10, meaning that at most ten metrics object with a `current` value equal to 0 will be retained by the metrics map.

## IcePatch2.\*

On this page:

- [IcePatch2.AdapterProperty](#)
- [IcePatch2.Directory](#)
- [IcePatch2.InstanceName](#)

### IcePatch2.AdapterProperty

#### Synopsis

```
IcePatch2.AdapterProperty=value
```

#### Description

IcePatch2 uses the adapter name `IcePatch2` for the server. Therefore, [adapter properties](#) can be used to configure this adapter.

### IcePatch2.Directory

#### Synopsis

```
IcePatch2.Directory=dir
```

#### Description

The IcePatch2 server uses this property to determine the data directory if no data directory is specified on the command line.

This property is also used by IcePatch2 clients to determine the local data directory.

### IcePatch2.InstanceName

#### Synopsis

```
IcePatch2.InstanceName=name
```

#### Description

Specifies the identity category for well-known IcePatch2 [objects](#). If defined, the identity of the `IcePatch2::Admin` interface becomes `name/admin` and the identity of the `IcePatch2::FileServer` interface becomes `name/server`.

If not defined, the default value is `IcePatch2`.

## IcePatch2Client.\*

On this page:

- [IcePatch2Client.ChunkSize](#)
- [IcePatch2Client.Directory](#)
- [IcePatch2Client.Proxy](#)
- [IcePatch2Client.Remove](#)
- [IcePatch2Client.Thorough](#)

### IcePatch2Client.ChunkSize

#### Synopsis

`IcePatch2Client.ChunkSize=kilobytes`

#### Description

The IcePatch2 client uses this property to determine how many kilobytes are retrieved with each call to `getFileCompressed`.

The default value is 100.

### IcePatch2Client.Directory

#### Synopsis

`IcePatch2Client.Directory=dir`

#### Description

The IcePatch2 client uses this property to determine the local data directory.

### IcePatch2Client.Proxy

#### Synopsis

`IcePatch2Client.Proxy=proxy`

#### Description

The IcePatch2 client uses this property to locate the IcePatch2 server.

### IcePatch2Client.Remove

#### Synopsis

`IcePatch2Client.Remove=num`

#### Description

This property determines whether IcePatch2 clients delete files that exist locally, but not on the server. A negative or zero value prevents removal of files. A value of 1 enables removal and causes the client to halt with an error if removal of a file fails. A value of 2 or greater also enables removal, but causes the client to silently ignore errors during removal.

The default value is 1.

## IcePatch2Client.Thorough

### **Synopsis**

`IcePatch2Client.Thorough=num`

### **Description**

This property determines whether IcePatch2 clients recompute checksums. Any value greater than zero is interpreted as true. The default value is 0 (false).

## IceSSL Property Overview

The IceSSL implementations for our supported platforms use many of the same configuration properties. However, there are some properties that are specific to certain platforms or languages. For properties with such limitations, we list the supported platforms or underlying SSL libraries in the synopsis and provide additional platform-specific notes if necessary. You'll see the following platforms, languages and SSL libraries listed in the property reference:

- SChannel (C++ on Windows)
- SecureTransport (C++ on OS X)
- OpenSSL (C++ on Linux)
- Java
- .NET
- iOS

A property is supported by all platforms if no limitations are mentioned.

Finally, note that Ice for Objective-C and the Ice extensions for Python, Ruby and PHP use IceSSL for C++, therefore they use the IceSSL properties for SChannel, SecureTransport or OpenSSL as appropriate for the target platform.

### JavaScript and Universal Windows (UWP) Apps

These IceSSL properties have no effect on JavaScript and UWP apps.

## IceSSL.Alias

### Synopsis

`IceSSL.Alias=alias` (Java)

### Description

Selects a particular certificate from the key store specified by `IceSSL.Keystore`. The certificate identified by `alias` is presented to the peer request during authentication.

## IceSSL.CAs

### Synopsis

`IceSSL.CAs=path` (SChannel, SecureTransport, OpenSSL, .NET, iOS)

### Description

Specifies the path name of a file containing the certificates of trusted certificate authorities (CAs).

If you wish to use the CA certificates bundled with your platform, leave this property unset and enable `IceSSL.UsePlatformCAs`.

### Platform Notes

#### SChannel, SecureTransport, .NET

The file can be encoded using the DER or PEM formats. When using PEM, the file can contain multiple certificates.

IceSSL attempts to locate `path` as specified; if the given path is relative but does not exist, IceSSL also attempts to locate `path` relative to the default directory defined by `IceSSL.DefaultDir`.

#### OpenSSL

The file must be encoded using the PEM format and can contain multiple certificates. If `path` refers to a directory, the directory must be prepared in advance using the OpenSSL utility `c_rehash`.

IceSSL attempts to locate `path` as specified; if the given path is relative but does not exist, IceSSL also attempts to locate `path` relative to the default directory defined by `IceSSL.DefaultDir`.

#### iOS

The certificate must be encoded using the DER format.

If `IceSSL.DefaultDir` is also defined, IceSSL attempts to open the specified CA certificate file as `Resources/DefaultDir/path` in the application's resource bundle and as `DefaultDir/path` in the file system.

If `IceSSL.DefaultDir` is not defined, IceSSL attempts to open the specified CA certificate file as `Resources/path` in the application's resource bundle and as `path` in the file system.

If this property is not defined, IceSSL looks for suitable CA certificates in the user's keychains and in the system keychain.

#### Java

See `IceSSL.Truststore`.

## IceSSL.CertFile

### Synopsis

IceSSL.CertFile=*file* (SecureTransport, .NET, iOS)  
 IceSSL.CertFile=*file*[;*file*] (SChannel)  
 IceSSL.CertFile=*file*[:*file*] (OpenSSL)

### Description

Specifies a file that contains the program's certificate and the corresponding private key. The file name may be specified relative to the default directory defined by `IceSSL.DefaultDir`.

### Platform Notes

#### SChannel

The file must use the PFX (PKCS#12) format and contain the certificate and its private key. If a password is required to load the file, the application must either install a [password handler](#) or supply the password using `IceSSL.Password`, otherwise IceSSL will reject the certificate.

This property accepts certificates for both RSA and DSA. To specify both certificates, separate the file names using the platform's path separator character.

IceSSL attempts to locate *file* as specified; if the given path is relative but does not exist, IceSSL also attempts to locate *file* relative to the default directory defined by `IceSSL.DefaultDir`.

#### SecureTransport

The file must use the PFX (PKCS#12) format and contain the certificate and its private key. If a password is required to load the file, OS X will use its default graphical password prompt unless the application has installed a [password handler](#) or supplied the password using `IceSSL.L.Password`. Define `IceSSL.Keychain` to import this certificate into the specified keychain.

IceSSL attempts to locate *file* as specified; if the given path is relative but does not exist, IceSSL also attempts to locate *file* relative to the default directory defined by `IceSSL.DefaultDir`.

#### OpenSSL

The file must use the PFX (PKCS#12) format and contain the certificate and its private key. If a password is required to load the file, OpenSSL will prompt the user at the terminal unless the application has installed a [password handler](#) or supplied the password using `IceSSL.L.Password`.

This property accepts certificates for both RSA and DSA. To specify both certificates, separate the file names using the platform's path separator character.

IceSSL attempts to locate *file* as specified; if the given path is relative but does not exist, IceSSL also attempts to locate *file* relative to the default directory defined by `IceSSL.DefaultDir`.

#### .NET

The file must use the PFX (PKCS#12) format and contain the certificate and its private key. The password for the file must be supplied using `IceSSL.Password`.

IceSSL attempts to locate *file* as specified; if the given path is relative but does not exist, IceSSL also attempts to locate *file* relative to the default directory defined by `IceSSL.DefaultDir`.

#### iOS

The file must use the PFX (PKCS#12) format and contain the certificate and its private key. The password for the file must be supplied using `IceSSL.Password`. The certificate is imported into the keychain identified by the `IceSSL.Keychain` property.

If `IceSSL.DefaultDir` is also defined, IceSSL attempts to open the specified certificate file as `Resources/DefaultDir/file` in the application's resource bundle and as `DefaultDir/file` in the file system.

If `IceSSL.DefaultDir` is not defined, IceSSL attempts to open the specified certificate file as `Resources/file` in the application's resource bundle and as *file* in the file system.

#### Java

See `IceSSL.Keystore`.

## IceSSL.CertStore

### Synopsis

IceSSL.CertStore=*name* (SChannel, .NET)

### Description

Specifies the name of a certificate store to use when locating certificates via [IceSSL.FindCert](#). Legal values for *name* include `AddressBook`, `AuthRoot`, `CertificateAuthority`, `Disallowed`, `My`, `Root`, `TrustedPeople`, and `TrustedPublisher`. You can also use an arbitrary value for *name*.

If not specified, the default value is `My`.

## IceSSL.CertStoreLocation

### Synopsis

IceSSL.CertStoreLocation=`CurrentUser` | `LocalMachine` (SChannel, .NET)

### Description

Specifies the location of a certificate store to use when locating certificates via [IceSSL.FindCert](#). If not specified, the default value is `CurrentUser`.

An Ice program running as a Windows service will typically need to set this property to `LocalMachine`.

## IceSSL.CertVerifier

### Synopsis

IceSSL.CertVerifier=*classname* (Java, .NET)

### Description

Specifies the name of a Java or .NET class that implements the `IceSSL.CertificateVerifier` interface for performing application-defined [certificate verification](#).

### Platform Notes

*SChannel*, *SecureTransport*, *OpenSSL*

C++ applications can install a [certificate verifier programmatically](#).

## IceSSL.CheckCertName

### Synopsis

IceSSL.CheckCertName=*num*

### Description

If *num* is a value greater than zero, IceSSL attempts to match the server's host name as specified in the proxy endpoint against the common name component of the server certificate's subject name. If no match is found, IceSSL attempts to match the host name against the DNS and IP address fields of the server certificate's subject alternative name. The search does not issue any DNS queries but simply performs a case-insensitive string match. The server's certificate is accepted if its common name or any of its DNS or IP addresses matches the host

name in the proxy endpoint. IceSSL skips this validation step if the server does not supply a certificate, or if the proxy endpoint does not include a host name and `Ice.Default.Host` is not defined. This property has no effect on a server's validation of a client's certificate. If no match is found, IceSSL aborts the connection attempt and raises an exception. If not defined, the default value is zero.

## IceSSL.CheckCRL

### Synopsis

`IceSSL.CheckCRL=num` (.NET)

### Description

If *num* is a value greater than zero, IceSSL checks the certificate revocation list (CRL) to determine if the peer's certificate has been revoked. The value for *num* determines the resulting behavior:

0	Disables CRL checking.
1	If a certificate is revoked, IceSSL aborts the connection, logs a message and raises an exception. If a certificate's revocation status is unknown, IceSSL logs a message but accepts the certificate.
2	If a certificate is revoked or its revocation status is unknown, IceSSL aborts the connection, logs a message and raises an exception.

The `IceSSL.Trace.Security` property must be set to a non-zero value to see CRL-related log messages. If `IceSSL.CheckCRL` is not defined, the default value is zero.

## IceSSL.Ciphers

### Synopsis

`IceSSL.Ciphers=ciphers` (SChannel, SecureTransport, OpenSSL, Java)

### Description

Specifies the cipher suites that IceSSL is allowed to negotiate. A cipher suite is a set of algorithms that satisfies the four requirements for establishing a secure connection: signing and authentication, key exchange, secure hashing, and encryption. Some algorithms satisfy more than one requirement, and there are many possible combinations.

If not specified, the plug-in uses the security provider's default cipher suites. Enable `IceSSL.Trace.Security` and carefully review the application's log output to determine which cipher suites are enabled by default, or to verify your cipher suite configuration.

### Platform Notes

#### SChannel

The value of this property is a whitespace-separated list that can include any of the following:

- 3DES
- AES\_128
- AES\_256
- DES
- RC2
- RC4

For example, the following setting enables AES cipher suites:

```
IceSSL.Ciphers=AES_128 AES_256
```

#### SecureTransport

The property value is interpreted as a list of tokens delimited by white space. The plug-in executes the tokens in the order of appearance in

order to assemble the list of enabled cipher suites. The table below describes the tokens:

ALL	Reserved keyword that enables all supported cipher suites. If specified, it must be the first token in the list. Use with caution as it may enable low-security cipher suites.
NONE	Reserved keyword that disables all cipher suites. If specified, it must be the first token in the list. Use <i>NONE</i> to start with an empty set of cipher suites and then add only those suites you want to allow.
NAME	Includes the cipher suite whose name matches <i>NAME</i> exactly.
!NAME	Excludes the cipher suite whose name matches <i>NAME</i> exactly.
(EXP)	Includes all cipher suites whose names contain the given regular expression <i>EXP</i> .
!(EXP)	Excludes all cipher suites whose names contain the given regular expression <i>EXP</i> .

For example, the following setting disables all cipher suites except those that support 256-bit AES with SHA256:

```
IceSSL.Ciphers=NONE (AES_256.*SHA256)
```

Note that no warning is given if an unrecognized cipher is specified.

### OpenSSL

The value of this property is passed directly to the OpenSSL library and the list of supported ciphers depends on how your installation of OpenSSL was compiled. You can obtain a complete list of the supported cipher suites using the command `openssl ciphers`. This command will likely generate a long list. To simplify the selection process, OpenSSL supports several classes of ciphers. Classes and ciphers can be excluded by prefixing them with an exclamation point. The special keyword `@STRENGTH` sorts the current cipher list in order of encryption algorithm key length. The classes are:

ALL	Enables all supported cipher suites. This class should be used with caution, as it may enable low-security cipher suites.
ADH	Anonymous ciphers.
LOW	Low bit-strength ciphers.
EXP	Export-crippled ciphers.

Here is an example of a reasonable setting:

```
IceSSL.Ciphers=ALL:!ADH:!LOW:!EXP:!MD5:@STRENGTH
```

This value excludes the ciphers with low bit-strength and known problems, and orders the remaining ciphers according to their key length. Note that no warning is given if an unrecognized cipher is specified.

### Java

The property value is interpreted as a list of tokens delimited by white space. The plug-in executes the tokens in the order of appearance in order to assemble the list of enabled cipher suites. The table below describes the tokens:

ALL	Reserved keyword that enables all supported cipher suites. If specified, it must be the first token in the list. Use with caution as it may enable low-security cipher suites.
NONE	Reserved keyword that disables all cipher suites. If specified, it must be the first token in the list. Use <i>NONE</i> to start with an empty set of cipher suites and then add only those suites you want to allow.
NAME	Enables the cipher suite matching the given name.

<code>!NAME</code>	Disables the cipher suite matching the given name.
<code>(EXP)</code>	Enables cipher suites whose names contain the regular expression <code>EXP</code> . For example, the value <code>NONE (.*DH_anon.*AES.*)</code> selects only cipher suites that use anonymous Diffie-Hellman authentication with AES encryption.
<code>!(EXP)</code>	Disables cipher suites whose names contain the regular expression <code>EXP</code> . For example, the value <code>ALL !(.*DH_anon.*AES.*)</code> enables all cipher suites except those that use anonymous Diffie-Hellman authentication with AES encryption.

## IceSSL.DefaultDir

### Synopsis

`IceSSL.DefaultDir=path`

### Description

Specifies the default directory in which to look for certificates, key stores, and other files. See the descriptions of the relevant properties for more information.

## IceSSL.DH.bits

### Synopsis

`IceSSL.DH.bits=file` (OpenSSL)

### Description

Specifies a `file` containing Diffie Hellman parameters whose key length is `bits`, as shown in the following example:

```
IceSSL.DH.1024=dhparams1024.pem
```

IceSSL supplies default parameters for key lengths of 512, 1024, 2048, and 4096 bits, which are used if no user-defined parameters of the desired key length are specified. The parameters must be encoded using the PEM format.

IceSSL attempts to locate `file` as specified; if the given path is relative but does not exist, IceSSL also attempts to locate `file` relative to the default directory defined by `IceSSL.DefaultDir`.

### Platform Notes

#### SChannel

Anonymous Diffie Hellman ciphers are not supported on Windows.

#### SecureTransport

See `IceSSL.DHParams`.

## IceSSL.DHParams

### Synopsis

`IceSSL.DHParams=file` (SecureTransport)

### Description

Specifies a *file* containing Diffie Hellman parameters. The parameters must be encoded using the DER format.

This property only affects server (incoming) connections. Clients obtain their DH parameters when negotiating a SSL/TLS connection with the server.

IceSSL attempts to locate *file* as specified; if the given path is relative but does not exist, IceSSL also attempts to locate *file* relative to the default directory defined by `IceSSL.DefaultDir`.

If this property is not specified, OS X will generate its own set of Diffie Hellman parameters for the process. Computing these parameters at run time can take up to 30 seconds, so we recommend generating them in advance and defining this property.

You can generate Diffie Hellman parameters using the `openssl dhparam` command.

### Platform Notes

#### SChannel

Anonymous Diffie Hellman ciphers are not supported on Windows.

#### OpenSSL

Use `IceSSL.DH.bits`.

## IceSSL.EntropyDaemon

### Synopsis

`IceSSL.EntropyDaemon=file` (OpenSSL)

### Description

Specifies a Unix domain socket for the entropy gathering daemon, from which OpenSSL gathers entropy data to initialize its random number generator.

## IceSSL.FindCert

### Synopsis

`IceSSL.FindCert=criteria` (SChannel, SecureTransport, .NET)

### Description

Builds a collection of certificates that will be used for authentication.

A server requires a certificate for authentication purposes, therefore IceSSL selects the first certificate in the accumulated collection. This is normally the certificate loaded via `IceSSL.CertFile`, if that property was defined. Otherwise, IceSSL selects one of the certificates identified by `IceSSL.FindCert`.

### Platform Notes

#### SChannel, .NET

IceSSL queries a certificate store for matching certificates and adds them to the application's certificate collection. The settings for `IceSSL.CertStore` and `IceSSL.CertStoreLocation` determine the target certificate store to be queried.

The value for *criteria* may be `*`, in which case all of the certificates in the store are selected. Otherwise, *criteria* must be one or more *field:value* pairs separated by white space. The valid field names are described below:

Issuer	Matches a substring of the issuer's name.
IssuerDN	Matches the issuer's entire distinguished name.
Serial	Matches the certificate's serial number.
Subject	Matches a substring of the subject's name.
SubjectDN	Matches the subject's entire distinguished name.
SubjectKeyId	Matches the certificate's subject key identifier.
Thumbprint	Matches the certificate's SHA1 hash.

The field names are case-insensitive. If multiple criteria are specified, only certificates that match all criteria are selected. Values must be enclosed in single or double quotes to preserve white space.

#### **SecureTransport**

IceSSL queries the keychain for matching certificates and adds them to the application's certificate collection. IceSSL uses the keychain identified in `IceSSL.Keychain`, or the user's default keychain if `IceSSL.Keychain` is not defined.

The value for `criteria` must be one or more `field:value` pairs separated by white space. The valid field names are described below:

Label	Matches the user-visible label.
Serial	Matches the certificate's serial number.
Subject	Matches a substring of the subject's name.
SubjectKeyId	Matches the certificate's subject key identifier.

The field names are case-insensitive. If multiple criteria are specified, only certificates that match all criteria are selected. Values must be enclosed in single or double quotes to preserve white space.

#### **Java**

Use `IceSSL.Alias`.

## **IceSSL.InitOpenSSL**

### **Synopsis**

`IceSSL.InitOpenSSL=num` (OpenSSL)

### **Description**

Indicates whether IceSSL should perform the global initialization tasks for the OpenSSL library. The default value is 1, meaning IceSSL will initialize OpenSSL. An application can set this property to zero if it wishes to perform the OpenSSL initialization itself, which can be useful when the application uses multiple components that depend on OpenSSL.

## **IceSSL.Keychain**

### **Synopsis**

`IceSSL.Keychain=name` (SecureTransport, iOS)

### **Description**

Specifies the name of a keychain in which to import the certificate identified by `IceSSL.CertFile`. Set `IceSSL.KeychainPassword` if the specified keychain has a password.

### **Platform Notes**

**SecureTransport**

A relative path name is opened relative to the current working directory. If the specified keychain file does not exist, a new file is created. If not defined, IceSSL uses the user's default keychain.

**iOS**

If not defined, the keychain named `login` is used by default. Note that this property is only relevant for the iPhone simulator and OS X targets.

**IceSSL.KeychainPassword****Synopsis**

`IceSSL.KeychainPassword=password` (SecureTransport, iOS)

**Description**

Specifies the password for the keychain identified by `IceSSL.Keychain`. If not defined, IceSSL attempts to open the keychain without a password.

**Platform Notes****SecureTransport**

If not defined and the keychain requires a password, OS X will ask the user in a graphical prompt.

**iOS**

This property is only relevant for the iPhone simulator and OS X targets.

**IceSSL.Keystore****Synopsis**

`IceSSL.Keystore=file` (Java)

**Description**

Specifies a key store file containing certificates and their private keys. If the key store contains multiple certificates, you should specify a particular one to use for authentication using `IceSSL.Alias`. IceSSL first attempts to open `file` as a class loader resource and then as a regular file. If the given path is relative but does not exist, IceSSL also attempts to locate it relative to the default directory defined by `IceSSL.DefaultDir`. The format of the file is determined by `IceSSL.KeystoreType`.

If this property is not defined, the application will not be able to supply a certificate during SSL handshaking. As a result, the application may not be able to negotiate a secure connection, or might be required to use an anonymous cipher suite.

**IceSSL.KeystorePassword****Synopsis**

`IceSSL.KeystorePassword=password` (Java)

**Description**

Specifies the password used to verify the integrity of the key store defined by `IceSSL.Keystore`. The integrity check is skipped if this property is not defined.

It is a security risk to use a plain-text password in a configuration file.

## IceSSL.KeystoreType

### Synopsis

IceSSL.KeystoreType=*type* (Java)

### Description

Specifies the format of the key store file defined by [IceSSL.Keystore](#). Legal values are JKS and PKCS12. If not defined, the JVM's default value is used (normally JKS).

## IceSSL.Password

### Synopsis

IceSSL.Password=*password*

### Description

Specifies the password necessary to decrypt the private key.

It is a security risk to use a plain-text password in a configuration file.

### Platform Notes

#### SChannel, SecureTransport, OpenSSL

This property supplies the password that was used to secure the private key contained in the file defined by [IceSSL.CertFile](#).

#### Java

This property supplies the password that was used to secure the private key contained in the key store defined by [IceSSL.Keystore](#). All of the keys in the key store must use the same password.

#### .NET

This property supplies the password that was used to secure the file defined by [IceSSL.CertFile](#).

#### iOS

This property supplies the password that was used to secure the file defined by [IceSSL.CertFile](#).

## IceSSL.PasswordCallback

### Synopsis

IceSSL.PasswordCallback=*classname* (Java, .NET)

### Description

Specifies the name of a Java or .NET class that implements the [IceSSL.PasswordCallback](#) interface. Using a [password callback](#) is a more secure alternative to specifying a password in a plain-text configuration file.

### Platform Notes

#### SChannel, SecureTransport, OpenSSL

Use [setPasswordPrompt](#) to install a password callback in the plug-in.

## IceSSL.PasswordRetryMax

### Synopsis

`IceSSL.PasswordRetryMax=num` (SChannel, SecureTransport, OpenSSL)

### Description

Specifies the number of attempts IceSSL should allow the user to make when entering a password. If not defined, the default value is 3.

## IceSSL.Protocols

### Synopsis

`IceSSL.Protocols=list` (SChannel, SecureTransport, OpenSSL, Java, .NET)

### Description

Specifies the protocols to allow during SSL handshaking. Legal values are SSL3, TLS1, TLS1\_0 (alias for TLS1), TLS1\_1, and TLS1\_2. You may also specify multiple values, separated by commas or white space. If this property is not defined, the default setting is as follows:

```
IceSSL.Protocols=TLS1_0, TLS1_1, TLS1_2
```

In C#, the options TLS1\_1 and TLS1\_2 require .NET 4.5 or later.

As of Ice 3.6, SSLv3 is disabled by default.

### Platform Notes

#### SecureTransport

Use `IceSSL.ProtocolVersionMin` and `IceSSL.ProtocolVersionMax`.

## IceSSL.ProtocolVersionMax

### Synopsis

`IceSSL.ProtocolVersionMax=prot` (SecureTransport)

### Description

Specifies the maximum protocol to allow during SSL handshaking. Legal values are SSL3, TLS1, TLS1\_0 (alias for TLS1), TLS1\_1, and TLS1\_2. If this property is not defined, the default value is TLS1\_0.

### Platform Notes

#### SChannel, OpenSSL, Java, .NET

Use `IceSSL.Protocols`.

## IceSSL.ProtocolVersionMin

**Synopsis**

`IceSSL.ProtocolVersionMin=prot` (SecureTransport)

**Description**

Specifies the minimum protocol to allow during SSL handshaking. Legal values are `SSL3`, `TLS1`, `TLS1_0` (alias for `TLS1`), `TLS1_1`, and `TLS1_2`. If this property is not defined, the platform's default is used.

**Platform Notes**

*SChannel, OpenSSL, Java, .NET*

Use `IceSSL.Protocols`.

**IceSSL.Random****Synopsis**

`IceSSL.Random=filelist` (OpenSSL, Java)

**Description**

Specifies one or more files containing data to use when seeding the random number generator. The file names should be separated using the platform's path separator.

**Platform Notes****OpenSSL**

IceSSL attempts to locate each file as specified; if a given path is relative but does not exist, IceSSL also attempts to locate it relative to the default directory defined by `IceSSL.DefaultDir`.

**Java**

IceSSL first attempts to open each file as a class loader resource and then as a regular file. If a given path is relative but does not exist, IceSSL also attempts to locate it relative to the default directory defined by `IceSSL.DefaultDir`.

**IceSSL.Trace.Security****Synopsis**

`IceSSL.Trace.Security=num` (SChannel, SecureTransport, OpenSSL, Java, .NET)

**Description**

The SSL plug-in trace level:

0	No security tracing (default).
1	Display diagnostic information about SSL connections.

**IceSSL.TrustOnly****Synopsis**

`IceSSL.TrustOnly=ENTRY[;ENTRY;...]` (SChannel, SecureTransport, OpenSSL, Java, .NET)

**Description**

Identifies [trusted and untrusted](#) peers. This family of properties provides an additional level of authentication by using the peer certificate's distinguished name (DN) to decide whether to accept or reject a connection.

Each *ENTRY* in the property value consists of relative distinguished name (RDN) components, formatted according to the rules in [RFC 2253](#). Specifically, the components must be separated by commas, and any component that contains a comma must be escaped or enclosed in quotes. For example, the following two property definitions are equivalent:

```
IceSSL.TrustOnly=O="Acme, Inc.",OU=Sales
IceSSL.TrustOnly=O=Acme\, Inc.,OU="Sales"
```

Use a semicolon to separate multiple entries in a property:

```
IceSSL.TrustOnly=O=Acme\, Inc.,OU=Sales;O=Acme\, Inc.,OU=Marketing
```

By default, each entry represents an acceptance entry. A `!` character appearing at the beginning of an entry signifies a rejection entry. The order of the entries in a property is not important.

After the SSL engine has successfully completed its authentication process, IceSSL evaluates the relevant `IceSSL.TrustOnly` properties in an attempt to find an entry that matches the peer certificate's DN. For a match to be successful, the peer DN must contain an exact match for all of the RDN components in an entry. An entry may contain as many RDN components as you wish, depending on how narrowly you need to restrict access. The order of the RDN components in an entry is not important.

The connection semantics are described below:

1. IceSSL aborts the connection if any rejection or acceptance entries are defined and the peer does not supply a certificate.
2. IceSSL aborts the connection if the peer DN matches any rejection entry. (This is true even if the peer DN also matches an acceptance entry.)
3. IceSSL accepts the connection if the peer DN matches any acceptance entry, or if no acceptance entries are defined.

Our original example limits access to people in the sales and marketing departments:

```
IceSSL.TrustOnly=O=Acme\, Inc.,OU=Sales;O=Acme\, Inc.,OU=Marketing
```

If it later becomes necessary to deny access to certain individuals in these departments, you can add a rejection entry and restart the program:

```
IceSSL.TrustOnly=O=Acme\, Inc.,OU=Sales; O=Acme\, Inc.,OU=Marketing;
!O=Acme\, Inc.,CN=John Smith
```

While testing your trust configuration, you may find it helpful to set the `IceSSL.Trace.Security` property to a non-zero value, which causes IceSSL to display the DN of each peer during connection establishment.

This property affects incoming and outgoing connections. IceSSL also supports similar properties that affect only incoming connections or only outgoing connections.

## IceSSL.TrustOnly.Client

### Synopsis

```
IceSSL.TrustOnly.Client=ENTRY[;ENTRY;...] (SChannel, SecureTransport, OpenSSL, Java, .NET)
IceSSL.TrustOnly.Client=ID (iOS)
```

### Description

Identifies trusted and untrusted peers for outgoing (client) connections. The entries defined in this property are combined with those of `IceS`

`SL.TrustOnly`.

### Platform Notes

#### iOS

For an outgoing connection to succeed, the peer certificate's subject key identifier must match the property value exactly. The property value is formatted as a series of hexadecimal values separated by colons or spaces, as shown in the example below:

```
C2:E8:D3:33:D7:83:99:6E:08:F7:C2:34:31:F7:1E:8E:44:87:38:57
```

Since this value is specific to a single certificate authority, this property is valid only when used in conjunction with `IceSSL.CertAuthFile`.

## IceSSL.TrustOnly.Server

### Synopsis

`IceSSL.TrustOnly.Server=ENTRY[;ENTRY;...]` (SChannel, SecureTransport, OpenSSL, Java, .NET)

### Description

Identifies trusted and untrusted peers for incoming ("server") connections. The entries defined in this property are combined with those of `IceSSL.TrustOnly`. To configure trusted and untrusted peers for a particular object adapter, use `IceSSL.TrustOnly.Server.AdapterName`.

## IceSSL.TrustOnly.Server.AdapterName

### Synopsis

`IceSSL.TrustOnly.Server.AdapterName=ENTRY[;ENTRY;...]` (SChannel, SecureTransport, OpenSSL, Java, .NET)

### Description

Identifies trusted and untrusted peers for incoming (server) connections to the object adapter `AdapterName`. The entries defined in this property are combined with those of `IceSSL.TrustOnly` and `IceSSL.TrustOnly.Server`.

## IceSSL.Truststore

### Synopsis

`IceSSL.Truststore=file` (Java)

### Description

Specifies a key store file containing the certificates of trusted certificate authorities. IceSSL first attempts to open `file` as a class loader resource and then as a regular file. If the given path is relative but does not exist, IceSSL also attempts to locate it relative to the default directory defined by `IceSSL.DefaultDir`. The format of the file is determined by `IceSSL.TruststoreType`.

If this property is not defined, IceSSL uses the value of `IceSSL.Keystore` by default. If no truststore is specified and the keystore does not contain a valid certificate chain, the application will not be able to authenticate the peer's certificate during SSL handshaking. As a result, the application may not be able to negotiate a secure connection, or might be required to use an anonymous cipher suite.

### Platform Notes

*SChannel, SecureTransport, OpenSSL, .NET*

Use [IceSSL.CAs](#).

## IceSSL.TruststorePassword

### Synopsis

`IceSSL.TruststorePassword=password` (Java)

### Description

Specifies the password used to verify the integrity of the key store defined by [IceSSL.Truststore](#). The integrity check is skipped if this property is not defined.

It is a security risk to use a plain-text password in a configuration file.

### Platform Notes

*SChannel, SecureTransport, OpenSSL, .NET*

Use [IceSSL.Password](#).

## IceSSL.TruststoreType

### Synopsis

`IceSSL.TruststoreType=type` (Java)

### Description

Specifies the format of the key store file defined by [IceSSL.Truststore](#). Legal values are `JKS` and `PKCS12`. If not defined, the default value is `JKS`.

## IceSSL.UsePlatformCAs

### Synopsis

`IceSSL.UsePlatformCAs=num`

### Description

If *num* is a value greater than zero, IceSSL uses the platform's bundled Root Certificate Authorities. This setting is ignored if [IceSSL.CAs](#) is defined.

If not defined, the default value is zero.

## IceSSL.VerifyDepthMax

### Synopsis

`IceSSL.VerifyDepthMax=num` (*SChannel, SecureTransport, OpenSSL, Java, .NET*)

### Description

Specifies the [maximum depth](#) of a trusted peer's certificate chain, including the peer's certificate. A value of zero accepts chains of any length. If not defined, the default value is 3.

## IceSSL.VerifyPeer

### Synopsis

IceSSL.VerifyPeer=*num* (SChannel, SecureTransport, OpenSSL, Java, .NET)

### Description

Specifies the verification requirements to use during SSL handshaking. The legal values are shown in the table below. If this property is not defined, the default value is 2.

0	For an outgoing connection, the client verifies the server's certificate (if an anonymous cipher is not used) but does not abort the connection if verification fails. For an incoming connection, the server does not request a certificate from the client.
1	For an outgoing connection, the client verifies the server's certificate and aborts the connection if verification fails. For an incoming connection, the server requests a certificate from the client and verifies it if one is provided, aborting the connection if verification fails.
2	For an outgoing connection, the semantics are the same as for the value 1. For an incoming connection, the server requires a certificate from the client and aborts the connection if verification fails.

### Platform Notes

#### .NET

This property has no effect on outgoing connections, since .NET always uses the semantics of value 2. For an incoming connection, the value 0 has the same semantics as the value 1.

## IceStorm Properties

IceStorm is an IceBox service that you can install using any name you like. For example:

```
IceBox.Service.DataFeed=IceStormService, . . .
```

The service name you choose is also used as the prefix for IceStorm's configuration properties. In the example above, the IceStorm configuration properties would use the `DataFeed` prefix, as in `DataFeed.Discard.Interval=10`.

In the property descriptions below, replace *service* with the service name from your IceStorm configuration.

On this page:

- [service.Discard.Interval](#)
- [service.Election.ElectionTimeout](#)
- [service.Election.MasterTimeout](#)
- [service.Election.ResponseTimeout](#)
- [service.Flush.Timeout](#)
- [service.InstanceName](#)
- [service.Node.AdapterProperty](#)
- [service.Nodeld](#)
- [service.Nodes.id](#)
- [service.Publish.AdapterProperty](#)
- [service.ReplicatedPublishEndpoints](#)
- [service.ReplicatedTopicManagerEndpoints](#)
- [service.Send.Timeout](#)
- [service.Send.QueueSizeMax](#)
- [service.Send.QueueSizeMaxPolicy](#)
- [service.TopicManager.AdapterProperty](#)
- [service.Trace.Election](#)
- [service.Trace.Replication](#)
- [service.Trace.Subscriber](#)
- [service.Trace.Topic](#)
- [service.Trace.TopicManager](#)
- [service.Transient](#)

### ***service.Discard.Interval***

#### **Synopsis**

```
service.Discard.Interval=num
```

#### **Description**

An IceStorm server detects when a subscriber to which it forwards events becomes non-functional and, at that point, stops delivery attempts to that subscriber for *num* seconds before trying to forward events to that subscriber again. The default value of this property is 60 seconds.

### ***service.Election.ElectionTimeout***

#### **Synopsis**

```
service.Election.ElectionTimeout=num
```

#### **Description**

This property is used by a [replicated IceStorm deployment](#). It specifies the interval in seconds at which a coordinator attempts to form larger groups of replicas. If not defined, the default value is 10.

**service.Election.MasterTimeout****Synopsis**

```
service.Election.MasterTimeout=num
```

**Description**

This property is used by a [replicated IceStorm deployment](#). It specifies the interval in seconds at which a slave checks the status of the coordinator. If not defined, the default value is 10.

**service.Election.ResponseTimeout****Synopsis**

```
service.Election.ResponseTimeout=num
```

**Description**

This property is used by a [replicated IceStorm deployment](#). It specifies the interval in seconds that a replica waits for replies to an invitation to form a larger group. Lower priority replicas wait for intervals inversely proportional to the maximum priority:

$$\text{ResponseTimeout} + \text{ResponseTimeout} * (\text{max} - \text{pri})$$

If not defined, the default value is 10.

**service.Flush.Timeout****Synopsis**

```
service.Flush.Timeout=num
```

**Description**

Defines the interval in milliseconds with which events are sent to [batch subscribers](#). The default is 1000ms.

**service.InstanceName****Synopsis**

```
service.InstanceName=name
```

**Description**

Specifies an alternate identity category for all [objects](#) hosted by the IceStorm object adapters. If not specified, the default identity category is IceStorm.

**service.Node.AdapterProperty**

**Synopsis**

```
service.Node.AdapterProperty=value
```

**Description**

In a replicated deployment, IceStorm uses the adapter name `service.Node` for the replica node's object adapter. Therefore, adapter properties can be used to configure this adapter.

**service.NodeId****Synopsis**

```
service.NodeId=value
```

**Description**

Specifies the node ID of an IceStorm replica, where *value* is a non-negative integer. The node ID is also used as the replica's priority, such that a larger value assigns higher priority to the replica. The replica with the highest priority becomes the coordinator of its group. This property must be defined for each replica.

**service.Nodes.id****Synopsis**

```
service.Nodes.id=value
```

**Description**

This property is used for a manual deployment of highly available IceStorm, in which each of the replicas must be explicitly configured with the proxies of all other replicas. The value is a proxy for the replica with the given node *id*. A replica's object identity has the form *instance-name/nodeid*, such as `DemoIceStorm/node2`.

**service.Publish.AdapterProperty****Synopsis**

```
service.Publish.AdapterProperty=value
```

**Description**

IceStorm uses the adapter name `service.Publish` for the object adapter that processes incoming requests from publishers. Therefore, a dapter properties can be used to configure this adapter.

**service.ReplicatedPublishEndpoints****Synopsis**

```
service.ReplicatedPublishEndpoints=value
```

**Description**

This property is used for a manual deployment of [highly available IceStorm](#). It specifies the set of endpoints returned for the publisher proxy returned from `IceStorm::Topic::getPublisher`.

If this property is not defined, the publisher proxy returned by a topic instance points directly at that replica and, should the replica become unavailable, publishers will not transparently failover to other replicas.

## **service.ReplicatedTopicManagerEndpoints**

### **Synopsis**

```
service.ReplicatedTopicManagerEndpoints=value
```

### **Description**

This property is used for a manual deployment of [highly available IceStorm](#). It specifies the set of endpoints used in proxies that refer to a replicated topic. This set of endpoints should contain the endpoints of each IceStorm replica.

For example, the operation `IceStorm::TopicManager::create` returns a proxy that contains this set of endpoints.

## **service.Send.Timeout**

### **Synopsis**

```
service.Send.Timeout=num
```

### **Description**

IceStorm applies a send timeout when it forwards events to subscribers. The value of this property determines how long IceStorm will wait for forwarding of an event to complete. If an event cannot be forwarded within *num* milliseconds, the subscriber is considered dead and its subscription is cancelled. The default value is 60 seconds. Setting this property to a negative value disables timeouts.

## **service.Send.QueueSizeMax**

### **Synopsis**

```
service.Send.QueueSizeMax=num (since Ice 3.6.3)
```

### **Description**

The value of this property determines how many events can be queued for a subscriber by IceStorm. When the maximum size is reached, the old events will either be dropped or the subscriber will be removed. Setting this property to a negative value specifies an infinite queue size. The default value is -1.

## **service.Send.QueueSizeMaxPolicy**

### **Synopsis**

```
service.Send.QueueSizePolicy=RemoveSubscriber|DropEvents (since Ice 3.6.3)
```

### **Description**

The value of this property specifies how IceStorm will behave if the maximum queue size is reached for a subscriber. If set to `RemoveSubscriber`, IceStorm will remove the subscriber as soon as the limit is reached. If set to `DropEvents`, older events will be removed to make

room for new events. The default value is `RemoveSubscriber`.

### ***service.TopicManager.AdapterProperty***

#### ***Synopsis***

```
service.TopicManager.AdapterProperty=value
```

#### ***Description***

IceStorm uses the adapter name `service.TopicManager` for the topic manager's object adapter. Therefore, [adapter properties](#) can be used to configure this adapter.

### ***service.Trace.Election***

#### ***Synopsis***

```
service.Trace.Election=num
```

#### ***Description***

Trace activity related to elections:

0	No election trace (default).
1	Trace election activity.

### ***service.Trace.Replication***

#### ***Synopsis***

```
service.Trace.Replication=num
```

#### ***Description***

Trace activity related to replication:

0	No replication trace (default).
1	Trace replication activity.

### ***service.Trace.Subscriber***

#### ***Synopsis***

```
service.Trace.Subscriber=num
```

#### ***Description***

The subscriber trace level:

0	No subscriber trace (default).
1	Trace topic diagnostic information on subscription and unsubscription.
2	Like 1, but more verbose, including state transitions for a subscriber (such as going offline after a temporary network failure, and going online again after a successful retry, etc.).

## **service.Trace.Topic**

### **Synopsis**

`service.Trace.Topic=num`

### **Description**

The topic trace level:

0	No topic trace (default).
1	Trace topic links, subscription, and unsubscription.
2	Like 1, but more verbose, including QoS information, and other diagnostic information.

## **service.Trace.TopicManager**

### **Synopsis**

`service.Trace.TopicManager=num`

### **Description**

The topic manager trace level:

0	No topic manager trace (default).
1	Trace topic creation.

## **service.Transient**

### **Synopsis**

`service.Transient=num`

### **Description**

If `num` is a value greater than zero, IceStorm runs in a fully transient mode in which no database is required. Replication is not supported in this mode. If not defined, the default value is zero.

## IceStormAdmin.\*

On this page:

- [IceStormAdmin.Host](#)
- [IceStormAdmin.Port](#)
- [IceStormAdmin.TopicManager.Default](#)
- [IceStormAdmin.TopicManager.name](#)

### IceStormAdmin.Host

#### Synopsis

`IceStormAdmin.Host=host`

#### Description

When used together with `IceStormAdmin.Port`, `icestormadmin` uses the [Finder](#) interface to discover the topic manager at the specified host and port.

`icestormadmin` ignores this setting if you define one or more `IceStormAdmin.TopicManager` properties.

### IceStormAdmin.Port

#### Synopsis

`IceStormAdmin.Port=port`

#### Description

When used together with `IceStormAdmin.Host`, `icestormadmin` uses the [Finder](#) interface to discover the topic manager at the specified host and port.

`icestormadmin` ignores this setting if you define one or more `IceStormAdmin.TopicManager` properties.

### IceStormAdmin.TopicManager.Default

#### Synopsis

`IceStormAdmin.TopicManager.Default=proxy`

#### Description

Defines the proxy for the default IceStorm topic manager. This property is used by `icestormadmin`. IceStorm applications may choose to use this property for their configuration as well.

### IceStormAdmin.TopicManager.name

#### Synopsis

`IceStormAdmin.TopicManager.name=proxy`

#### Description

Defines a proxy for an IceStorm topic manager for `icestormadmin`. Properties with this pattern are used by `icestormadmin` if multiple topic managers are in use, for example:

```
IceStormAdmin.TopicManager.A=A/TopicManager:tcp -h x -p 9995
IceStormAdmin.TopicManager.B=Foo/TopicManager:tcp -h x -p 9995
IceStormAdmin.TopicManager.C=Bar/TopicManager:tcp -h x -p 9987
```

This sets the proxies for three topic managers. Note that `name` need not match the instance name of the corresponding topic manager — `name` simply serves as a tag. With these property settings, the `icestormadmin` commands that accept a topic can now specify a topic manager other than the default topic manager that is configured with `IceStormAdmin.TopicManager.Default`. For example:

```
current Foo
create myTopic
create Bar/myOtherTopic
```

This sets the current topic manager to the one with instance name `Foo`; the first `create` command then creates the topic within that topic manager, whereas the second `create` command uses the topic manager with instance name `Bar`.

# Ice Release Notes

The release notes provide information about an Ice release, including descriptions of significant new features and changes, instructions for upgrading from an earlier release, and important platform-specific details.

## Topics

- [Supported Platforms for Ice and Ice Touch 3.6.4](#)

## New Features

Ice 3.6 includes a number of significant new features, many of them in response to requests from our commercial users.

### JavaScript Mapping and WebSocket Transports

Ice for JavaScript offers a native and compact implementation of the Ice run time that you can incorporate into your web apps and gain seamless access to back-end Ice services. Our native JavaScript implementation of the Ice run time features a compact footprint, complete support for all Slice data types, compatibility with modern browsers as well as NodeJS, and an intuitive API to get you productive as quickly as possible.

Here's a really simple but complete example to give you an idea of what it's like to make a remote invocation using Ice in JavaScript:

### JavaScript

```
var communicator = Ice.initialize();
var proxy = communicator.stringToProxy("hello:wss -h www.myhost.com -p
443");
var hello = HelloPrx.uncheckedCast(proxy);
hello.sayHello().then(
 function() { console.log("sayHello done!"); }
).exception(
 function(ex) { console.log("something went wrong!"); }
).finally(
 function() { return communicator.destroy(); }
);
```

Experienced JavaScript developers might recognize our API's use of *promises*, which is a common solution for managing asynchronous activities. Our promise implementation follows existing conventions and offers a tremendous amount of power and convenience for simplifying your application code.

There have been a few changes to the JavaScript mapping since the preview release, as described in the [upgrade guide](#).

Please refer to the [manual](#) for complete details on the JavaScript mapping.

JavaScript clients running in the browser use the industry-standard WebSocket protocol. They can talk directly to Ice servers listening on WebSocket endpoints. In our example above, the endpoint `wss -h www.myhost.com -p 443` directs the client to use a secure WebSocket connection via the standard HTTPS port. The WebSocket protocol is supported by all Ice language mappings.

The use of WebSockets isn't useful just for JavaScript clients running in the browser -- it can also be used by regular Ice clients as well. The WebSocket protocol can indeed greatly ease network deployment by allowing the use of the standard HTTP or HTTPS port as well as your existing Web infrastructure. For instance, the client can connect to:

- an Ice server listening directly on port 80 (HTTP) or port 443 (HTTPS),
- an HTTP server (e.g., Nginx) that supports reverse proxying of WebSocket connections,
- an HTTP load balancer (e.g., HAProxy) that supports forwarding WebSocket connections.

Here's how it works when using an HTTP server reverse proxy:

The client connects to the HTTP server and sends an HTTP request to upgrade the existing connection to support WebSocket. The message includes a resource path, such as `/MyService` in the example above, that the HTTP server translates into a target back-end service. The HTTP server establishes its own connection to the service and then relays messages between the client and the service. The service is an Ice server listening on a WS or WSS endpoint.

The WebSocket protocol provides an alternative to opening a port on your corporate firewall. You can instead leverage your existing web infrastructure to allow Ice clients on the other side of your firewall to access your Ice services.

## Objective-C Mapping

The Objective-C mapping from Ice Touch is now included in the Ice distribution.

It currently lacks support for the following features:

- Asynchronous method dispatch (AMD)

Please refer to the [manual](#) for complete details on the Objective-C mapping.

## Multicast Discovery

In an effort to simplify bootstrapping and minimize configuration, we're introducing two new components that facilitate the discovery of Ice servers via UDP multicast.

### IceDiscovery

`IceDiscovery` provides a lightweight location service that enables clients to discover objects at run time. Implemented as an Ice plug-in, the service requires only minimal configuration and very few changes to your application code. `IceDiscovery` is an ideal solution for applications that don't need the additional features that `IceGrid` offers, such as server activation and centralized administration, but could still take advantage of the benefits provided by indirect proxies and replication.

Consider the following code example:

```

Java

Ice.ObjectPrx proxy = communicator.stringToProxy("hello");
HelloPrx hello = HelloPrxHelper.checkedCast(proxy);
hello.sayHello();
```

Notice here that the code translates the stringified proxy "hello" containing no endpoint information. Ice resolves such proxies using a locator supplied by the `IceDiscovery` plug-in, all we need to do is configure the client to load the plug-in:

```

Client configuration
Ice.Plugin.IceDiscovery=IceDiscovery:IceDiscovery.PluginFactory
```

At the proxy's first remote invocation (the call to `checkedCast` in the example above), `IceDiscovery` issues a multicast query to determine if any servers are available that provide the `hello` object. If more than one server responds, it means the object is replicated and the client selects one of the servers based on additional configuration settings. This discovery process is handled internally by the plug-in and is transparent to clients and servers.

UDP multicast is only used by `IceDiscovery` to locate available servers. Clients and servers communicate using the transport of your choosing.

In practical terms, using the plug-in means a client no longer needs to hard-code the addressing information of its servers in its source code or configuration files. Assuming the underlying network supports multicast, `IceDiscovery` enables servers to start, stop, and migrate to different hosts without affecting the ability of clients to find them, and without requiring any administrative changes.

### IceLocatorDiscovery

In previous versions of Ice, using `IceGrid` was the primary way for applications to leverage the benefits of indirect proxies; the only other alternative was to write a custom "locator" service. Indirect proxies help to minimize coupling between clients and servers by eliminating most of the addressing information from application code and configuration files. The one exception has always been the `Ice.Default.Locator` property, which needed to contain at least one endpoint for an `IceGrid` registry:

```
Client configuration before IceLocatorDiscovery
Ice.Default.Locator=IceGrid/Locator:tcp -h registryhost -p 4061
```

In a replicated IceGrid deployment consisting of a master replica and one or more slave replicas, the `Ice.Default.Locator` property would normally include endpoints for some or all of the replicas.

The `IceLocatorDiscovery` plug-in alleviates the need to statically configure locator endpoints by using UDP multicast to dynamically discover the active locators in a network. Integrating the plug-in simply requires updating client configuration files to install the plug-in and remove the `Ice.Default.Locator` property. No changes are necessary in your application code.

## IceGrid Custom Load Balancing

We've enhanced the IceGrid registry to support [pluggable load balancing strategies](#), making it possible for you to implement application-specific load balancing algorithms or filter the registry's results based on user input.

Two kinds of filters are supported:

- **Replica group filter**  
The registry invokes a replica group filter each time a client requests the endpoints of a replica group or object adapter, as well as for calls to `findAllReplicas`. The registry passes information about the query that the filter can use in its implementation, including the list of object adapters participating in the replica group whose nodes are active at the time of the request. The object adapter list is initially ordered using the load balancing type configured for the replica group; the filter can modify this list however it chooses.
- **Type filter**  
The registry invokes a type filter for each query that a client issues to find a well-known object by type using the operations `findObjectByType`, `findAllObjectsByType`, and `findObjectByTypeOnLeastLoadedNode`. Included in the information passed to the filter is a list of proxies for the matching well-known objects; the filter implementation decides which of these proxies are returned to the client.

Filters are implemented in C++ as regular Ice plug-ins that you install in the IceGrid registry via configuration properties.

## Invocation Timeouts

Timeout semantics have changed for the better with the addition of [invocation timeouts](#). Ice still supports the existing timeout facility, referred to as a connection timeout or endpoint timeout, but now it only affects network activities. The new invocation timeout facility enables you to set an arbitrary timeout per invocation, independent of the connection timeout. Furthermore, when an invocation timeout occurs, it only affects that invocation and the connection remains open. The code below demonstrates the new semantics:

```
C++
```

```
Ice::ObjectPrx proxy = communicator->stringToProxy(...);
proxy = proxy->ice_timeout(2000); // Connection timeout: 2sec
proxy = proxy->ice_invocationTimeout(5000); // Invocation timeout: 5sec
try {
 proxy->ice_ping();
} catch (const Ice::InvocationTimeoutException& ex) {
 // server's busy?
} catch (const Ice::TimeoutException& ex) {
 // network problem!
}
```

Review the [upgrade guide](#) to learn how your existing application might be impacted by and benefit from these changes.

## Invocation Cancellation

It's now possible to cancel an asynchronous invocation using the `cancel` method of the `Ice::AsyncResult` object. This method prevents a queued invocation from being sent or, if the invocation has already been sent, ignores a reply if the server sends one. It has no effect on the server. A canceled invocation is considered to be completed and the result of the invocation is an `Ice::InvocationCanceledException`.

## Active Connection Management

We've enhanced the [Active Connection Management](#) facility to give applications more control over ACM behavior. Included in these enhancements is a new "heartbeat" feature that you can use in your applications when you need to ensure that a connection remains open. For example, you can use heartbeats to keep a Glacier2 session alive or prevent a bidirectional connection from being closed prematurely. This feature eliminates the need for an application to implement its own background thread to keep a connection or session alive. We've also added the ability to register a callback with the connection that is notified when the connection closes or receives a heartbeat. The code below shows how to enable heartbeats and install a callback on a connection:

```
C++
```

```
class CallbackI : public Ice::ConnectionCallback
{
 virtual void heartbeat(const Ice::ConnectionPtr& connection)
 {
 std::cout << "received heartbeat for connection:\n" <<
connection->toString() << std::endl;
 }

 virtual void closed(const Ice::ConnectionPtr& connection)
 {
 std::cout << "connection closed:\n" << connection->toString()
<< std::endl;
 }
};
Ice::ObjectPrx proxy = communicator->stringToProxy(...);
Ice::ConnectionPtr connection proxy->ice_getConnection();
connection->setACM(5, Ice::CloseOnInvocationAndIdle,
Ice::HeartbeatAlways);
connection->setCallback(new CallbackI());
```

Refer to our [upgrade guide](#) for more information on how the ACM changes can impact existing Ice applications.

## SSL

We've essentially re-written the IceSSL plug-in to make use of a platform's native SSL APIs where possible. On OS X, the plug-in now uses Apple's Secure Transport facility, and on Windows it now uses SChannel. Linux is the only platform on which IceSSL still uses OpenSSL.

By using native SSL APIs instead of OpenSSL for secure communications on OS X and Windows, your applications can more easily take advantage of any hotfixes provided by the operating system vendors when security issues arise.

If you use IceSSL, we recommend reviewing the [upgrade guide](#) because there have been some changes to the IceSSL APIs and configuration properties.

## Other New Features

This section describes several more additions and improvements in Ice 3.6 that we'd like to bring to your attention.

## Remote Logging

The Ice administrative facility adds a new [logger facet](#) that allows remote access to a program's log activity. The IceGrid administrative tools now use this feature to let you view the recent log output of Ice servers, IceBox services, and IceGrid nodes and registries.

## Garbage Collection Improvements

Ice for C++ has included a [garbage collection](#) facility for many years, but it suffered from one significant flaw: it was impossible to guarantee that object graphs could be collected in a thread-safe manner. In this release, we've improved the implementation and modified the API to ensure it's efficient and thread-safe. The application is now responsible for telling the Ice run time when an object graph is eligible for collection by calling the `Object::ice_collectable(bool)` method. Ice assumes that a graph eligible for collection is immutable, therefore you must not update the structure of the graph after marking it as collectable. The code below demonstrates the new API:

```

C++

NodePtr root = new Node();
NodePtr child = new Node();
root->left = child;
child->left = root; // Create a cycle

// Mark the graph as collectable. At this point you should no longer
// modify the structure of the graph referenced by "root".
root->ice_collectable(true);

```

Users of previous Ice versions should refer to the [upgrade guide](#) for details on what has changed.

## Transport Improvements

Aside from adding the WebSocket transports and overhauling our SSL plug-in, we've made a few more enhancements to the Ice transports.

## HTTP Proxy

Outgoing TCP and SSL connections can now be mediated by an HTTP network proxy service that supports HTTP CONNECT tunneling. The new properties `Ice.HTTPProxyHost` and `Ice.HTTPProxyPort` configure the addressing information for the proxy.

## Source Address

Proxy endpoints can now include the `--sourceAddress` option to specify a network interface on which to bind outgoing connections. The `Ice.Default.SourceAddress` property supplies a default value when the endpoint option is not used.

## Batch Invocations

We made some significant changes to the way [batch invocations](#) work in Ice 3.6, making them more reliable and more consistent with other invocation modes. Please review the [upgrade guide](#) for details.

## Collocated Invocations

Collocated invocations have been reimplemented to provide [location transparency](#) semantics that are much more consistent with those of regular remote invocations. For example, you can now make asynchronous invocations on a collocated servant, and the Python language mapping now supports collocated invocations.

If your application relies on collocated invocations, you should review our [upgrade guide](#) for more information.

## Finder Interfaces

Router and locator implementations are now required to implement a *finder* interface that allows a client to obtain a proxy for the service while knowing only its address and port. A finder object has a well-known identity that a client can combine with addressing information to compose its initial proxy. Using the finder proxy, the client can request a proxy for the target service. For example, the IceGrid administrative utility only needs to prompt the user for addressing details but does not need to ask for the identity of the service's well-known object, which may have been customized in the service's configuration.

In addition to [routers](#) and [locators](#), [IceStorm](#) also supports a finder interface for obtaining the topic manager proxy.

## Java Interrupts

Ice for Java now allows an application to safely interrupt a thread that's blocked in a call to the Ice run time. Attempting to use interrupts in previous Ice releases led to undefined and generally undesirable behavior, but in Ice 3.6 the semantics are clearly defined. Consider this example:

```

Java

HelloPrx helloProxy = ...;
try {
 helloProxy.sayHello();
} catch (Ice.OperationInterruptedException ex) {
 // interrupted by another thread!
}

```

Here we've shown how an application can deal with an interrupt that occurs during a remote invocation. Calls to other blocking Ice APIs, such as `Communicator.waitForShutdown()`, can also be interrupted. Consult the [manual](#) for a complete description of the semantics and a list of the valid interruption points.

## Java Lambda Functions

Ice 3.6 adds support for Java 8, which means you can now use lambda functions for asynchronous callbacks. As an example of how lambda functions can simplify your code, consider these two equivalent invocations:

```

Java

```

// Using an anonymous callback object
p.begin_ice_ping(new Ice.Callback_Object_ice_ping()
{
    @Override
    public void response()
    {
        System.out.println("done!");
    }
    @Override
    public void exception(Ice.LocalException ex)
    {
        System.out.println("error!");
    }
});

// Using Java 8 lambdas
p.begin_ice_ping(
    () -> System.out.println("done!"),
    (Ice.Exception ex) -> System.out.println("error!"));

```

```

## Java Buffers

The new metadata tag `"java:buffer"` can be applied to sequences of certain primitive types, causing the translator to use subclasses of `java.nio.Buffer` instead of the default mapping to a native Java array. The [buffer mapping](#) is especially convenient when an application already has data in a buffer object because it eliminates the need to create and fill a temporary array just to call a Slice operation. The buffer mapping also avoids copying when receiving these sequences by directly referencing Ice's unmarshaling buffer.

Here's a simple example:

```

Slice

```

sequence<byte> Bytes;
sequence<int> Ints;

interface Sender {
    ["java:buffer"] Ints translate(["java:buffer"] Bytes input);
};

```

```

The `translate` operation maps to the following Java method:

```

Java

```

java.nio.IntBuffer translate(java.nio.ByteBuffer input);

```

```

On the client side, a call to the `translate proxy` method returns an `IntBuffer` view of the data in the results buffer. On the server side, the implementation receives a `ByteBuffer` wrapper of the relevant portion of the incoming parameter buffer.

## C++ View Types

The new `cpp:type:view-type` metadata directive allows you to safely use "view" C++ types for operation parameters. Such C++ types point to memory held by other objects and don't copy memory. A typical example is the experimental C++14 `string_view` type. `cpp:type:view-type` can be applied to string, sequence and dictionary parameters, to speed-up your application by reducing the number of copies made during remote invocations. See [the `cpp:type` and `cpp:view-type` Metadata Directives](#) for details.

## Linking with C++ Libraries on Windows

You no longer need to list Ice import libraries (such as `IceD.lib`) when linking with Ice C++ libraries on Windows. `pragma` directives in Ice header files provide these import library names to the linker, for example:

**C++**

```
// For Ice C++ library
#if defined(_MSC_VER)
if !defined(ICE_BUILDING_ICE)
if defined(_DEBUG) && !defined(ICE_OS_WINRT)
pragma comment(lib, "IceD.lib")
else
pragma comment(lib, "Ice.lib")
endif
endif
#endif
#endif
```

The [Ice Builder for Visual Studio](#) automatically configures the `$(IceLib)` directory that contains these import libraries. `$(IceLib)` depends on the versions of Ice and Visual Studio you're using, and on the target architecture. For example, `$(IceLib)` for a Ice 3.6, Visual Studio 2012 and a x64 target is `$(IceHome)\lib\vc110\x64`.

## C++ Plug-in for Crypt Password Files

Both the Glacier2 router and IceGrid registry provide a [simple file-based authentication mechanism](#) using a "crypt password" file that contains a list of user name and password-hash pairs.

In Ice 3.5 and earlier releases, the Glacier2 router and IceGrid registry use the archaic [DES-based Unix Crypt](#) algorithm to hash the provided password and verify if this hash matches the hash in the password-file. This DES Unix Crypt implementation was provided by OpenSSL on all platforms.

Ice 3.6 supports more recent and secure hash formats and algorithms:

- Windows and OS X: [PBKDF2](#) with SHA-1, SHA-256, or SHA-512 as digest algorithm
- Linux: [SHA-256](#) and [SHA-512 Crypt](#), plus the old [DES-based Unix Crypt](#) for compatibility with earlier releases

Windows and OS X no longer rely on OpenSSL for this password hashing, nor for anything else.

In Ice 3.6, we have also moved the implementation of this authentication mechanism to a separate C++ plug-in, the `Glacier2CryptPermissionsVerifier` plug-in. This plug-in is loaded automatically by Glacier2 or IceGrid if you configure a crypt passwords file using one of the existing `CryptPasswords` properties `Glacier2.CryptPasswords`, `IceGrid.Registry.AdminCryptPasswords` and `IceGrid.Registry.CryptPasswords`. If you don't use the simple authentication mechanism provided by the `CryptPasswords` properties, you don't need to include this plug-in with your application.

## Support for `-fvisibility=hidden` with GCC and clang

Ice for C++ is now built by default with `-fvisibility=hidden` on Linux (with GCC) and OS X (with clang). You can also build code

generated by `slice2cpp` with `-fvisibility=hidden`, and use the `--dll-export` option to export symbols from such generated code.

## Backward Compatibility of Ice Versions

The subsections below describe how Ice maintains (or does not maintain) backwards compatibility between versions.

On this page:

- [Source-code compatibility](#)
- [Binary compatibility](#)
- [On-the-wire compatibility](#)
- [Database compatibility](#)
- [Interface compatibility](#)
  - [IceGrid](#)
  - [IceStorm](#)

### Source-code compatibility

Ice maintains source-code compatibility between a patch release (e.g., 3.6.4) and the most recent minor release (e.g., 3.6.0), but does not guarantee source-code compatibility between minor releases (e.g., between 3.5 and 3.6).

[Upgrading your Application from Ice 3.5](#) describes the significant API changes in this release that may impact source-code compatibility. Furthermore, the subsections [Removed APIs](#) and [Deprecated APIs](#) summarize additional changes to Ice APIs that could affect your application.

### Binary compatibility

As for source-code compatibility, Ice maintains backward binary compatibility between a patch release and the most recent minor release, but does not guarantee binary compatibility between minor releases.

The requirements for upgrading to a new minor (or major) release depend on the language mapping used by your application:

- For statically-typed languages (C++, Java, .NET), the application must be recompiled.
- For scripting languages that use static translation, your Slice files must be recompiled.
- No action is necessary for a Python or Ruby script that loads its Slice files dynamically.

### On-the-wire compatibility

Ice always maintains "on the wire" compatibility with prior releases. A client using Ice version *x* can communicate with a server using Ice version *y* and vice versa.

The Ice [message format](#) is governed by two sets of rules: the protocol rules and the encoding rules. The protocol rules define the number of message types as well as the format of the message headers. The encoding rules specify how Slice types are marshaled. Ice maintains separate versions for the protocol and encoding, which makes it possible for them to evolve independently.

Several features introduced in Ice 3.5 required changes to the way that Slice classes and exceptions are marshaled. These changes make the encoding incompatible with previous releases, and therefore Ice 3.5 introduced version 1.1 of the Ice encoding. No additional encoding changes were made in Ice 3.6.

The protocol remains the same since the first version Ice, with protocol version number 1.0.

Changing the protocol or encoding format can be disruptive and does not happen often. Naturally, these changes raise the issue of backward compatibility with applications that use earlier versions of Ice, and more specifically, applications that use version 1.0 of the Ice encoding. Ice 3.5 and 3.6 use the following semantics:

- Encoding version 1.1 is the default for these releases. You can change this default using the `Ice.Default.EncodingVersion` property.
- A proxy is marshaled with an embedded encoding version representing the highest version supported by the target object, so the receiver of a proxy always knows the encoding version(s) it is allowed to use when invoking operations on that proxy. A proxy created locally uses the default encoding version, which can be inspected and changed using proxy methods.
- The results of an operation are encoded using the same version as the incoming request.
- As you would expect, the features provided by the 1.1 encoding are unavailable when an Ice application is forced to use the 1.0

encoding.

See [Encoding Version 1.1](#) for additional details.

## Database compatibility

Upgrading to a new minor release of Ice often includes an upgrade to the supported version of Berkeley DB. In turn, this may require an application to migrate its databases, either because the format of Berkeley DB's database files has changed, or due to a change in the schema of the data stored in those databases.

For example, if your application uses Freeze, it may be necessary for you to migrate your databases even if your schema has not changed.

Certain Ice services also use Freeze in their implementation. If your application uses these services (IceGrid and IceStorm), it may be necessary for you to migrate their databases as well.

Please refer to the relevant subsections below for migration instructions.

## Interface compatibility

Although Ice always maintains compatibility at the protocol level, changing Slice definitions can also lead to incompatibilities. As a result, Ice maintains interface compatibility between a patch release and the most recent minor release, but does not guarantee compatibility between minor releases.

This issue is particularly relevant if your application uses Ice services such as IceGrid or IceStorm, as a change to an interface in one of these services may adversely affect your application.

Interface changes in an Ice service can also impact compatibility with its administrative tools, which means it may not be possible to administer an Ice 3.6.x service using a tool from a previous minor release (or vice-versa).

### IceGrid

Starting with Ice 3.2.0, IceGrid registries and nodes are interface-compatible so you can use different IceGrid registry and node versions within the same deployment. For example, you can use an IceGrid node from Ice 3.2 with a registry from Ice 3.4.

IceGrid master and slaves can have different versions as long as they use the same database format. Since the IceGrid database format changed in Ice 3.6, an IceGrid slave from earlier versions will not be able to synchronize with an IceGrid master from Ice 3.6 or later. You need to upgrade all your IceGrid registries to Ice 3.6 to ensure replication between the registries work.

An IceGrid node can activate Ice servers that use different Ice releases, for example, an IceGrid node version 3.6 can activate an Ice 3.4 server.

The IceGrid graphical and command-line administrative tools can only administer an IceGrid registry with the same `major.minor` version. For example, you have to use the 3.6 administrative tools to administer an IceGrid 3.6 registry; you cannot use an administrative tool from an earlier Ice version. The reverse is also true: you cannot administer an IceGrid 3.5 registry with an IceGrid 3.6 administration tool.

### IceStorm

Topic linking is supported between all IceStorm versions released after 3.0.0.

## Upgrading your Application from Ice 3.6.0 or later

The subsections below provide information about upgrading existing Ice 3.6-based applications to Ice 3.6.4.

On this page:

- [Full Source and Binary Compatibility](#)
- [Policy Assemblies for .NET Applications](#)

### Full Source and Binary Compatibility

Ice 3.6.4 maintains full source and binary compatibility with earlier Ice 3.6.x versions: you can upgrade your application from Ice 3.6.0 or later to Ice 3.6.4 without recompiling or relinking anything.

The database formats used by Ice services such as IceGrid and IceStorm have not changed, therefore no database migration is required. Generally speaking, you are free to use any combination of Ice 3.6.x applications and Ice services.

Some internal Ice interfaces may change in a patch release such as Ice 3.6.4, and therefore you must always upgrade all the Ice components of a given application together. For example, you should not use version 3.6.4 of the `ice36.dll` with version 3.6.0 of the `icessl36.dll` in the same application.

### Policy Assemblies for .NET Applications

For a .NET application, Ice for .NET includes policy assemblies that supply the .NET run time with the required compatibility information. Policy assemblies have names of the form `policy.3.6.package.dll`. For example, the policy assembly for IceBox is `policy.3.6.IceBox.dll`. One way to upgrade an existing .NET application to a new patch release while maintaining binary compatibility is to install the policy assemblies into the Global Assembly Cache (GAC) with `gacutil`:

```
gacutil -i <policy.dll>
```

Another option is to modify the `.config` file of your application to add `bindingRedirect` directives, as explained in the links below:

<http://msdn.microsoft.com/en-us/library/7wd6ex19.aspx>

<http://msdn.microsoft.com/en-us/library/yx7xezcf.aspx>

For example, in the `.config` file of an application you can modify the configuration of the Ice and IceBox assemblies as follows:

**XML**

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
<runtime>
<assemblyBinding xmlns="urn:schemas-microsoft-com:asm.v1">

<dependentAssembly>
 <assemblyIdentity name="Ice" culture="neutral"
publicKeyToken="cdd571ade22f2f16"/>
 <bindingRedirect oldVersion="3.6.0.0" newVersion="3.6.4.0"/>
</dependentAssembly>

<dependentAssembly>
 <assemblyIdentity name="Ice" culture="neutral"
publicKeyToken="cdd571ade22f2f16"/>
```

```
<bindingRedirect oldVersion="3.6.1.0" newVersion="3.6.4.0"/>
</dependentAssembly>

<dependentAssembly>
 <assemblyIdentity name="Ice" culture="neutral"
publicKeyToken="cdd571ade22f2f16"/>
 <bindingRedirect oldVersion="3.6.2.0" newVersion="3.6.4.0"/>
</dependentAssembly>

<dependentAssembly>
 <assemblyIdentity name="Ice" culture="neutral"
publicKeyToken="cdd571ade22f2f16"/>
 <bindingRedirect oldVersion="3.6.3.0" newVersion="3.6.4.0"/>
</dependentAssembly>

<dependentAssembly>
 <assemblyIdentity name="IceBox" culture="neutral"
publicKeyToken="cdd571ade22f2f16"/>
 <bindingRedirect oldVersion="3.6.0.0" newVersion="3.6.4.0"/>
</dependentAssembly>

<dependentAssembly>
 <assemblyIdentity name="IceBox" culture="neutral"
publicKeyToken="cdd571ade22f2f16"/>
 <bindingRedirect oldVersion="3.6.1.0" newVersion="3.6.4.0"/>
</dependentAssembly>

<dependentAssembly>
 <assemblyIdentity name="IceBox" culture="neutral"
publicKeyToken="cdd571ade22f2f16"/>
 <bindingRedirect oldVersion="3.6.2.0" newVersion="3.6.4.0"/>
</dependentAssembly>

<dependentAssembly>
 <assemblyIdentity name="IceBox" culture="neutral"
publicKeyToken="cdd571ade22f2f16"/>
 <bindingRedirect oldVersion="3.6.3.0" newVersion="3.6.4.0"/>
</dependentAssembly>

</assemblyBinding>
```

```
</runtime>
</configuration>
```

This `.config` file can be used for `iceboxnet.exe` (as `iceboxnet.exe.config`), to load a simple IceBox service built with Ice 3.6.0 with `iceboxnet 3.6.4`.

Note that `cdd571ade22f2f16` is the token corresponding to ZeroC's public key for signing the assemblies in binary distributions. If you build Ice from sources, your assemblies are signed using the development key found in `config/IceDevKey.snk`. The token for this development key is `1f998c50fec78381`.

The advantage of installing the policy assemblies into the GAC is that they establish binary compatibility for all Ice applications, whereas modifying a `.config` file must be done for each application individually.

## Upgrading your Application from Ice 3.5

The subsections below provide additional information about upgrading to Ice 3.6, including administrative procedures for the supported platforms.

### Timeout changes

In previous Ice versions, the timeout set for a connection also served as the timeout for all invocations on that connection, such that an invocation timeout would cause Ice to close the connection and consequently report a timeout exception for all pending invocations on that connection.

With the addition of invocation timeouts, Ice now provides a much cleaner separation between two distinct features:

- [Connection timeouts](#)  
These timeouts should be used as a fail-safe strategy for handling unrecoverable network errors in a timely fashion.
- [Invocation timeouts](#)  
You can now safely abort an invocation that's taking too long to complete without affecting other invocations pending on the same connection.

Together with the new heartbeat functionality offered by Ice's [Active Connection Management](#) facility, applications now have much more control over their connections.

Existing Ice applications could configure connection timeouts in several ways, such as by setting `Ice.Override.Timeout`, or with the `-t` option in endpoints, or by calling `ice_timeout` on proxies. Ice still supports all of these options, and they all configure connection timeouts just like in previous Ice versions. However, you should carefully review these settings to see that they match the true purpose of connection timeouts. Specifically, connection timeouts should normally be chosen based on the speed of the network on which a connection takes place; a small timeout value is fine for a relatively fast network, but a larger value may be necessary for slower connections. Ice enforces connection timeouts when performing network operations such as connection establishment, reading, writing, and closing; setting a timeout allows Ice (and therefore the application) to detect a network problem within a well-defined time period without waiting for low-level network protocols to detect and report the issue.

We recommend that every application enable connection timeouts, and as a result they are now enabled by default as defined by the new property `Ice.Default.Timeout`.

The timeout semantics in previous Ice versions made it difficult for developers to employ invocation timeouts correctly. Using a small timeout value in order to detect network issues reasonably soon risked the possibility that some invocations might time out prematurely. These conflicting goals may have caused developers to modify their application designs to avoid long-running invocations. With the introduction of a separate invocation timeout feature, it's now possible to set connection timeouts appropriately for network errors while using invocation timeouts only for those operations that require them. Unlike connection timeouts, where setting different timeout values causes Ice to open separate connections, invocation timeouts of various values can be freely mixed on the same connection.

The default invocation timeout in Ice 3.6 is "infinite", meaning invocations do not time out by default. You can change the default setting using the new property `Ice.Default.InvocationTimeout`. For individual proxies, the method `ice_invocationTimeout` returns a new proxy configured with the desired invocation timeout. If you need to continue using the timeout semantics of previous Ice versions, set `Ice.Default.InvocationTimeout` to `-2` or call `ice_invocationTimeout` with the value `-2` on a given proxy.

Note that retry semantics differ between connection and invocation timeouts. Ice still performs [automatic retries](#) if possible for connection timeouts, but does not retry invocations that fail due to an invocation timeout.

## ACM changes

The [Active Connection Management](#) (ACM) facility now offers additional control over its behavior, along with a new automatic heartbeat feature. Client-side ACM was enabled by default in prior Ice versions, which means an existing Ice application most likely uses ACM unless the application explicitly disabled it.

There are several ACM changes that may affect an existing application:

- The `Ice.ACM.Client` and `Ice.ACM.Server` properties have been deprecated and replaced by `Ice.ACM.Client.Timeout` and `Ice.ACM.Server.Timeout`, respectively.
- With the new heartbeat feature, Ice automatically sends heartbeat messages at regular intervals. You can use this feature in place of a dedicated background thread that was commonly used in previous versions of Ice for keeping a session or a bidirectional connection active.
- It's no longer necessary to disable ACM in [Glacier2](#) clients as long as you enable ACM heartbeats.
- Server-side ACM is now enabled by default. Like with the previous versions, the default server-side configuration doesn't close idle connections. However, it now enables heartbeats while incoming requests are pending. This ensures the client doesn't close the connection prematurely while there are long invocations pending.

## IceGrid and Glacier2 sessions

The [ACM changes](#) in Ice 3.6 offer new implementation strategies for applications that create Glacier2 or IceGrid sessions. Since a session is tightly bound to a connection, we strongly recommended in prior releases that you disable ACM altogether to avoid the risk of ACM prematurely closing a connection and consequently terminating a session. As of Ice 3.6, it's no longer necessary to disable ACM in these situations. Furthermore, the addition of ACM heartbeats means you can remove existing code that creates a background thread just to keep a session alive.

The `Ice::Connection` interface provides several new operations, including the ability to obtain and modify a connection's current ACM settings. If you use the Glacier2 helper classes, they call the `Connection` operations to tailor the ACM timeout and heartbeat based on the router's ACM configuration. Applications that manually create a Glacier2 session can configure ACM like this:

**C++**

```

Glacier2::RouterPrx router = ...
// Create a session...
int acmTimeout = router->getACMTimeout();
if(acmTimeout > 0)
{
 Ice::ConnectionPtr connection = router->ice_getCachedConnection();
 connection->setACM(acmTimeout, IceUtil::None, Ice::HeartbeatAlways);
}

```

The new operation `Glacier2::Router::getACMTimeout` returns the router's server-side ACM timeout. In this example, the client calls `setACM` on its connection to the router, passing this same timeout value to ensure consistency between client and server. The client also enables automatic heartbeats so that the connection remains active and prevents the router's server-side ACM from closing the connection.

The ACM improvements include changes to the ACM configuration properties. You can use these properties to achieve the same result as the code above, however the properties can potentially affect other connections as well.

Finally, another new operation on the `Connection` interface lets you specify a callback object that will be notified when the connection receives a heartbeat message, and when the connection closes. This feature can be especially useful for session-based applications that need to closely monitor their connections.

## Glacier2 compatibility for helper classes

The Glacier2 helper classes in Ice 3.6 now depend on the ACM heartbeat features described above to keep a session alive. This functionality requires a Glacier2 router that also uses Ice 3.6 or later. If you're upgrading a client to Ice 3.6, we strongly recommend upgrading the Glacier2 router to 3.6 as well. Using an earlier version of Glacier2 will require your application to manually keep the session alive.

## SSL changes

IceSSL for C++ has been overhauled to make use of platform-native SSL APIs where possible:

- IceSSL on Windows now uses SChannel
- IceSSL on OS X now uses Secure Transport
- Linux platforms continue to use OpenSSL as in previous releases

As a result, there have been a number of changes to the IceSSL configuration properties and its C++ API. In the [IceSSL property reference](#), you'll see platform differences marked with **C++ using Windows**, **C++ using OS X**, and **C++ using OpenSSL**, respectively.

We discuss the affected platforms below, along with other general SSL changes.

These changes also affect applications that use Ice for Python, Ice for Ruby, and Ice for PHP because these language mappings are based on Ice for C++.

## SSLv3 disabled by default

To improve security, IceSSL now disables the SSLv3 protocol by default. In other words, only TLS protocols are enabled by default.

Although we do not recommend it, you can enable SSLv3 using the following settings:

```
Enable only SSLv3
IceSSL.Protocols=SSL3

Enable SSLv3 and TLS
IceSSL.Protocols=SSL3, TLS1_0, TLS1_1, TLS1_2

OS X only: Enables SSLv3 and TLS
IceSSL.ProtocolVersionMin = "SSLv3"
```

Refer to [IceSSL.\\*](#) for more information on these settings.

## Certificate verification

The default value of the `IceSSL.VerifyDepthMax` property is now three (it was previously two). This allows certificate chains of three certificates, such as a chain consisting of a peer certificate, a CA certificate, and a Root CA certificate.

The certificate chain provided in `IceSSL::ConnectionInfo` should now always include the root certificate if the chain is successfully verified.

We also added a `verified` member to `IceSSL::ConnectionInfo`, which indicates whether or not the peer certificate was successfully verified. For a client that sets `IceSSL.VerifyPeer=0`, this member allows the client to check the verification status of the server's certificate. For server connections, the member should always be true since servers always reject invalid client certificates.

## SSL changes on OS X

By using Secure Transport, IceSSL on OS X has now become very similar to IceSSL in Ice Touch. For example, you can use OS X keychains, take advantage of the system's default graphical password prompt, and use many of the same configuration properties.

### General Changes

- Password prompt  
In previous releases, OpenSSL would attempt to prompt command-line users for a password if the application failed to define a password or supply a password callback. Now OS X will use its default graphical password prompt in this situation.
- DSA certificates  
DSA certificates are no longer supported on OS X. If you used DSA certificates, you will need to generate RSA equivalents. The `IceSSL.CertFile` property still accepts the same syntax in that it allows you to specify two files (one RSA certificate file and one DSA certificate file), but it will ignore the DSA certificate.
- MD5 signatures  
OS X does not support certificates with MD5 signatures. We recommend using SHA256 instead.

### API Changes

- Since IceSSL on OS X no longer uses OpenSSL, the native C++ class `IceSSL::Plugin` does not support the `setContext` and `getContext` methods.
- The method `IceSSL::Certificate::verify(const PublicKeyPtr&)` has been deprecated. The new method `IceSSL::Certificate::verify(const CertificatePtr&)` takes its place.

### Property Changes

- Keychains  
The properties `IceSSL.Keychain` and `IceSSL.KeychainPassword` are now supported on OS X.
- Certificate authorities

Use the new property `IceSSL.CAs` to denote a file containing the certificates of your trusted certificate authorities. If you'd rather use the system's default certificate authorities, enable `IceSSL.UsePlatformCAs` instead.

- **Certificates**  
Use the `IceSSL.CertFile` property to denote a PKCS12 file containing both a certificate and a private key. The `IceSSL.KeyFile` property is now deprecated and should no longer be used to denote a separate private key file.
- **Certificate queries**  
The new property `IceSSL.FindCert` lets you query a keychain to find a certificate matching certain criteria.
- **Diffie Hellman parameters**  
The new property `IceSSL.DHParams` allows you to specify the name of a file containing pre-generated Diffie Hellman parameters. The property `IceSSL.DH.bits` is no longer supported on OS X.
- **Protocol limits**  
The `IceSSL.Protocols` property is no longer supported on OS X for specifying the versions of SSL/TLS that a program will accept. Use the new properties `IceSSL.ProtocolVersionMin` and `IceSSL.ProtocolVersionMax` instead.

Refer to [deprecated APIs](#) for information about obsolete properties.

## SSL changes on Windows

By using SChannel, IceSSL on Windows has now become very similar to IceSSL for .NET. For example, you can use certificate stores and many of the same configuration properties.

### General Changes

- **Password prompt**  
In previous releases, OpenSSL would attempt to prompt command-line users for a password if the application failed to define a password or supply a password callback. Windows does not have a default password prompt, so this situation will now result in a run-time exception.
- **Anonymous Diffie Hellman (ADH)**  
ADH ciphers are no longer supported on Windows.
- **Certificate formats**  
Windows is able to load a certificate in PEM format if no password is required. Use the PFX (PKCS#12) format for password-protected certificates and keys.

### API Changes

- Since IceSSL on Windows no longer uses OpenSSL, the native C++ class `IceSSL::Plugin` does not support the `setContext` and `getContext` methods.
- The method `IceSSL::Certificate::verify(const PublicKeyPtr&)` has been deprecated. The new method `IceSSL::Certificate::verify(const CertificatePtr&)` takes its place.

### Property Changes

- **Certificate authorities**  
Use the new property `IceSSL.CAs` to denote a file containing the certificates of your trusted certificate authorities. If you'd rather use the system's default certificate authorities, enable `IceSSL.UsePlatformCAs` instead.
- **Certificates**  
Use the `IceSSL.CertFile` property to denote a PKCS12 file containing both a certificate and a private key. The `IceSSL.KeyFile` property is now deprecated and should no longer be used to denote a separate private key file.
- **Certificate queries**  
The new property `IceSSL.FindCert` lets you query a certificate store to find a certificate matching certain criteria.

Refer to [deprecated APIs](#) for information about obsolete properties.

## SSL changes on Linux

## API Changes

- The method `IceSSL::Certificate::verify(const PublicKeyPtr&)` has been deprecated. The new method `IceSSL::Certificate::verify(const CertificatePtr&)` takes its place.

## Property Changes

- **Certificate authorities**  
Use the new property `IceSSL.CAs` to denote a file containing the certificates of your trusted certificate authorities. If you'd rather use the system's default certificate authorities, enable `IceSSL.UsePlatformCAs` instead.
- **Certificates**  
Use the `IceSSL.CertFile` property to denote a PKCS12 file containing both a certificate and a private key. The `IceSSL.KeyFile` property is now deprecated and should no longer be used to denote a separate private key file.

Refer to [deprecated APIs](#) for information about obsolete properties.

## Collocated Invocation changes

Ice has always supported [location transparency](#), where a proxy invocation should ideally have the same semantics regardless of whether the target object is on a different host, a different process on the same host, or collocated in the current process. For this latter case, a collocated invocation is defined as a proxy invocation on a target object that is hosted by an object adapter in the same process and created using the same communicator as the proxy. In previous versions of Ice, the semantics of collocated invocations differed in several ways from regular "remote" invocations:

- Classes and exceptions were never sliced. Instead, the receiver always received a class or exception as the derived type that was sent by the sender.
- If a collocated invocation threw an exception that was not in an operation's exception specification, the original exception was raised in the client instead of `UnknownUserException`. (This applied to the C++ mapping only.)
- Class factories were ignored.
- Invocation timeouts were ignored.
- If an operation implementation used an in parameter that was passed by reference as a temporary variable, the change affected the value of the in parameter in the caller (instead of modifying a temporary copy of the parameter on the callee side only).
- Asynchronous semantics were not supported for collocated invocations.

Ice 3.6 eliminates all of these differences. Most notably, you can now use the asynchronous invocation API on a collocated servant, and collocated invocations are now supported in Python.

Note however that a few differences in semantics still remain:

- Most collocated invocations are dispatched in the server-side thread pool just like regular invocations; the only exceptions are synchronous twoway collocated invocations with no invocation timeout, which are dispatched in the calling thread.
- The state of the servant's object adapter is ignored: collocated invocations proceed normally even if the servant's adapter is not yet activated or is in the holding state.
- AMI callbacks for asynchronous collocated invocations are dispatched from the servant's thread and not from the client-side thread pool unless AMD is used for the servant dispatch. In this case, the AMI callback is called from the client-side thread pool.
- Invocation timeouts work as usual, but connection timeouts are ignored.

If your application relies on collocated invocations, test it carefully with Ice 3.6 to ensure that it still behaves as expected.

## Batch Invocation changes

We made some significant changes to the way [batch invocations](#) work in Ice 3.6. The following table compares the behavior of batch invocations between previous releases and Ice 3.6:

Batch invocation behavior in Ice 3.5 and earlier	Batch invocation behavior in Ice 3.6

A batch request is queued by the connection associated with the proxy.	A batch request is queued by the proxy used for the invocation. The only exception is for a <a href="#">fixed proxy</a> , in which case batch requests continue to be queued by the connection associated with the proxy.
If a proxy was not already associated with a connection, the initial batch request could trigger a connection attempt.	A batch request does not trigger any network activity.
Calling <code>Communicator::flushBatchRequests</code> flushes all queued requests for all connections.	Calling <code>Communicator::flushBatchRequests</code> only flushes queued requests invoked using fixed proxies.
Calling <code>Connection::flushBatchRequests</code> flushes queued requests for all proxies associated with that connection.	Calling <code>Connection::flushBatchRequests</code> only flushes queued requests invoked using fixed proxies associated with that connection.
A batch of requests is compressed when at least one of the proxies used to create the requests in this batch has compression enabled.	A batch of requests is compressed when the proxy used to flush this batch has compression enabled. Batched requests flushed through <code>Communicator::flushBatchRequests</code> or <code>Connection::flushBatchRequest</code> never use compression.
Batch requests are not affected by proxy lifecycles because the requests are queued by connections.	Batch requests queued by a proxy are discarded when the proxy is deallocated.
Batch requests could be silently lost if an error occurred during a flush.	Calling <code>ice_flushBatchRequests</code> on a regular (non-fixed) proxy behaves like a oneway request: failures that occur during network activity trigger automatic retries and can eventually raise an exception. Furthermore, the <code>sent</code> callback is invoked for asynchronous calls to <code>ice_flushBatchRequests</code> .

With these changes, Ice's batch invocation facility has become more reliable and behaves more consistently with other invocation modes.

To give you more control over batch requests, we've also added a new `BatchInterceptor` API. You can configure a communicator with a custom batch interceptor in order to implement your own auto-flush algorithms or to receive notification when an auto-flush fails.

## Logger changes

We added a new operation `getPrefix` to the local interface `Logger`.

**Slice**

```

module Ice {
 local interface Logger {
 ...
 string getPrefix();
 };
};

```

If you implement your own logger, you will need to update your implementation with a new `getPrefix`. `getPrefix` returns the prefix associated with this logger.

## Crypt Password changes

Both the Glacier2 router and IceGrid registry provide a [simple file-based authentication mechanism](#) using a "crypt password" file that contains a list of user name and password-hash pairs. In Ice 3.5 and earlier releases, the Glacier2 router and IceGrid registry use the archaic [DES-based Unix Crypt](#) algorithm to hash the provided password and verify if this hash matches the hash in the password-file.

Ice 3.6 no longer supports this hash format on Windows and OS X. As a result, you need to regenerate your crypt password files on these platforms when upgrading to Ice 3.6.

## C++ changes

### Garbage collection changes

We've made significant changes to the garbage collection facility for cyclic object graphs. If your application uses this facility, note that we've removed the following:

- `Ice.GC.Interval` property
- `Ice.Trace.GC` property
- `Ice::collectGarbage()` function

The new property `Ice.CollectObjects` determines whether garbage collection is enabled by default for Slice class instances that are unmarshaled by the Ice run time. Refer to the [garbage collection](#) discussion for more information on using this feature.

### String converter changes

A number of changes have been made to the C++ string conversion API in this release:

- The `stringConverter` and `wstringConverter` members of `Ice::InitializationData` have been removed. Applications should use the [process-wide string converter API](#) instead.
- The classes and functions have moved from the `Ice` namespace to the `IceUtil` namespace.
- Overloaded versions of the `nativeToUTF8` and `UTF8ToNative` [convenience functions](#) that accepted a communicator argument have been removed.
- The arguments have changed for the `stringToWstring` and `wstringToString` [convenience functions](#).

### OS X with C++

C++ developers on OS X need to be aware of several changes:

- **C++11 libraries**  
With Ice 3.5, C++11 applications needed to link with a separate set of C++11-specific Ice libraries located in `<Ice installation directory>/lib/c++11`. The Ice 3.6 binary distribution includes a single set of libraries that also support C++11, so you'll need to modify your application's library path to use `<Ice installation directory>/lib` instead.
- **Minimum required version**  
Ice 3.6 supports OS X 10.9 and 10.10, therefore the C++ libraries in the Ice binary distribution are built with `macosx-min-version=10.9`. Consequently, these libraries require `libc++` and are not compatible with `libstdc++`.

## Java changes

### Java mapping changes

The default constructor generated for Slice structures, exceptions and classes behaves differently for Ice 3.6 than in previous releases. Specifically, the default constructor now initializes string data members to an empty string, enumerator data members to the first enumerator in the enumeration, and structure data members to a default-constructed value.

In previous releases, the default constructor initialized these data members to null. Applications that depend on this behavior will require updating.

For situations where the overhead of default-constructing structure data members is undesirable, applications can call the one-shot constructor instead.

The Java mapping has also relaxed its marshaling prerequisites: it is no longer necessary to initialize data members of type structure or enumerator prior to an invocation. In Ice 3.6, passing a null value for a structure or enumerator causes Ice to marshal a default-constructed

structure or the first enumerator, respectively.

## New Java features

We have added several features that you may wish to incorporate into your Java application:

- [Interrupts](#)
- [Buffers](#)
- [Java 8 and lambdas](#)

## C# changes

### C# mapping changes

The default constructor generated for Slice structures, exceptions and classes behaves differently for Ice 3.6 than in previous releases. Specifically, the default constructor now initializes string data members to an empty string and structure data members to a default-constructed value.

In previous releases, the default constructor did not explicitly initialize these data members and so they had the default C# values. Applications that depend on this behavior will require updating.

For situations where the overhead of default-constructing structure data members is undesirable, applications can call the one-shot constructor instead.

The C# mapping has also relaxed its marshaling prerequisites: it is no longer necessary to initialize data members of type structure prior to an invocation. In Ice 3.6, passing a null value for a structure causes Ice to marshal a default-constructed structure.

### C# serialization changes

One of the new features in Ice 3.6 is support for .NET serialization for all Slice types (except proxies). Existing applications may be affected by this change because the `Ice.Optional` type now implements `ISerializable` and the serialized format of an optional value is different than in Ice 3.5.

## Python changes

Developers who are migrating existing Ice applications from Ice 3.5 should be aware of a change that affects the Python language mapping. The `Ice.Unset` value now has `False` semantics, making it more convenient to test whether an optional Slice data member has a value:

```

Python
Only valid with Ice 3.6!
if obj.optionalMember:
 # optionalMember has a value

```

With Ice 3.5, the code above would not have the intended behavior because the test would be true even when `optionalMember` is set to `Ice.Unset`. The correct way to write this using Ice 3.5 is shown below:

```

Python
Correct test with Ice 3.5
if obj.optionalMember is not Ice.Unset:
 # optionalMember has a value

```

This code will also have the correct behavior with Ice 3.6, but the new style is easier to read. Also note that the Ice 3.6 semantics mean you need to use caution for optional values that can legally be set to `None`:

### Python

```
if obj.optionalMember: # Fails for None AND Ice.Unset!
 # optionalMember is not Ice.Unset or None
```

You can distinguish between `Ice.Unset` and `None` as follows:

### Python

```
if obj.optionalMember is Ice.Unset:
 # optionalMember is unset
elif obj.optionalMember is None:
 # optionalMember is set to None
else:
 # optionalMember is set to a value other than None
```

We recommend that you review for correctness all uses of `Ice.Unset` and tests of optional data members.

## PHP changes

No changes to the PHP mapping in Ice 3.6 affect compatibility for existing applications.

## Ruby changes

No changes to the Ruby mapping in Ice 3.6 affect compatibility for existing applications.

## JavaScript changes

### JavaScript mapping changes

The default constructor generated for Slice structures, exceptions and classes behaves differently for Ice 3.6 than in previous releases. Specifically, the default constructor now initializes string data members to an empty string and structure data members to a default-constructed value.

In previous releases, the default constructor initialized these data members to null. Applications that depend on this behavior will require updating.

For situations where the overhead of default-constructing structure data members is undesirable, applications can call the one-shot constructor instead.

The JavaScript mapping has also relaxed its marshaling prerequisites: it is no longer necessary to initialize data members of type structure or enumerator prior to an invocation. In Ice 3.6, passing a null value for a structure or enumerator causes Ice to marshal a default-constructed structure or the first enumerator, respectively.

### JavaScript packaging changes

The NodeJS packaging has changed from the original Ice for JavaScript 0.1 release, meaning existing JavaScript applications will need to modify their `require` statements. All of the top-level Ice modules (`Ice`, `Glacier2`, etc.) are now accessible by including the `ice` package:

**JavaScript**

```
var Ice = require("ice").Ice;
var Glacier2 = require("ice").Glacier2;
// ...
```

Loading the generated code for your own Slice definitions looks similar. Suppose we have the following definitions in `Hello.ice`:

**Slice**

```
module Demo {
 interface Hello {
 idempotent void sayHello(int delay);
 void shutdown();
 };
};
```

To make the `Demo` module conveniently accessible in our code, we can write:

**JavaScript**

```
var Demo = require("Hello").Demo;
var proxy = Demo.HelloPrx.uncheckedCast(...);
```

Nothing has changed for browser-based JavaScript applications, where loading `Ice.js` adds the Ice definitions to the global window object, and other Ice modules (`Glacier2.js`, etc.) must be loaded individually.

Note that Ice 3.6 adds support for the WebSocket transport to the Ice core, and includes new implementations of the WebSocket transport in Java and C#. This means you no longer need to use `Glacier2` as an intermediary if your JavaScript client needs to communicate with a Java or C# server.

## Objective-C changes

The default `init` method and convenience constructor generated for Slice structures, exceptions and classes behave differently for Ice 3.6 than in previous releases. Specifically, these methods now initialize string data members to an empty string, enumerator data members to the first enumerator, and structure data members to a default-constructed value.

In previous releases, the default constructor zero-initialized these data members. Applications that depend on this behavior will require updating.

For situations where the overhead of default-constructing structure data members is undesirable, applications can call the one-shot constructor instead.

The Objective-C mapping has also relaxed its marshaling prerequisites: it is no longer necessary to initialize data members of type structure prior to an invocation. In Ice 3.6, passing a null value for a structure causes Ice to marshal a default-constructed structure.

## Ubuntu packages

Users of Ice 3.5 on Ubuntu had the choice of using Debian's packages or ZeroC's own experimental packages. We called them "experimental" because we expected we might eventually change the packaging structure, and in fact we have [changed the structure](#) for Ice

## 3.6.

Upgrading an existing installation of the ZeroC packages for Ice 3.5 on Ubuntu to Ice 3.6 is relatively straightforward. First add the Ice repository to the system and update the package list:

```
$ sudo apt-add-repository "deb http://zeroc.com/download/Ice/3.6/ubuntu14.04 stable main"
```

```
$ sudo apt-get update
```

To upgrade all of the run-time packages:

```
$ sudo apt-get install zeroc-ice-all-runtime
```

To upgrade all of the development packages:

```
$ sudo apt-get install libzeroc-ice-dev libzeroc-ice-java zeroc-ice-all-dev
```

Refer to our [binary distribution](#) page for details on the individual packages.

## Migrating IceGrid databases from Ice 3.5

Ice 3.6 supports the migration of IceGrid databases from Ice 3.3, 3.4 and 3.5. To migrate from earlier Ice versions, you will first need to migrate the databases to the Ice 3.3 format. If you require assistance with such migration, please contact [support@zeroc.com](mailto:support@zeroc.com).

To migrate, first stop the IceGrid registry you wish to upgrade.

Next, copy the IceGrid database environment to a second location:

```
$ cp -r db recovered.db
```

Locate the correct version of the Berkeley DB recovery tool (usually named `db_recover`). It is essential that you use the `db_recover` executable that matches the Berkeley DB version of your existing Ice release. For Ice 3.3, use `db_recover` from Berkeley DB 4.6. For Ice 3.4, use `db_recover` from Berkeley DB 4.8. For Ice 3.5, use `db_recover` from Berkeley DB 5.3. You can verify the version of your `db_recover` tool by running it with the `-v` option:

```
$ db_recover -v
```

Now run the utility on your copy of the database environment:

```
$ db_recover -h recovered.db
```

Change to the location where you will store the database environments for IceGrid 3.6:

```
$ cd <new-location>
```

Next, run the `upgradeicegrid36.py` utility located in the `config` directory of your Ice distribution (or in `/usr/share/Ice-3.6` if using an RPM installation). The first argument is the path to the old database environment. The second argument is the path to the new database environment.

In this example we'll create a new directory `db` in which to store the migrated database environment:

```
$ mkdir db
$ upgradeicegrid36.py <path-to-recovered.db> db
```

Upon completion, the `db` directory contains the migrated IceGrid databases.

By default, the migration utility assumes that the servers deployed with IceGrid also use Ice 3.6. If your servers still use an older Ice version, you need to specify the `--server-version` command-line option when running `upgradeicegrid36.py`:

```
$ upgradeicegrid36.py --server-version 3.5.1 <path-to-recovered.db> db
```

The migration utility will set the `server descriptor` attribute `ice-version` to the specified version and the IceGrid registry will generate configuration files compatible with the given version.

If you are upgrading the master IceGrid registry in a replicated environment and the slaves are still running, you should first restart the master registry in read-only mode using the `--readonly` option, for example:

```
$ icegridregistry --Ice.Config=config.master --readonly
```

Next, you can connect to the master registry with `icegridadmin` or the IceGrid administrative GUI from Ice 3.6 to ensure that the database is correct. If everything looks fine, you can shutdown and restart the master registry without the `--readonly` option.

IceGrid slaves from Ice 3.3, 3.4 or 3.5 won't interoperate with the IceGrid 3.6 master. You can leave them running during the upgrade of the master to not interrupt your applications. Once the master upgrade is done, you should upgrade the IceGrid slaves to Ice 3.6 using the instructions above.

## Migrating IceStorm databases from Ice 3.5

No changes were made to the database schema for IceStorm in this release. Furthermore, Ice 3.5 and Ice 3.6 use the same version of Berkeley DB (Berkeley DB 5.3.x). You can use IceStorm databases created with Ice 3.5 with Ice 3.6 without any transformation.

## Migrating Freeze databases from Ice 3.5

No changes were made that would affect the content of your [Freeze](#) databases. Furthermore, Ice 3.5 and Ice 3.6 use the same version of Berkeley DB (Berkeley DB 5.3.x). You can use Freeze databases created with Ice 3.5 with Ice 3.6 without any transformation.

## Migrating Android applications from Ice 3.5

Our recommended development environment for Android applications is [Android Studio](#). Refer to the *Using the Binary Distribution* page appropriate for your platform for instructions on configuring a project in Android Studio.

## Changed APIs

This section describes APIs whose semantics have changed, potentially in ways that are incompatible with previous releases.

The following APIs were changed in Ice 3.6:

- **String conversion in C++**  
Several changes were made to the [string conversion](#) API in C++.
- **IceSSL**  
The native [IceSSL APIs](#) changed on some platforms.
- **C++ garbage collection**  
The `Ice::collectGarbage` function was removed and replaced by a new [garbage collection](#) facility.

## Removed APIs

This section generally describes APIs that were deprecated in a previous release and have now been removed. Your application may no longer compile or operate successfully if it relies on one of these APIs.

The following APIs were removed in Ice 3.6:

- **Deprecated API for asynchronous method invocations (AMI)**  
This API, which uses proxy operations such as `sayHello_async`, was deprecated in Ice 3.4 and is no longer available. The new API should be used instead. Refer to the appropriate language mapping section for more information.
- **Stats facility**  
This functionality was deprecated in Ice 3.5 and is now provided by the [Instrumentation facility](#) and the [Metrics facet](#).
- `Ice.GC.Interval`  
`Ice.Trace.GC`  
`Ice::collectGarbage()`  
[Significant changes](#) were made to the C++ garbage collection facility.
- `Ice.MonitorConnections`

This setting is no longer necessary.

- `IceSSL::Plugin::setContext()`  
`IceSSL::Plugin::getContext()`  
These C++ methods are no longer available on Windows or OS X.
- `Ice::InitializationData::stringConverter`  
`Ice::InitializationData::wstringConverter`  
These C++ data members are no longer available. Use `IceUtil::setProcessStringConverter` and `IceUtil::setProcessWStringConverter` instead.
- `Ice::Router::addProxy()`  
`IceGrid::Admin::writeMessage()`  
`IceStorm::Topic::subscribe()`  
These Slice operations were deprecated in previous Ice releases.
- `IceUtil.Version`  
This Java class was deprecated in previous Ice releases. Use `Ice.Util.stringVersion()` and `Ice.Util.intValue()` instead.
- `Ice::Object::ice_getHash()`  
This C++ method was deprecated in Ice 3.5.
- `IcePatch2.ChunkSize`  
`IcePatch2.Directory`  
`IcePatch2.Remove`  
`IcePatch2.Thorough`  
These properties were deprecated in previous Ice releases and replaced by properties that use the prefix `IcePatch2Client`.
- `Glacier2.AddSSLContext`  
This property was deprecated in Ice 3.3.1 and replaced by `Glacier2.AddConnectionContext`.

The following components were removed in Ice 3.6:

- Qt SQL database plug-ins for IceGrid and IceStorm, which were deprecated in Ice 3.5. Freeze is now the only persistence mechanism for these services.

## Deprecated APIs

This section discusses APIs and components that are now deprecated. These APIs will be removed in a future Ice release, therefore we encourage you to update your applications and eliminate the use of these APIs as soon as possible.

The following APIs were deprecated in Ice 3.6:

- `Ice.ACM.Client`  
`Ice.ACM.Server`  
Use `Ice.ACM.Client.Timeout` and `Ice.ACM.Server.Timeout` instead. See [Active Connection Management](#) for more information.
- `IceSSL.CertAuthFile`  
Use the new property `IceSSL.CAs` to specify the path name of a PEM file containing the Root Certificate Authorities.
- `IceSSL.CertAuthDir` (OpenSSL only)  
Use the new property `IceSSL.CAs` to specify the path name of a directory containing the Root Certificate Authorities.
- `IceSSL.KeyFile`  
Use `IceSSL.CertFile` to configure the IceSSL identity using a PKCS12 file.
- `IceSSL.ImportCert.*` (.NET only)  
This property caused the IceSSL plug-in to import a certificate into a Windows certificate store. Going forward, users will need to install certificates in a store using Windows-provided tools if necessary. However, it is now possible to use trusted CA certificates from a file without loading them into a store. See `IceSSL.CAs` for more information.
- `IceSSL.PersistKeySet` (.NET only)  
Only used by the now-deprecated `IceSSL.ImportCert` property.

- `IceSSL.KeySet` (.NET only)  
Use `IceSSL.CertStoreLocation` instead.
- `IceSSL::Certificate::verify` (C++ only)  
The method `verify(const PublicKeyPtr&)` has been deprecated. The new method `verify(const CertificatePtr&)` takes its place.
- `IceBox.InstanceName`  
`IceBox.ServiceManager.AdapterProperty`  
These properties are no longer necessary because their functionality is provided by the [service manager administrative facet](#).
- `clr:collection`  
`Ice.CollectionBase`  
`Ice.DictionaryBase`  
The `clr:collection` metadata tag, along with the C# classes `Ice.CollectionBase` and `Ice.DictionaryBase`, were originally provided for backward compatibility with Ice versions prior to 3.3 and are now deprecated. Existing applications should migrate their code to use the standard C# collection types.
- `Ice::StringConverterPlugin` (C++ only)  
The `StringConverterPlugin` base class is deprecated. You should use a regular `Ice::Plugin` to install your string converter(s).
- `Ice::CollocatedOptimizationException`  
This exception is no longer used now that [collocated invocations](#) have become much more flexible.
- `Ice.BatchAutoFlush`  
This property controlled whether the Ice run time would automatically flush batch requests for a connection after enough requests had been queued to reach the limit established by `Ice.MessageSizeMax`. We're deprecating this property in favor of a new one, `Ice.BatchAutoFlushSize`, whose value Ice now uses as the limit for automatic flushing. If your application sets `Ice.BatchAutoFlush=0` to disable automatic flushing, you can achieve the same behavior by setting `Ice.BatchAutoFlushSize=0`.

## Visual C++ compiler warnings

The Ice 3.5 header files downgrade the following Visual C++ warnings to level 4:

C++
<pre># pragma warning( 4 : 4250 ) // ... : inherits ... via dominance # pragma warning( 4 : 4251 ) // class ... needs to have dll-interface to be used by clients of class ...</pre>

This downgrade affects any file that includes these Ice header files.

Ice 3.6 no longer disables or downgrades any warning in your C++ code. As a result, when upgrading to Ice 3.6, your Ice application may produce compiler warnings that were not reported before. To eliminate these warnings, you can modify your source code, add `pragmas` or [disable these warnings](#) in your Visual Studio projects.

## Upgrading your Application from Ice 3.4

In addition to the information provided in [Upgrading your Application from Ice 3.5](#), users who are upgrading from Ice 3.4 should also review this page.

On this page:

- [Deprecated APIs in Ice 3.5](#)

### Slicing behavior in Ice 3.5

In version 1.0 of the Ice encoding, Slice classes and user exceptions are always marshaled in a format that allows a receiver to "slice" an unknown derived type to a known base type. An application that uses Ice 3.4 or earlier may depend on this behavior. For example, the slicing feature makes it possible for a sender to evolve independently of a receiver, adding more derived types that the receiver does not understand without causing the receiver to fail should it encounter one of these new types.

Version 1.1 of the Ice encoding introduces two [formats](#) for classes and exceptions. The compact format, which is used by default, does not support the slicing feature, meaning an application that relies on this feature may begin to receive `NoObjectFactoryException` or `UnknownUserException` errors after upgrading to Ice 3.5. There are several possible solutions:

- Continue using version 1.0 of the Ice encoding by setting `Ice.Default.EncodingVersion` to 1.0 in all senders and receivers.
- If you wish to take advantage of other features offered by encoding version 1.1, you can make the sliced format the default by setting `Ice.Default.SlicedFormat` to 1 in all senders and receivers.
- Annotate your interfaces or operations with [metadata](#) so that the sliced format is only used where necessary.

### Slice language changes in Ice 3.5

The term `optional` is now a Slice keyword in Ice 3.5, which means existing Slice definitions that use this term as an identifier will generate an error. To continue using `optional` as an identifier, you can use the Slice syntax for escaping keywords:

Slice
<pre>struct Example {     bool \optional; };</pre>

### C++ changes in Ice 3.5

The `slice2cpp` translator no longer generates C++ comparison operators for all Slice structures. Comparison operators are only generated for structures that qualify as a [legal dictionary key type](#). To generate a comparison operator for a Slice structure that doesn't qualify as such,

you can prefix the [ "cpp:comparable" ] metadata to your Slice struct definition.

## Java changes in Ice 3.5

The generated code and supporting classes for the various Ice services are now provided as separate JAR files:

JAR File	Description
Freeze.jar	Freeze classes
Glacier2.jar	Glacier2 generated code and helper classes
Ice.jar	The core Ice run time, including the IceSSL plugin
IceBox.jar	IceBox server, generated code, admin utility
IceGrid.jar	IceGrid generated code
IcePatch2.jar	IcePatch2 generated code
IceStorm.jar	IceStorm generated code

Also note that the manifest in `Freeze.jar` no longer contains a reference to `db.jar`, so you may need to update your class path to include `db.jar`.

The Eclipse Plug-in still includes only `Ice.jar` by default, but you can easily include additional JAR files by changing the `Slice2Java` properties for your project.

## Python changes in Ice 3.5

Ice 3.5 adds support for Python 3. Developers who are migrating existing Ice applications from Python 2 to Python 3 should be aware of the following changes that affect the Python language mapping:

- One of the most significant changes in Python 3 is its unification of the unicode and string types into just one type, `str`. Python developers must convert any existing unicode literals and variables into their string equivalents. For Ice developers, a benefit of this unification is that all string values sent "over the wire" are now sent and received as unicode strings. With Python 2.x, the Ice run time behavior remains unchanged: string and unicode values are both accepted as inputs, but only string values are returned as outputs.
- The Python 3 mapping for the Slice type `sequence<byte>` now defaults to the new Python type `bytes`. A string value is no longer accepted as a legal value for `sequence<byte>` with Python 3.

## PHP changes in Ice 3.5

For compatibility with newer PHP releases, the Ice extension no longer supports "call-time" reference arguments when calling `Ice_initialize` and `Ice_createProperties`. For example, existing applications may invoke `Ice_initialize` with an explicit reference argument as follows:

**PHP**

```
$communicator = Ice_initialize(&$argv);
```

The proper way to call this function using Ice 3.5 is shown below:

### PHP

```
$communicator = Ice_initialize($argv);
```

Ice-specific arguments are now removed from the given argument vector.

## IPv6 changes in Ice 3.5

IPv6 is now enabled by default on all platforms. You can disable the use of IPv6 in Ice by setting the `Ice.IPv6` property to 0, which may be necessary in environments that lack IPv6 support. The new property `Ice.PreferIPv6Address` determines whether IPv4 or IPv6 addresses take precedence when resolving host names.

## Migrating IceGrid databases from Ice 3.4

Ice 3.5 supports the migration of IceGrid databases from Ice 3.3 and from Ice 3.4. To migrate from earlier Ice versions, you will first need to migrate the databases to the Ice 3.3 format. If you require assistance with such migration, please contact [support@zeroc.com](mailto:support@zeroc.com).

To migrate, first stop the IceGrid registry you wish to upgrade.

Next, copy the IceGrid database environment to a second location:

```
$ cp -r db recovered.db
```

Locate the correct version of the Berkeley DB recovery tool (usually named `db_recover`). It is essential that you use the `db_recover` executable that matches the Berkeley DB version of your existing Ice release. For Ice 3.3, use `db_recover` from Berkeley DB 4.6. For Ice 3.4, use `db_recover` from Berkeley DB 4.8. You can verify the version of your `db_recover` tool by running it with the `-V` option:

```
$ db_recover -V
```

Now run the utility on your copy of the database environment:

```
$ db_recover -h recovered.db
```

Change to the location where you will store the database environments for IceGrid 3.5:

```
$ cd <new-location>
```

Next, run the `upgradeicegrid35.py` utility located in the `config` directory of your Ice distribution (or in `/usr/share/Ice-3.5` if using an RPM installation). The first argument is the path to the old database environment. The second argument is the path to the new database environment.

In this example we'll create a new directory `db` in which to store the migrated database environment:

```
$ mkdir db
$ upgradeicegrid35.py <path-to-recovered.db> db
```

Upon completion, the `db` directory contains the migrated IceGrid databases.

By default, the migration utility assumes that the servers deployed with IceGrid also use Ice 3.5. If your servers still use an older Ice version, you need to specify the `--server-version` command-line option when running `upgradeicegrid35.py`:

```
$ upgradeicegrid.py --server-version 3.4.2 <path-to-recovered.db> db
```

The migration utility will set the `server descriptor` attribute `ice-version` to the specified version and the IceGrid registry will generate configuration files compatible with the given version.

If you are upgrading the master IceGrid registry in a replicated environment and the slaves are still running, you should first restart the master registry in read-only mode using the `--readonly` option, for example:

```
$ icegridregistry --Ice.Config=config.master --readonly
```

Next, you can connect to the master registry with `icegridadmin` or the IceGrid administrative GUI from Ice 3.5 to ensure that the database is correct. If everything looks fine, you can shutdown and restart the master registry without the `--readonly` option.

IceGrid slaves from Ice 3.3 or 3.4 won't interoperate with the IceGrid 3.5 master. You can leave them running during the upgrade of the master to not interrupt your applications. Once the master upgrade is done, you should upgrade the IceGrid slaves to Ice 3.5 using the instruction above.

## Migrating IceStorm databases from Ice 3.4

No changes were made to the database schema for IceStorm in this release. However, you still need to update your databases as described [below](#).

## Migrating Freeze databases from Ice 3.4

No changes were made that would affect the content of your [Freeze](#) databases. However, we upgraded the version of Berkeley DB and the new 1.1 encoding may require that you re-create your indices or set some additional configuration if you use Freeze maps. If you only use Freeze evictors, you only need to upgrade your databases to the new Berkeley DB format. See [Encoding Version 1.1](#).

## Upgrading to the Berkeley DB 5.3 format

When upgrading to Ice 3.5, you must upgrade your database to the Berkeley DB 5.3 format. The only change that affects Freeze is the format of Berkeley DB's log file.

The instructions below assume that the database environment to be upgraded resides in a directory named `db` in the current working directory. For a more detailed discussion of database migration, please refer to the [Berkeley DB Upgrade Process](#).

To migrate your database:

1. Shut down the old version of the application.
2. Make a backup copy of the database environment:

```
> cp -r db backup.db (Unix)
> xcopy /E db backup.db (Windows)
```

3. Locate the correct version of the Berkeley DB recovery tool (usually named `db_recover`). It is essential that you use the `db_recover` executable that matches the Berkeley DB version of your existing Ice release. For Ice 3.4, use `db_recover` from Berkeley DB 4.8. You can verify the version of your `db_recover` tool by running it with the `-V` option:

```
> db_recover -V
```

4. Use the `db_recover` tool to run recovery on the database environment:

```
> db_recover -h db
```

5. Recompile and install the new version of the application.
6. Force a checkpoint using the `db_checkpoint` utility. Note that you must use the `db_checkpoint` utility from Berkeley DB 5.3 when performing this step.

```
> db_checkpoint -l -h db
```

7. Restart the application.

## Freeze maps and the 1.1 encoding

The majority of Freeze maps will work out of the box with the new 1.1 encoding and without additional configuration. However there are a few cases where you will be required to take special action or add some configuration:

- If your Freeze maps use keys with Slice enumerations having more than 127 elements, the encoding of those keys will be incompatible with the 1.1 encoding. You will need to set the `Freeze.DbEnv.<env-name>.EncodingVersion` property to 1.0 to ensure that you decode the keys with the 1.0 encoding and not with the default 1.1 encoding.
- If your Freeze maps use indices and those indices use Slice classes, or use Slice enumerations having more than 127 elements, you have two options:
  1. Re-create the indices with the 1.1 encoding. To recreate your indices, you have to recreate the Freeze maps using the `recreate` method generated on the Freeze map classes by `slice2freezej`. See the [Freeze Maps](#) documentation for more information.
  2. Set the `Freeze.DbEnv.<env-name>.EncodingVersion` property to 1.0 to ensure that Freeze still uses the 1.0 encoding for your indices.
- If you use indices with Java Freeze maps and the map value uses classes, you have to recreate the indices because of a bug in the encoding of the Ice 3.4 indices. This only affects Java Freeze maps; C++ Freeze maps are not affected by this issue.

If you configure your Freeze database environment to use the 1.0 encoding, you will not be able to take advantage of the new features provided with the 1.1 encoding, such as optional values and the new formats for classes.

## Migrating Android applications from Ice 3.4

Prior versions of the Ice plug-in for Eclipse (including the version released for Ice 3.5b) created a workspace variable named `ICE_HOME` that referred to the Ice installation directory configured in Eclipse's *Preferences* dialog. After adding the Slice2Java builder to a project, the builder updated the project's build path to include Ice JAR files relative to `ICE_HOME`. For example, `Ice.jar` was configured as the library reference `ICE_HOME/lib/Ice.jar`.

As of Ice 3.5.0, the Eclipse plug-in no longer uses the `ICE_HOME` variable. Instead, it now uses the workspace variable `ICE_JAR_HOME` to refer to the subdirectory containing `Ice.jar`, equivalent to the previous setting of `ICE_HOME/lib`. Consequently, a new project's build path now includes the library reference `ICE_JAR_HOME/Ice.jar`.

The plug-in does not attempt to modify the build path of an existing Ice for Android project to use `ICE_JAR_HOME`, nor does it remove `ICE_HOME` from the workspace. An existing project can continue to use the `ICE_HOME` variable in its build path, but moving or copying the project to a new workspace where `ICE_HOME` is no longer defined means the project's build path must be updated.

## Changed APIs in Ice 3.5

This section describes APIs whose semantics have changed, potentially in ways that are incompatible with previous releases.

The following APIs were changed in Ice 3.5:

- The [dynamic invocation and dispatch](#) API now requires encapsulations for input parameters and output results. For example, when calling `ice_invoke`, the value for `inParams` must be an encapsulation of the input parameters:

### C++

```
Ice::OutputStreamPtr out = Ice::createOutputStream();
out->startEncapsulation();
// marshal parameters
out->endEncapsulation();
Ice::ByteSeq inParams;
out->finished(inParams);
// invoke operation...
```

Similarly, the byte sequence containing the results must also be an encapsulation:

**C++**

```
Ice::ByteSeq results;
// invoke operation...
Ice::InputStreamPtr in = Ice::wrapInputStream(results);
in->startEncapsulation();
// unmarshal results
in->endEncapsulation();
```

- The **streaming** API uses new methods to mark the beginning and end of objects and exceptions: `startObject/endObject` and `startException/endException`.

## Removed APIs in Ice 3.5

This section describes APIs that were deprecated in a previous release and have now been removed. Your application may no longer compile successfully if it relies on one of these APIs.

The following APIs were removed in Ice 3.5:

- `Ice.Default.CollocationOptimization`  
Use `Ice.Default.CollocationOptimized` instead.
- `proxy.CollocationOptimization`  
Use `proxy.CollocationOptimized` instead.
- `adapter.RegisterProcess`  
This property caused the Ice run time to register a proxy with the locator registry that allowed the process to be shut down remotely. The new **administrative facility** has replaced this functionality.
- `Ice.ServerId`  
As with `adapter.RegisterProcess`, this property was used primarily for IceGrid integration and has been replaced by a similar mechanism in the **administrative facility**.
- `Ice.Trace.Location`  
This property has been replaced by `Ice.Trace.Locator`.
- `Glacier2.Admin` and `IcePatch2.Admin`  
These are the names of administrative object adapters in **Glacier2** and **IcePatch2**, respectively. The functionality offered by these object adapters has been replaced by that of the **administrative facility**, therefore these adapters (and their associated configuration properties) are no longer necessary.
- `Ice.Util.generateUUID()`  
In Java use `java.util.UUID.randomUUID().toString()`. In C# use `System.Guid.NewGuid.ToString()`.
- `Object.ice_hash()`  
`ObjectPrx.ice_getHash()`  
`ObjectPrx.ice_toString()`  
Ice no longer defines hash methods for objects and proxies. To convert a proxy into a string, use the standard platform methods: `toString` in Java, `ToString` in C#.

## Deprecated APIs in Ice 3.5

This section discusses APIs and components that are now deprecated. These APIs will be removed in a future Ice release, therefore we encourage you to update your applications and eliminate the use of these APIs as soon as possible.

The following APIs were deprecated in Ice 3.5:

- `Stats` facility  
This functionality is now provided by the [Instrumentation facility](#) and the [Metrics facet](#).

The following components were deprecated in Ice 3.5:

- Qt SQL database plug-ins for IceGrid and IceStorm  
Freeze is now the only supported persistence mechanism for these services.

## Upgrading your Application from Ice 3.3

### Java language mapping changes in Ice 3.4

The Java2 language mapping, which was deprecated in Ice 3.3, is no longer supported. The Slice compiler and Ice API now use the Java5 language mapping exclusively, therefore upgrading to Ice 3.4 may require modifications to your application's source code. The subsections below discuss the language mapping features that are affected by this change and describe how to modify your application accordingly.

#### Metadata

The global metadata directives `java:java2` and `java:java5` are no longer supported and should be removed from your Slice files. The Slice compiler now emits a warning about these directives.

Support for the portable metadata syntax has also been removed. This syntax allowed Slice definitions to define custom type metadata that the Slice compiler would translate to match the desired target mapping. For example:

**Slice**

```
["java:type:{java.util.ArrayList}"] sequence<String> StringList;
```

The braces surrounding the custom type `java.util.ArrayList` directed the Slice compiler to use `java.util.ArrayList<String>` in the Java5 mapping and `java.util.ArrayList` in the Java2 mapping.

All uses of the portable metadata syntax must be changed to use the corresponding Java5 equivalent.

## Dictionaries

Now that Slice dictionary types use the Java5 mapping, recompiling your Slice files and your application may cause the Java compiler to emit "unchecked" warnings. This occurs when your code attempts to assign an untyped collection class such as `java.util.Map` to a generic type such as `java.util.Map<String, String>`. Consider the following example:

```

Slice

dictionary<string, int> ValueMap;

interface Table
{
 void setValues(ValueMap m);
};
```

A Java2 application might have used these Slice definitions as shown below:

```

Java

java.util.Map values = new java.util.HashMap();
values.put(...);

TablePrx proxy = ...;
proxy.setValues(values); // Warning
```

The call to `setValues` is an example of an unchecked conversion. We recommend that you compile your application using the compiler option shown below:

```
javac -Xlint:unchecked ...
```

This option causes the compiler to generate descriptive warnings about occurrences of unchecked conversions to help you find and correct the offending code.

## Request Contexts

The Slice type for [request contexts](#), `Ice::Context`, is defined as follows:

```

Slice

module Ice
{
 dictionary<string, string> Context;
};
```

As a dictionary, the `Context` type is subject to the same issues regarding unchecked conversions described for [#Dictionaries](#). For example,

each proxy operation maps to two overloaded methods, one that omits the trailing `Context` parameter and one that includes it:

Java
<pre>interface TablePrx {     void setValues(java.util.Map&lt;String, Integer&gt; m); // No context      void setValues(java.util.Map&lt;String, Integer&gt; m,                    java.util.Map&lt;String, String&gt; ctx); } </pre>

If your proxy invocations make use of this parameter, you will need to change your code to use the generic type shown above in order to eliminate unchecked conversion warnings.

## Enumerations

The Java2 language mapping for a Slice enumeration generated a class whose API differed in several ways from the standard Java5 enum type. Consider the following enumeration:

Slice
<pre>enum Color { red, green, blue }; </pre>

The Java2 language mapping for `Color` is shown below:

### Java

```
public final class Color
{
 // Integer constants
 public static final int _red = 0;
 public static final int _green = 1;
 public static final int _blue = 2;

 // Enumerators
 public static final Color red = ...;
 public static final Color green = ...;
 public static final Color blue = ...;

 // Helpers
 public static Color convert(int val);
 public static Color convert(String val);
 public int value();

 ...
}
```

The first step in migrating to the Java5 mapping for enumerations is to modify all `switch` statements that use an enumerator. Before Java added native support for enumerations, the `switch` statement could only use the integer value of the enumerator and therefore the Java2 mapping supplied integer constants for use in `case` statements. For example, here is a `switch` statement that uses the Java2 mapping:

### Java

```
Color col = ...;
switch(col.value())
{
case Color._red:
 ...
 break;
case Color._green:
 ...
 break;
case Color._blue:
 ...
 break;
}
```

The Java5 mapping eliminates the integer constants because Java5 allows enumerators to be used in `case` statements. The resulting code becomes much easier to read and write:

### Java

```
Color col = ...;
switch(col)
{
case red:
 ...
 break;
case green:
 ...
 break;
case blue:
 ...
 break;
}
```

The next step is to replace any uses of the `value` or `convert` methods with their Java5 equivalents. The base class for all Java5 enumerations (`java.lang.Enum`) supplies methods with similar functionality:

### Java

```
static Color[] values() // replaces convert(int)
static Color valueOf(String val) // replaces convert(String)
int ordinal() // replaces value()
```

For example, here is the Java5 code to convert an integer into its equivalent enumerator:

### Java

```
Color r = Color.values()[0]; // red
```

Note however that the `convert(String)` method in the Java2 mapping returned null for an invalid argument, whereas the Java5 enum method `valueOf(String)` raises `IllegalArgumentException` instead.

Refer to the [manual](#) for more details on the mapping for enumerations.

## Changes to the Java API for Freeze maps in Ice 3.4

The Java API for [Freeze maps](#) has been revised to use Java5 generic types and enhanced to provide additional functionality. This section describes these changes in detail and explains how to migrate your Freeze application to the API in Ice 3.4.

### General changes to Freeze maps in Java

The Freeze API is now entirely type-safe, which means compiling your application against Ice 3.4 is likely to generate unchecked conversion warnings. The generated class for a Freeze map now implements the `java.util.SortedMap<K, V>` interface, where `K` is the key type and `V` is the value type. As a result, applications that relied on the untyped `SortedMap` API (where all keys and values were treated as

instances of `java.lang.Object`) will encounter compiler warnings in Ice 3.4.

For example, an application might have iterated over the entries in a map as follows:

```

Java

```

// Old API
Object key = new Integer(5);
Object value = new Address(...);
myMap.put(key, value);
java.util.Iterator i = myMap.entrySet().iterator();
while (i.hasNext())
{
    java.util.Map.Entry e = (java.util.Map.Entry)i.next();
    Integer myKey = (Integer)e.getKey();
    Address myValue = (Address)e.getValue();
    ...
}

```

```

This code will continue to work, but the new API is both type-safe and self-documenting:

```

Java

```

// New API
int key = 5;
Address value = new Address(...);
myMap.put(key, value); // The key is autoboxed to Integer.
for (java.util.Map.Entry<Integer, Address> e : myMap.entrySet())
{
    Integer myKey = e.getKey();
    Address myValue = e.getValue();
    ...
}

```

```

Although migrating to the new API may require some effort, the benefits are worthwhile because your code will be easier to read and less prone to defects. You can also take advantage of the "autoboxing" features in Java5 that automatically convert values of primitive types (such as `int`) into their object equivalents (such as `Integer`).

Please refer to the [manual](#) for complete details on the new API.

## Enhancements to Freeze maps in Java

Java6 introduced the `java.util.NavigableMap` interface, which extends `java.util.SortedMap` to add some useful new methods. Although the Freeze map API cannot implement `java.util.NavigableMap` directly because Freeze must remain compatible with Java5, we have added the `Freeze.NavigableMap` interface to provide much of the same functionality. A generated Freeze map class implements `NavigableMap`, as do the sub map views returned by map methods such as `headMap`. The `NavigableMap` interface is described in the [manual](#), and you can also refer to the Java6 API documentation.

## Backward compatibility for Freeze maps in Java

The Freeze Map API related to indices underwent some significant changes in order to improve type safety and avoid unchecked conversion warnings. These changes may cause compilation failures in a Freeze application.

In the previous API, index comparator objects were supplied to the Freeze map constructor in a map (in Java5 syntax, this comparators map would have the type `java.util.Map<String, java.util.Comparator>`) in which the index name was the key. As part of our efforts to improve type safety, we also wanted to use the fully-specified type for each index comparator (such as `java.util.Comparator<Integer>`). However, given that each index could potentially use a different key type, it is not possible to retain the previous API while remaining type-safe.

Consequently, the index comparators are now supplied as data members of a static nested class of the Freeze map named `IndexComparators`. If your application supplied custom comparators for indices, you will need to revise your code to use `IndexComparators` instead. For example:

### Java

```
// Old API
java.util.Map indexComparators = new java.util.HashMap();
indexComparators.put("index", new MyComparator());
MyMap map = new MyMap(..., indexComparators);

// New API
MyMap.IndexComparators indexComparators = new MyMap.IndexComparators();
indexComparators.valueComparator = new MyComparator();
MyMap map = new MyMap(..., indexComparators);
```

We also encourage you to modify the definition of your comparator classes to use the Java5 syntax, as shown in the example below:

### Java

```
// Old comparator
class IntComparator implements java.util.Comparator
{
 public int compare(Object o1, Object o2)
 {
 return ((Integer)o1).compareTo(o2);
 }
}

// New comparator
class IntComparator implements java.util.Comparator<Integer>
{
 public int compare(Integer i1, Integer i2)
 {
 return i1.compareTo(i2);
 }
}
```

The second API change that might cause compilation failures is the removal of the following methods:

## Java

```
java.util.SortedMap headMapForIndex(String name, Object key);
java.util.SortedMap tailMapForIndex(String name, Object key);
java.util.SortedMap subMapForIndex(String name, Object from, Object to);
java.util.SortedMap mapForIndex(String name);
```

Again, this API cannot be retained in a type-safe fashion, therefore `slice2freezej` now generates equivalent (and type-safe) methods for each index in the Freeze map class.

Please refer to the [manual](#) for complete details on the new API.

## Finalizers in Freeze

In previous releases, Freeze for Java used finalizers to close objects such as maps and connections that the application neglected to close. Most of these finalizers have been removed in Ice 3.4, and the only remaining finalizers simply log warning messages to alert you to the fact that connections and iterators are not being closed explicitly. Note that, given the uncertain nature of Java finalizers, it is quite likely that the remaining finalizers will not be executed.

## Freeze packaging changes in Ice 3.4

All Freeze-related classes are now stored in a separate JAR file named `Freeze.jar`. As a result, you may need to update your build scripts, deployment configuration, and run-time environment to include this additional JAR file.

## PHP changes in Ice 3.4

The Ice extension for PHP has undergone many changes in this release. The subsections below describe these changes in detail. Refer to the [PHP Mapping](#) for more information about the language mapping.

### Static translation in PHP

In prior releases, Slice files were deployed with the application and loaded at Web server startup by the Ice extension. Before each page request, the extension directed the PHP interpreter to parse the code that was generated from the Slice definitions.

In this release, Slice files must be translated using the new compiler `slice2php`. This change offers several advantages:

- Applications may have more opportunities to improve performance through the use of opcode caching.
- It is no longer necessary to restart the Web server when you make changes to your Slice definitions, which is especially useful during development.
- Errors in your Slice files can now be discovered in your development environment, rather than waiting until the Web server reports a failure and then reviewing the server log to determine the problem.
- The development process becomes simpler because you can easily examine the generated code if you have questions about the API or language mapping rules.
- PHP scripts can now use all of the Ice local exceptions. In prior releases, only a subset of the local exception types were available, and all others were mapped to `Ice_UnknownLocalException`. See the section [Run-time exceptions in PHP](#) below for more information.

All of the Slice files for Ice and Ice services are translated during an Ice build and available for inclusion in your application. At a minimum, you must include the file `Ice.php`:

**PHP**

```
require 'Ice.php';
```

`Ice.php` contains definitions for core Ice types and includes a minimal set of generated files. To use an Ice service such as `IceStorm`, include the appropriate generated file:

**PHP**

```
require 'Ice.php';
require 'IceStorm/IceStorm.php';
```

## Deploying a PHP application

With the transition to static code generation, you no longer need to deploy Slice files with your application. Instead, you will need to deploy the PHP code generated from your Slice definitions, along with `Ice.php`, the generated code for the Ice core, and the generated code for any Ice services your application might use.

## Using communicators in PHP

In prior releases, each PHP page request could access a single Ice communicator via the `$ICE` global variable. The configuration of this communicator was derived from the profile that the script loaded via the `Ice_loadProfile` function. The communicator was created on demand when `$ICE` was first used and destroyed automatically at the end of the page request.

In this release, a PHP script must create its own communicator using an API that is similar to other Ice language mappings:

**PHP**

```
function Ice_initialize()
function Ice_initialize($args)
function Ice_initialize($initData)
function Ice_initialize($args, $initData)
```

`Ice_initialize` creates a new communicator using the configuration provided in the optional arguments. `$args` is an array of strings representing command-line options, and `$initData` is an instance of `Ice_InitializationData`.

An application that requires no configuration can initialize a communicator as follows:

**PHP**

```
$communicator = Ice_initialize();
```

More elaborate configuration scenarios are described in the section [#PHP configuration](#) below.

A script may optionally destroy its communicator:

## PHP

```
$communicator->destroy();
```

At the completion of a page request, Ice by default automatically destroys any communicator that was not explicitly destroyed.

### Using registered communicators in PHP

PHP applications may benefit from the ability to use a communicator instance in multiple page requests. Reusing a communicator allows the application to minimize the overhead associated with the communicator lifecycle, including such activities as opening and closing connections to Ice servers.

This release includes new APIs for registering a communicator in order to prevent Ice from destroying it automatically at the completion of a page request. For example, a session-based application can create a communicator, establish a [Glacier2](#) session, and register the communicator. In subsequent page requests, the PHP session can retrieve its communicator instance and continue using the Glacier2 session.

The [manual](#) provides more information on this feature, and a new sample program can be found in `Glacier2/hello`.

### PHP configuration

Prior releases supported four INI settings in PHP's configuration file:

- `ice.config`
- `ice.options`
- `ice.profiles`
- `ice.slice`

The `ice.slice` directive is no longer supported since Slice definitions are now compiled statically. The remaining options are still supported but their semantics are slightly different. They no longer represent the configuration of a communicator; instead, they define property sets that a script can retrieve and use to initialize a communicator.

The global INI directives `ice.config` and `ice.options` configure the default property set. The `ice.profiles` directive can optionally nominate a separate file that defines any number of named profiles, each of which configures a property set.

As before, the profiles use an INI file syntax:

```
[Name1]
config=file1
options="--Ice.Trace.Network=2 ..."
```

```
[Name2]
config=file2
options="--Ice.Trace.Locator=1 ..."
```

A new directive, `ice.hide_profiles`, overwrites the value of the `ice.profiles` directive as a security measure. This directive has a default value of 1, meaning it is enabled by default.

A script can obtain a property set using the new function `Ice_getProperties`. Called without an argument (or with an empty string), the function returns the default property set:

**PHP**

```
$props = Ice_getProperties();
```

Alternatively, you can pass the name of the desired profile:

**PHP**

```
$props = Ice_getProperties("Name1");
```

The returned object is an instance of `Ice_Properties`, which supports the standard Ice API.

For users migrating from an earlier release, you can replace a call to `Ice_loadProfile` as follows:

**PHP**

```
// PHP - Old API
Ice_loadProfile('Name1');

// PHP - New API
$initData = new Ice_InitializationData;
$initData->properties = Ice_getProperties('Name1');
$ICE = Ice_initialize($initData);
```

(Note that it is not necessary to use the symbol `$ICE` for your communicator. However, using this symbol may ease your migration to this release.)

`Ice_loadProfile` also installed the PHP definitions corresponding to your Slice types. In this release you will need to add `require statements` to include your generated code.

Finally, if you wish to manually configure a communicator, you can create a property set using `Ice_createProperties`:

**PHP**

```
function Ice_createProperties($args=null, $defaultProperties=null)
```

`$args` is an array of strings representing command-line options, and `$defaultProperties` is an instance of `Ice_Properties` that supplies default values for properties.

As an example, an application can configure a communicator as shown below:

**PHP**

```

$initData = new Ice_InitializationData;
$initData->properties = Ice_createProperties();
$initData->properties->setProperty("Ice.Trace.Network", "1");
...
$ICE = Ice_initialize($initData);

```

**PHP namespaces**

This release includes optional support for PHP namespaces, which was introduced in PHP 5.3. Support for PHP namespaces is disabled by default; to enable it, you must build the Ice extension from source code with `USE_NAMESPACES=yes` (see `Make.rules` or `Make.rules.mk` in the `php/config` subdirectory). Note that the extension only supports one mapping style at a time; installing a namespace-enabled version of the extension requires all Ice applications on the target Web server to use namespaces.

With namespace support enabled, you must modify your script to include a different version of the core Ice types:

**PHP**

```
require 'Ice_ns.php'; // Namespace version of Ice.php
```

You must also recompile your Slice files using the `-n` option to generate namespace-compatible code:

```
% slice2php -n MySliceFile.ice
```

This mapping translates Slice modules into PHP namespaces instead of using the "flattened" (underscore) naming scheme. For example, `Ice_Properties` becomes `\Ice\Properties` in the namespace mapping. However, applications can still refer to global Ice functions by their traditional names (such as `Ice_initialize`) or by their namespace equivalents (`\Ice\initialize`).

**Run-time exceptions in PHP**

As mentioned earlier, prior releases of Ice for PHP only supported a limited subset of the standard [run-time exceptions](#). An occurrence of an unsupported local exception was mapped to `Ice_UnknownLocalException`.

This release adds support for all local exceptions, which allows an application to more easily react to certain types of errors:

### PHP

```

try
{
 $proxy->sayHello();
}
catch(Ice_ConnectionLostException $ex)
{
 // Handle connection loss
}
catch(Ice_LocalException $ex)
{
 // Handle other errors
}

```

This change represents a potential backward compatibility issue: applications that previously caught `Ice_UnknownLocalException` may need to be modified to catch the intended exception instead.

## Downcasting in PHP

In prior releases, to downcast a proxy you had to invoke the `ice_checkedCast` or `ice_uncheckedCast` method on a proxy and supply a type ID:

### PHP

```
$hello = $proxy->ice_checkedCast("::Demo::Hello");
```

This API is susceptible to run-time errors because no validation is performed on the type ID string. For example, renaming the `Hello` interface to `Greeting` requires that you not only change all occurrences of `Demo_Hello` to `Demo_Greeting`, but also fix any type ID strings that your code might have embedded. The PHP interpreter does not provide any assistance if you forget to make this change, and you will only discover it when that particular line of code is executed and fails.

To improve this situation, a minimal class is now generated for each proxy type. The purpose of this class is to supply `checkedCast` and `uncheckedCast` static methods:

### PHP

```

class Demo_HelloPrx
{
 public static function checkedCast($proxy, $facetOrCtx=null,
 $ctx=null);

 public static function uncheckedCast($proxy, $facet=null);
}

```

Now your application can downcast a proxy as follows:

### PHP

```
$hello = Demo_HelloPrx::checkedCast($proxy);
```

You can continue to use `ice_checkedCast` and `ice_uncheckedCast` but we recommend migrating your application to the new methods.

## Other API changes for PHP

This section describes additional changes to the Ice API in this release:

- The global variable `$ICE` is no longer defined. An application must now initialize its own communicator as [described above](#).
- Removed the following communicator methods:

### PHP

```
$ICE->setProperty()
$ICE->getProperty()
```

The equivalent methods are:

### PHP

```
$communicator->getProperties()->setProperty()
$communicator->getProperties()->getProperty()
```

- Removed the following global functions:

### PHP

```
Ice_stringToIdentity()
Ice_identityToString()
```

The equivalent methods are:

### PHP

```
$communicator->stringToIdentity()
$communicator->identityToString()
```

- These functions have also been removed:

### PHP

```
Ice_loadProfile()
Ice_loadProfileWithArgs()
Ice_dumpProfile()
```

Refer to [PHP configuration](#) for more information.

## Thread pool changes in Ice 3.4

A [thread pool](#) supports the ability to automatically grow and shrink as the demand for threads changes, within the limits set by the thread pool's configuration. In prior releases, the rate at which a thread pool shrinks was not configurable, but Ice 3.4.0 introduces the [ThreadIdleTime](#) property to allow you to specify how long a thread pool thread must remain idle before it terminates to conserve resources.

## IceSSL changes in Ice 3.4

With the addition of the `ConnectionInfo` classes in this release, the `IceSSL::ConnectionInfo` structure has changed from a native type to a Slice class. This change has several implications for existing applications:

- As a Slice class, `IceSSL::ConnectionInfo` cannot provide the X509 certificate chain in its native form, therefore the chain is provided as a sequence of strings representing the encoded form of each certificate. You can use language-specific facilities to convert these strings back to certificate objects.
- For your convenience, we have added a native subclass of `IceSSL::ConnectionInfo` called `IceSSL::NativeConnectionInfo`. This class provides the certificate chain as certificate objects.
- The `CertificateVerifier` interface now uses `NativeConnectionInfo` instead of `ConnectionInfo`. If your application configures a custom certificate verifier, you will need to modify your implementation accordingly.
- In C++, also note that `NativeConnectionInfo`s are now managed by a smart pointer, therefore the signature of the certificate verifier method becomes the following:

### C++

```
virtual bool verify(const IceSSL::NativeConnectionInfoPtr&) = 0;
```

- The `getConnectionInfo` helper function has been removed because its functionality has been replaced by the `Connection::getInfooperation`. For example, in prior releases a C++ application would do the following:

### C++

```
Ice::ConnectionPtr con = ...
IceSSL::ConnectionInfo info = IceSSL::getConnectionInfo(con);
```

Now the application should do this:

**C++**

```
Ice::ConnectionPtr con = ...
IceSSL::ConnectionInfoPtr info =
IceSSL::ConnectionInfoPtr::dynamicCast(con->getInfo());
```

Alternatively, the application can downcast to the native class:

**C++**

```
Ice::ConnectionPtr con = ...
IceSSL::NativeConnectionInfoPtr info =
 IceSSL::NativeConnectionInfoPtr::dynamicCast(con->getInfo());
```

## Migrating IceStorm and IceGrid databases from Ice 3.3

No changes were made to the database schema for IceStorm or IceGrid in this release. However, you still need to update your databases as described [below](#).

## Migrating Freeze databases from Ice 3.3

No changes were made that would affect the content of your [Freeze](#) databases. However, we upgraded the version of Berkeley DB, therefore when upgrading to Ice 3.4 you must also upgrade your database to the Berkeley DB 4.8 format. The only change that affects Freeze is the format of Berkeley DB's log file.

The instructions below assume that the database environment to be upgraded resides in a directory named `db` in the current working directory. For a more detailed discussion of database migration, please refer to the [Berkeley DB Upgrade Process](#).

To migrate your database:

1. Shut down the old version of the application.
2. Make a backup copy of the database environment:

```
> cp -r db backup.db (Unix)
> xcopy /E db backup.db (Windows)
```

3. Locate the correct version of the Berkeley DB recovery tool (usually named `db_recover`). It is essential that you use the `db_recover` executable that matches the Berkeley DB version of your existing Ice release. For Ice 3.3, use `db_recover` from Berkeley DB 4.6. You can verify the version of your `db_recover` tool by running it with the `-v` option:

```
> db_recover -V
```

4. Use the `db_recover` tool to run recovery on the database environment:

```
> db_recover -h db
```

5. Recompile and install the new version of the application.
6. Force a checkpoint using the `db_checkpoint` utility. Note that you must use the `db_checkpointutility` from Berkeley DB 4.8 when performing this step.

```
> db_checkpoint -l -h db
```

7. Restart the application.

## Removed APIs in Ice 3.4.0

This section describes APIs that were deprecated in a previous release and have now been removed. Your application may no longer compile successfully if it relies on one of these APIs.

The following APIs were removed in Ice 3.4.0:

- `Glacier2.AddUserToAllowCategories`  
Use `Glacier2.Filter.Category.AcceptUser` instead.
- `Glacier2.AllowCategories`  
Use `Glacier2.Filter.Category.Accept` instead.
- `Ice.UseEventLog`  
Ice services (applications that use the C++ class `Ice::Service`) always use the Windows event log by default.
- `Communicator::setDefaultContext`
- `Communicator::getDefaultContext`
- `ObjectPrx:ice_defaultContext`  
Use the communicator's [implicit request context](#) instead.
- `nonmutating` keyword  
This keyword is no longer supported.
- `Freeze.UseNonmutating`  
Support for this property was removed along with the `nonmutating` keyword.
- `Ice::NegativeSizeException`  
The run time now throws `UnmarshalOutOfBoundsException` or `MarshalException` instead.
- `slice2docbook`  
This utility is no longer included in Ice.
- `Ice::AMD_Array_Object_ice_invoke`  
A new overloading of `ice_response` in the `AMD_Object_ice_invoke` class makes `AMD_Array_Object_ice_invoke` obsolete.
- Java2 mapping  
The Java2 mapping is no longer supported. Refer to [Java language mapping changes in Ice 3.4](#) for more information.

## Deprecated APIs in Ice 3.4.0

This section discusses APIs and components that are now deprecated. These APIs will be removed in a future Ice release, therefore we encourage you to update your applications and eliminate the use of these APIs as soon as possible.

The following APIs were deprecated in Ice 3.4.0:

- Asynchronous Method Invocation (AMI) interface  
The AMI interface in Ice 3.3 and earlier is now deprecated for C++, Java, and C#.
- `Glacier2.AddSSLContext`  
Replaced by `Glacier2.AddConnectionContext`.
- Standard platform methods should be used instead of the following:

#### Java

```
Ice.Object.ice_hash() // Use hashCode
Ice.ObjectPrx.ice_getHash() // Use hashCode
Ice.ObjectPrx.ice_toString() // Use toString
```

In Java, use `hashCode` and `toString`. In C#, use `GetHashCode` and `ToString`. In Ruby, use `hash` instead of `ice_getHash`.

- `Ice.Util.generateUUID()`  
In Java use `java.util.UUID.randomUUID().toString()`. In C# use `System.Guid.NewGuid().ToString()`.

## Upgrading your Application from Ice 3.2 or Earlier Releases

In addition to the information provided in [Upgrading your Application from Ice 3.3](#), users who are upgrading from Ice 3.2 or earlier should also review this page.

On this page:

- [Migrating IceStorm databases from Ice 3.2](#)
- [Migrating IceGrid databases from Ice 3.2](#)
- [Migrating Freeze databases from Ice 3.2](#)
- [Removed APIs in Ice 3.3](#)
  - [Thread per connection](#)
  - [.NET metadata](#)
  - [C++](#)
  - [Java](#)
  - [.NET](#)
  - [Python](#)
  - [General](#)
  - [Ice.LoggerPlugin](#)
- [Deprecated APIs in Ice 3.3](#)
  - [Sequences as dictionary keys](#)
  - [LocalObject](#)
  - [Ice.Trace.Location](#)
  - [Ice.Default.CollocationOptimization](#)
  - [<Adapter>.RegisterProcess](#)
  - [Ice.ServerId](#)
  - [Glacier2.Admin and IcePatch2.Admin](#)

### Migrating IceStorm databases from Ice 3.2

Ice 3.4 supports the migration of IceStorm databases from Ice 3.1 and from Ice 3.2. Migration from earlier Ice versions may work, but is not officially supported. If you require assistance with such migration, please contact [support@zeroc.com](mailto:support@zeroc.com).

To migrate, first stop your IceStorm servers.

Next, copy the IceStorm database environment to a second location:

```
$ cp -r db recovered.db
```

Locate the correct version of the Berkeley DB recovery tool (usually named `db_recover`). It is essential that you use the `db_recover` executable that matches the Berkeley DB version of your existing Ice release. For Ice 3.1, use `db_recover` from Berkeley DB 4.3.29. For Ice 3.2, use `db_recover` from Berkeley DB 4.5. You can verify the version of your `db_recover` tool by running it with the `-V` option:

```
$ db_recover -V
```

Now run the utility on your copy of the database environment:

```
$ db_recover -h recovered.db
```

Change to the location where you will store the database environments for IceStorm 3.4:

```
$ cd <new-location>
```

Next, run the `icestormmigrate` utility. The first argument is the path to the old database environment. The second argument is the path to the new database environment.

In this example we'll create a new directory `db` in which to store the migrated database environment:

```
$ mkdir db
$ icestormmigrate <path-to-recovered.db> db
```

Upon completion, the `db` directory contains the migrated IceStorm databases.

## Migrating IceGrid databases from Ice 3.2

Ice 3.4 supports the migration of IceGrid databases from Ice 3.1 and from Ice 3.2. Migration from earlier Ice versions may work, but is not officially supported. If you require assistance with such migration, please contact [support@zeroc.com](mailto:support@zeroc.com).

To migrate, first stop the IceGrid registry you wish to upgrade.

Next, copy the IceGrid database environment to a second location:

```
$ cp -r db recovered.db
```

Locate the correct version of the Berkeley DB recovery tool (usually named `db_recover`). It is essential that you use the `db_recover` executable that matches the Berkeley DB version of your existing Ice release. For Ice 3.1, use `db_recover` from Berkeley DB 4.3.29. For Ice 3.2, use `db_recover` from Berkeley DB 4.5. You can verify the version of your `db_recover` tool by running it with the `-V` option:

```
$ db_recover -V
```

Now run the utility on your copy of the database environment:

```
$ db_recover -h recovered.db
```

Change to the location where you will store the database environments for IceGrid 3.4:

```
$ cd <new-location>
```

Next, run the `upgradeicegrid.py` utility located in the `config` directory of your Ice distribution (or in `/usr/share/Ice-3.4.1` if using an RPM installation). The first argument is the path to the old database environment. The second argument is the path to the new database environment.

In this example we'll create a new directory `db` in which to store the migrated database environment:

```
$ mkdir db
$ upgradeicegrid.py <path-to-recovered.db> db
```

Upon completion, the `db` directory contains the migrated IceGrid databases.

By default, the migration utility assumes that the servers deployed with IceGrid also use Ice 3.4. If your servers still use an older Ice version, you need to specify the `--server-version` command-line option when running `upgradeicegrid.py`:

```
$ upgradeicegrid.py --server-version 3.2.1 <path-to-recovered.db> db
```

The migration utility will set the `server descriptor` attribute `ice-version` to the specified version and the IceGrid registry will generate configuration files compatible with the given version.

If you are upgrading the master IceGrid registry in a replicated environment and the slaves are still running, you should first restart the master registry in read-only mode using the `--readonly` option, for example:

```
$ icegridregistry --Ice.Config=config.master --readonly
```

Next, you can connect to the master registry with `icegridadmin` or the IceGrid administrative GUI to ensure that the database is correct. If everything looks fine, you can shutdown and restart the master registry without the `--readonly` option.

## Migrating Freeze databases from Ice 3.2

No changes were made that would affect the content of your [Freeze](#) databases. However, we upgraded the version of Berkeley DB, therefore when upgrading to Ice 3.4 you must also upgrade your database to the Berkeley DB 4.8 format. The only change that affects Freeze is the format of Berkeley DB's log file.

The instructions below assume that the database environment to be upgraded resides in a directory named `db` in the current working directory. For a more detailed discussion of database migration, please refer to the [Berkeley DB Upgrade Process](#).

To migrate your database:

1. Shut down the old version of the application.
2. Make a backup copy of the database environment:

```
> cp -r db backup.db (Unix)
> xcopy /E db backup.db (Windows)
```

3. Locate the correct version of the Berkeley DB recovery tool (usually named `db_recover`). It is essential that you use the `db_recover` executable that matches the Berkeley DB version of your existing Ice release. For Ice 3.1, use `db_recover` from Berkeley DB 4.3.29. For Ice 3.2, use `db_recover` from Berkeley DB 4.5. You can verify the version of your `db_recover` tool by running it with the `-v` option:

```
> db_recover -V
```

4. Use the `db_recover` tool to run recovery on the database environment:

```
> db_recover -h db
```

5. Recompile and install the new version of the application.
6. Force a checkpoint using the `db_checkpoint` utility. Note that you must use the `db_checkpoint` utility from Berkeley DB 4.8 when performing this step.

```
> db_checkpoint -l -h db
```

7. Restart the application.

## Removed APIs in Ice 3.3

This section describes APIs that were deprecated in a previous release and have been removed in Ice 3.3. Your application may no longer compile successfully if it relies on one of these APIs.

Please refer to [Removed APIs in Ice 3.4.0](#) for information on APIs that were removed in Ice 3.4.

## Thread per connection

The primary purpose of this concurrency model was to serialize the requests received over a connection, either because the application needed to ensure that requests are dispatched in the order they are received, or because the application did not want to implement the synchronization that might be required when using the [thread pool](#) concurrency model.

Another reason for using the thread-per-connection concurrency model is that it was required by the [IceSSL](#) plug-ins for Java and C#. This requirement has been eliminated.

The ability to serialize requests is now provided by the thread pool and enabled via a new configuration property:

```
<threadpool>.Serialize=1
```

Please refer to the [manual](#) for more details on this feature.

Aside from the potential semantic changes involved in migrating your application to the thread pool concurrency model, other artifacts of thread-per-connection may be present in your application and must be removed:

- The configuration properties `Ice.ThreadPerConnection` and `<proxy>.ThreadPerConnection`
- The proxy methods `ice_threadPerConnection` and `ice_isThreadPerConnection`

## .NET metadata

The metadata directive `cs:collection` is no longer valid. Use `[ "clr:collection" ]` instead.

## C++

The following C++ methods have been removed:

- `Application::main(int, char*[], const char*, const Ice::LoggerPtr&)`

Use `Application::main(int, char*[], const InitializationData&)` instead.

- `initializeWithLogger`
- `initializeWithProperties`
- `initializeWithPropertiesAndLogger`

Use `initialize(int, char*[], const InitializationData&)` instead.

- `stringToIdentity`
- `identityToString`

Use the equivalent [operations](#) on `Communicator`.

## Java

The following methods have been removed:

- `Application.main(String, String[], String, Logger)`

Use `Application.main(String, String[], InitializationData)` instead.

- `initializeWithLogger`
- `initializeWithProperties`
- `initializeWithPropertiesAndLogger`

Use `initialize(String[], InitializationData)` instead.

## .NET

The following methods have been removed:

- `Application.main(string, string[], string, Logger)`

Use `Application.main(string, string[], InitializationData)` instead.

- `initializeWithLogger`
- `initializeWithProperties`
- `initializeWithPropertiesAndLogger`

Use `initialize(ref string[], InitializationData)` instead.

## Python

The following methods have been removed:

- `initializeWithLogger`
- `initializeWithProperties`
- `initializeWithPropertiesAndLogger`

Use `initialize(args, initializationData)` instead.

- `stringToIdentity`
- `identityToString`

Use the equivalent [operations](#) on `Communicator`.

## General

The following methods have been removed:

- `ice_hash`
- `ice_communicator`

- `ice_collocationOptimization`
- `ice_connection`

These proxy methods were replaced by ones of the form `ice_get...`, such as `ice_getCommunicator`. `ice_collocationOptimization` is now `ice_getCollocationOptimized`.

- `ice_newIdentity`
- `ice_newContext`
- `ice_newFacet`
- `ice_newAdapterId`
- `ice_newEndpoints`

These proxy methods were replaced by ones that do not use `new` in their names. For example, `ice_newIdentity` was replaced by `ice_identity`.

### **Ice.LoggerPlugin**

This property provided a way to install a custom logger implementation. It has been replaced by a more [generalized facility](#) for installing custom loggers.

## **Deprecated APIs in Ice 3.3**

This section discusses APIs and components that are deprecated in Ice 3.3. These APIs will be removed in a future Ice release, therefore we encourage you to update your applications and eliminate the use of these APIs as soon as possible.

Please refer to [Deprecated APIs in Ice 3.4.0](#) for information on APIs that were deprecated in Ice 3.4.

### **Sequences as dictionary keys**

The use of sequences, and structures containing sequences, as the key type of a Slice dictionary is now deprecated.

### **LocalObject**

The mappings for the `LocalObject` type have changed in Java, .NET, and Python. The new mappings are shown below:

Java	<code>java.lang.Object</code>
.NET	<code>System.Object</code>
Python	<code>object</code>

The types `Ice.LocalObject` and `Ice.LocalObjectImpl` are deprecated.

### **Ice.Trace.Location**

This property has been replaced by [Ice.Trace.Locator](#).

### **Ice.Default.CollocationOptimization**

This property, as well as the corresponding proxy property, have been replaced by [Ice.Default.CollocationOptimized](#) and `<proxy>.CollocationOptimized`, respectively.

### **<Adapter>.RegisterProcess**

This property caused the Ice run time to register a proxy with the locator registry (e.g., `IceGrid`) that allowed the process to be shut down remotely. The new [administrative facility](#) has replaced this functionality.

### **Ice.ServerId**

As with `<Adapter>.RegisterProcess`, this property was used primarily for IceGrid integration and has been replaced by a similar mechanism in the [administrative facility](#).

### **Glacier2.Admin and IcePatch2.Admin**

These are the names of administrative object adapters in [Glacier2](#) and [IcePatch2](#), respectively. The functionality offered by these object adapters has been replaced by that of the [administrative facility](#), therefore these adapters (and their associated configuration properties) are deprecated.

## Platform Notes for Ice 3.6

This page provides platform-specific notes for Ice 3.6.

On this page:

- [Android notes](#)
  - [Socket connection issue in Android emulator](#)
- [Java notes](#)

### Android notes

#### Socket connection issue in Android emulator

An Ice application that attempts to connect to an invalid address can generate "spurious wakeup" messages in logcat when running under an emulator for Android 4.2 or later. This issue does not occur on hardware devices, however you can still experience lengthy delays before receiving an exception. As a defensive measure, it is a good idea to always set reasonable timeouts on your proxies to avoid unexpected delays.

### Java notes

#### IceGrid Admin GUI

The [IceGrid graphical administrative utility](#) can be used with Java7 or Java8, however the [metrics graph](#) feature is only available when running with JavaFX.

#### SSL issues in Java

##### Anonymous Diffie Hellman ciphersuites

Recent versions of Java7 and Java8 require low-strength ADH ciphersuites to be disabled when using TLS 1.0. It is no longer sufficient to use this IceSSL configuration:

```
IceSSL.Ciphers=NONE (DH_anon)
IceSSL.VerifyPeer=0
```

We recommend using this setting instead:

```
IceSSL.Ciphers=NONE (DH_anon.*AES)
IceSSL.VerifyPeer=0
```

## Entropy pool causes hangs

When using the Ice for Java SSL plug-in (IceSSL), you may experience occasional hangs. The most likely reason is that your system's entropy pool is empty. If you have sufficient system privileges, you can solve this issue by editing the file `java.home/jre/lib/security/java.security` and changing it to use `/dev/urandom` instead of `/dev/random`. If you do not have permission to modify the security file, you can also use the command-line option shown below:

```
java -Djava.security.egd=file:/dev/urandom MyClass ...
```

## IPv6 hang in Java

On systems with IPv6 enabled, you may experience [occasional hangs](#) the first time an Ice object adapter is activated within a JVM. A work-around is to disable IPv6 support by setting the Java property `java.net.preferIPv4Stack` to true. For example:

```
java -Djava.net.preferIPv4Stack=true MyClass ...
```

## SLES 12 notes

### OpenJDK 1.7.0

We do not recommend using OpenJDK 1.7.0\_85 on SLES 12. The `IceBox/configuration` test fails with an unexpected `java.io.IOException` exception from the selector implementation when run with SSL. The Oracle and IBM JDKs do not exhibit this issue and should be used for Java applications on SLES.

## Windows notes

Windows users should be aware of the following issues.

### Anti-Virus when testing WebSocket

If your anti-virus intercepts `http` traffic on localhost, a number of tests in the Ice test suite may fail due to timeouts when running the test suite with the `ws` (WebSocket) protocol. The work-around is to disable the "web access protection" feature of the anti-virus entirely or at least for localhost (127.0.0.1).

### Multicast and Windows Store Apps

Network isolation for Windows Store Apps blocks multicast datagrams on the loopback interface. As a result, `IceDiscovery` and `IceLocatorDiscovery` won't be able to discover peers listening on the loopback interface.

## Using the Windows Binary Distribution

This page provides important information for users of the Ice binary distribution on Windows platforms.

On this page:

- [Overview of the Windows binary distribution](#)

- [Ice installer registry key](#)
- [Third-party packages for Windows](#)

### Overview of the Windows binary distribution

The Ice binary distribution for Windows provides the Ice run-time and SDKs for the following programming languages and platforms:

- for C++, using Visual Studio 2010, 2012, 2013 or 2015
- for .NET, using Visual Studio 2012, 2013 or 2015
- for Java, using Java 7 or Java 8
- for Android, using Android 4.2 or later
- for PHP, using PHP 5.6

You only need the development environment for your target programming language to use this distribution. For example, if you want to build Ice applications in Java, you need to install a JDK, but do not need to install Visual Studio or PHP.

#### Ice Builders

You should also install the Ice Builder for your development environment, such as the [Ice Builder for Visual Studio](#) or the [Ice Builder for Gradle](#). These Ice Builders are not included in the Windows binary distribution, and typically support several versions of Ice.

When upgrading to a new version of Ice, please remember to update the [Ice Home configuration](#) of the Ice Builder for Visual Studio.

#### C++ run-time

The Ice binary distribution for Windows installs the Visual Studio 2013 32-bit C++ run-time on your computer. It does not install any other C++ run-time.

This allows you to execute all C++ programs installed in the main `bin` directory (such as `icegridregistry.exe` and `slice2java.exe`) without having to install Visual Studio 2013 or the [Visual Studio 2013 C++ x64 redistributable package](#). However, if you want to execute C++ programs installed in the `bin` subdirectories, such as `bin\x64\icegridregistry.exe` or `bin\vc110\icegridregistry.exe`, you need to install the corresponding Visual Studio C++ redistributable package.

### Setting up your Windows environment to use Ice

After installing Ice, read the relevant language-specific sections below to learn how to configure your environment and start programming

with Ice.

Please note that the instructions below assume that Ice was installed in the default location `C:\Program Files (x86)\ZeroC\Ice-3.6.4`.

## C++

To use Ice for C++ you need to add one or more of the Ice `bin` directories to your `PATH`. The changes you must make depend on your compiler and architecture, as listed below. If you don't want to rely on the `PATH` environment variable to locate the Ice for C++ DLLs, you can also copy the DLLs into the same directory as your executable.

### PATH Environment Variable

Assuming you set `ICE_HOME` to your Ice home installation directory, by default `C:\Program Files (x86)\ZeroC\Ice-3.6.4`:

```
set ICE_HOME=C:\Program Files (x86)\ZeroC\Ice-3.6.4
```

Add the following directory or directories to your `PATH`:

Visual Studio Version	Alias	PATH for 32-bit Applications	PATH for 64-bit Applications
Visual Studio 2015	vc140	<pre>set PATH=%ICE_HOME%\bin\vc140;%PATH%</pre>	<pre>set PATH=%ICE_HOME%\bin\vc140;%PATH%</pre>
Visual Studio 2013	vc120 (default for Ice 3.6)	<pre>set PATH=%ICE_HOME%\bin;%PATH%</pre>	<pre>set PATH=%ICE_HOME%\bin;%PATH%</pre>
Visual Studio 2012	vc110	<pre>set PATH=%ICE_HOME%\bin\vc110;%PATH%</pre>	<pre>set PATH=%ICE_HOME%\bin\vc110;%PATH%</pre>
Visual Studio 2010	vc100	<pre>set PATH=%ICE_HOME%\bin\vc100;%PATH%</pre>	<pre>set PATH=%ICE_HOME%\bin\vc100;%PATH%</pre>

### Compiler Flags

The Release versions of the Ice libraries are compiled with `/MD` to select the multi-threaded Visual C++ run-time library, while the Debug versions use `/MDd` to select the debug multi-threaded run-time library. Both versions of the Ice libraries are compiled with `/EHsc` to select an [exception handling model](#).

Your application must be compiled with the same flags as the Ice libraries:

- Release: `/MD /EHsc`
- Debug: `/MDd /EHsc`

## Import Libraries

You no longer need to list Ice import libraries such as `IceD.lib` when linking with Ice libraries. See [Linking with C++ Libraries on Windows](#) for additional details.

## ZeroC Symbol Server

The ZeroC symbol server, <https://symbols.zeroc.com>, provides debug symbols for all C++ binaries included in the Ice binary distribution for Windows.

To use this symbol server, add its URL on Visual Studio's Symbols page:

Check "Enable source server support" in Visual Studio's debugging options to allow Visual Studio to fetch the corresponding source code.

## Debug Symbols and Stack Traces for C++ Applications

Ice C++ applications can print stack traces for Ice exceptions, which can be very helpful for debugging. In order to get usable stack traces, you need to install the corresponding Ice debug symbols in a local folder, and configure your system to look for debug symbols in this folder. We recommend you do the following:

1. Download and install the [Debugging Tools for Windows](#).
2. Add these tools to your PATH, for example:

```
set PATH=C:\Program Files (x86)\Windows
Kits\10\Debuggers\x64;%PATH%
```

3. Download the debug symbols of your Ice NuGet package(s) to your local `SymbolCache` folder, with the `symchk` tool included in the

Debugging Tools for Windows. For example:

```
symchk /v /r C:\Program Files (x86)\ZeroC\Ice-3.6.4\bin* /s
SRV*%TEMP%\SymbolCache*https://symbols.zeroc.com
```

(remove the `/v` option for a quieter output)

This copies debug symbols for all the binaries in the selected folder and subfolders to `%TEMP%\SymbolCache`. `%TEMP%\SymbolCache` is also the default symbol cache folder for Visual Studio.

4. Set the environment variable `_NT_SYMBOL_PATH` to point to this local `SymbolCache` folder, for example:

```
set _NT_SYMBOL_PATH=%TEMP%\SymbolCache
```

## .NET

### Locating the .NET assemblies

To use Ice for .NET, you can either copy the .NET assemblies to the directory of your executable or add the .NET assemblies to the Global Assembly Cache (GAC).

Copying the Ice for .NET assemblies to the executable directory is the simplest solution. You can set up your Visual Studio projects to copy the assemblies by setting the `Copy Local` property to `True`. To access this property in the Solution Explorer, open the `References` folder of your project and click on the assembly to access its properties in the `Properties` panel.

You can also add the Ice for .NET assemblies to the GAC. To do this, open a command prompt window with Administrator privileges and use `gacutil`:

```
gacutil /i <library.dll>
```

The `gacutil` tool is included with your Visual Studio installation. You can find which `gacutil` you are using with the `where` command, for example:

```
where gacutil
C:\Program Files (x86)\Microsoft SDKs\Windows\v8.1A\bin\NETFX 4.5.1
Tools\x64\gacutil.exe
```

Once installed in the GAC, the assemblies will always be located correctly without having to set environment variables or copy them into the same directory as an executable.

### Line numbers for stack traces

If you've installed the Ice assemblies in the GAC and want line numbers for stack traces, you must also install the PDB (.pdb) files in the GAC. Unfortunately, you cannot do this using Explorer, so you have to do it from the command line. Open a command shell window and navigate to `C:\Windows\Microsoft.NET\assembly\GAC_MSIL\Ice` (assuming `C:\Windows` is your system root). Doing a directory listing there, you will find a directory named `v4.0_3.6.4.0__<UUID>`, for example:

```
v4.0_3.6.4.0__cdd571ade22f2f16
```

Change to that directory (making sure that you use the correct version number for this release of Ice). In this directory, you will see the `Ice.dll` you installed into the GAC in the preceding step. Now copy the `Ice.pdb` file into this directory:

```
copy C:\Program Files (x86)\ZeroC\Ice-3.6.4\Assemblies\Ice.pdb
```

## Using protocol compression

The Ice for .NET run time implements protocol compression by dynamically loading the native library `bzip2.dll` from a directory in your `PATH`. Ice disables the protocol compression feature if it is unable to load the `bzip2` library successfully.

This DLL is included in your Ice distribution, therefore the Ice `bin` directory must be added to your `PATH`:

```
set PATH=C:\Program Files (x86)\ZeroC\Ice-3.6.4\bin;%PATH%
```

On 64-bit Windows, use the following setting instead:

```
set PATH=C:\Program Files (x86)\ZeroC\Ice-3.6.4\bin\x64;%PATH%
```

If the wrong `PATH` is set, the Ice run time prints a warning to the console when it detects a `bzip2.dll` format mismatch during start-up.

## Using managed code in .NET

The main Ice for .NET assembly (`Ice.dll`) included in the Windows binary distribution uses unmanaged code. If you require only managed code then you can clone the [ice repository](#) and build Ice for .NET in a purely managed version. Note that the managed version of Ice for .NET omits support for protocol compression and for signal handling in the `Ice.Application` class.

## PHP

The Ice extension for PHP included in this installer is compiled with VC11 for compatibility with the PHP binary distribution. To use this extension, you will need a compatible PHP binary distribution as well as a compatible Web server. If you wish to use Apache, you can obtain a VC11 build of Apache from alternate sources as Apache does not provide a VC11 build (PHP [recommends](#) the builds by [Apache Lounge](#)).

If you require a version of the Ice extension for a different environment, you will need to compile the extension from source. Clone the [ice repository](#) and review the `php/INSTALL` file for details.

We provide instructions below for configuring PHP to use the Ice extension. Please defer to your web server's instructions to configure it to run PHP. These instructions make several assumptions:

- PHP is installed in `C:\PHP`
- `C:\PHP` is in your system path
- Ice is installed in `C:\Program Files (x86)\ZeroC\Ice-3.6.4`

If you have a different installation, you will need to make the appropriate changes as you follow the instructions.

### 1. Determine the location of your PHP configuration file

Check for the location of your `php.ini` file by examining the output of the `php -i` command, or by calling the `phpinfo()` function from a script, for the line `Loaded Configuration File`. For example:

```
C:\PHP\php.ini
```

If no file has been loaded then you will need to create one. PHP provides templates for development and production use:

- `C:\PHP\php.ini-development`
- `C:\PHP\php.ini-production`

Depending on your environment, copy the correct file to a new file, `C:\PHP\php.ini`, and configure it as needed. Verify that it is loaded as described above.

As an administrator, open the `php.ini` in a text editor and append the following line:

```
extension = php_ice.dll
```

The file `php_ice.dll` contains the Ice extension for PHP.

## 2. Install the Ice extension DLL

Look for the `extension_dir` setting in the output of the command `php -i`:

```
extension_dir = "C:\PHP\ext"
```

If instead the `extension_dir` setting contains a relative path, it is resolved relative to the working directory of the web server process (For example, Apache's working directory is usually its installation directory.)

Copy the DLL for the Ice extension to PHP's extension directory:

```
copy "C:\Program Files (x86)\ZeroC\Ice-3.6.4\php\php_ice.dll"
"C:\PHP\ext"
```

## 3. Verify that the dependent libraries can be loaded

Regardless of the location of PHP's extension directory, the Ice extension's dependent libraries must be located in the executable search path of the calling process, either your web server or directly from the command line.

The Ice extension depends on the following libraries:

- `bzip2.dll`
- `ice36.dll`
- `iceutil36.dll`
- `slice36.dll`

All of these files can be found in the `bin` subdirectory of your Ice installation (e.g., `C:\Program Files (x86)\ZeroC\Ice-3.6.4\bin\vc110`). To add the Ice installation directory to the system `PATH`, open the System control panel and change the system `PATH` to include `C:\Program Files (x86)\ZeroC\Ice-3.6.4\bin\vc110`. Note that Windows must be restarted for this change to take effect.

If you're using Apache and it cannot find or access a DLL, Apache startup may fail with an access violation, or the PHP module may ignore the Ice extension and continue its initialization. Consequently, a successful Apache startup does not necessarily mean that the Ice extension has been loaded. Unfortunately, the message reported by PHP in Apache's error log is not very helpful; the error might imply that it cannot find `php_ice.dll` when in fact it was able to open `php_ice.dll` but a dependent DLL was missing or inaccessible.

## 4. Review access rights

Review the access rights on PHP's extension directory, the Ice extension DLL, and its dependent libraries. For example when running as a Windows service, Apache runs in the `Local System` account (also known as `NT Authority\SYSTEM`). You can use the `icacls` utility in a command window to view and modify access rights. For example, run the following commands to review the current access rights of the Ice extension:

```
cd \PHP\ext
icacls php_ice.dll
```

## 5. Locate the Ice run-time files

Your application will also need to include at least some of the Ice for PHP run-time source files (installed in `C:\Program Files (x86)\ZeroC\Ice-3.6.4\php`). To make these files available to your application, you can either modify PHP's include path or copy the necessary files to a directory that is already in the interpreter's include path. You can determine the current include path by running the

command `php -i` and searching for an entry named `include_path`.

If you want to make the Ice run-time files available to all PHP applications on the host, you can modify the `include_path` setting in `php.ini` to add the installation directory:

```
include_path = C:\Program Files (x86)\ZeroC\Ice-3.6.4;...
```

Another option is to modify the include path from within your script prior to including any Ice run-time file:

```

PHP
ini_set('include_path', ini_get('include_path') . PATH_SEPARATOR .
'C:/Program Files (x86)/ZeroC/Ice-3.6.4/php')
require 'Ice.php'; // Load the core Ice run time definitions.
```

## Using the sample programs on Windows

The Ice sample programs are provided in a [GitHub repository](#). You can browse this repository to see build and usage instructions for all supported programming languages.

During installation, you can choose to install the sample programs for all supported programming languages in a folder of your choice (by default a sub-folder of your `Documents` folder). You'll then find a shortcut to this folder in your Start menu.

Alternatively, you can clone the `ice-demos` repository and use its 3.6 branch:

```
git clone -b 3.6 https://github.com/zeroc-ice/ice-demos.git
cd ice-demos
```

## Configuration files for IceGrid and Glacier2 services

The `config` subdirectory of your Ice installation includes sample configuration files for the Glacier2 router, IceGrid node, and IceGrid registry. These files provide a good starting point on which to base your own configurations, and they contain comments that describe the settings in detail.

The [Ice manual](#) provides more information on installing and running the IceGrid registry, IceGrid node, and Glacier2 router as Windows services.

## Starting IceGrid Admin on Windows

You can launch IceGrid Admin using the shortcut that the Ice installer created in your Start menu as **IceGrid Admin**. IceGrid Admin is a Java program and requires JRE 7u6 or later.

## Unattended installation

The Ice installer supports unattended installation. For example, in an administrative command window you can run:

```
start /wait Ice-3.6.4.msi /qn /l*v install.log
```

Windows may prompt you to confirm the installation, otherwise the installer runs using its default configuration (i.e., default installation directory with no optional components) but without any user interface. The installer will create a log of its activities in the file `install.log`.

Use the `/qb` option instead to install the default configuration while showing a progress dialog:

```
start /wait Ice-3.6.4.msi /qb /l*v install.log
```

## Ice installer registry key

The Ice installer adds information to the Windows registry to indicate where it was installed. Developers can use this information to locate the Ice files in their applications.

The registration key used by this installer is:

```
HKEY_LOCAL_MACHINE\Software\ZeroC\Ice 3.6.4
```

The install location is stored as a string value named `InstallDir`.

## Third-party packages for Windows

The binary distribution for Windows includes the following third-party packages as separate binaries:

- Berkeley DB 5.3.28 (C/C++ and Java run-time)
- Bzip2 1.0.6 (C run-time)
- Expat 2.1.0 (C run-time)

## Using the Linux Binary Distributions

This page provides important information for users of the Ice binary distributions on Linux platforms.

## Overview of the Ice Binary Distributions for Linux

### Ubuntu Packages

ZeroC provides the following packages for Ubuntu:

Package	Description
<code>zeroc-ice-all-dev</code>	Meta package that installs all development packages
<code>zeroc-ice-all-runtime</code>	Meta package that installs all run-time packages, servers and utilities
<code>libzeroc-freeze3.6</code>	Freeze for C++ run-time libraries
<code>libzeroc-ice-dev</code>	C++ header files, libraries, and Slice compiler for C++
<code>libzeroc-ice-java</code>	Java development kit, including JAR files and Slice compiler for Java
<code>libzeroc-ice3.6</code>	C++ run-time libraries
<code>libzeroc-icestorm3.6</code>	IceStorm service for IceBox C++
<code>php5-zeroc-ice</code>	PHP extension and run time files
<code>php5-zeroc-ice-dev</code>	Slice compiler for PHP development
<code>zeroc-glacier2</code>	Glacier2 service
<code>zeroc-ice-slice</code>	Slice files
<code>zeroc-ice-utils</code>	Utilities necessary for administering an Ice installation
<code>zeroc-ice-utils-java</code>	Additional utilities that require Java, such as the IceGrid Admin GUI
<code>zeroc-icebox</code>	IceBox server for C++
<code>zeroc-icegrid</code>	IceGrid service
<code>zeroc-icepatch2</code>	IcePatch2 service

## Debian Packages

ZeroC provides the following packages for Debian:

Package	Co-installable	Description
<i>zeroc-ice-all-dev</i>	no	Meta package that installs all development packages
<i>zeroc-ice-all-runtime</i>	no	Meta package that installs all run-time packages, servers and utilities
<i>libzeroc-freeze3.6</i>	yes	Freeze for C++ run-time libraries
<i>libzeroc-ice-dev</i>	yes	Ice for C++ libraries and header files
<i>libzeroc-ice3.6</i>	yes	C++ run-time libraries
<i>libzeroc-ice3.6-java</i> (Debian 9)	n/a	Ice for Java run-time libraries
<i>libzeroc-icestorm3.6</i>	yes	IceStorm publish-subscribe event distribution service
<i>php-zeroc-ice</i> (Debian 9)	no	PHP extension
<i>python3-zeroc-ice</i> (Debian 9)	no	Python 3 extension
<i>zeroc-glacier2</i>	no	Glacier2 service
<i>zeroc-ice-compilers</i>	no	Slice compilers for developing Ice applications
<i>zeroc-ice-slice</i>	n/a	Slice files
<i>zeroc-ice-utils</i>	no	Ice utilities and admin tools
<i>zeroc-icebox</i>	no	IceBox server for C++
<i>zeroc-icegrid</i> (Debian 9)	no	IceGrid service
<i>zeroc-icegridgui</i> (Debian 9)	n/a	IceGrid GUI admin tool
<i>zeroc-icepatch2</i> (Debian 9)	no	IcePatch2 service

A co-installable package is a package for which you can install several architectures (amd64, armhf...) at the same time.

The main difference between the Ubuntu and Debian packages is the location of the Slice compilers. With the Ubuntu packages, they are packaged alongside the other dev-kit files, for example `slice2cpp` is included in `libzeroc-ice-dev`. With the Debian packages, all the Slice compilers are in the `zeroc-ice-compilers` package.

## RPM Packages

ZeroC provides the following RPMs for Red Hat Enterprise Linux, SUSE Linux Enterprise Server, and Amazon Linux:

RPM	Description
<i>ice-all-devel</i>	Meta package that installs all development packages

<code>ice-all-runtime</code>	Meta package that installs all run-time packages, servers and utilities
<code>glacier2</code>	Glacier2 service
<code>ice-utils</code>	Utilities necessary for administering an Ice installation
<code>ice-utils-java</code>	Additional utilities that require Java, such as the IceGrid Admin GUI
<code>ice-slice</code>	Slice files
<code>icebox</code>	IceBox server for C++
<code>icegrid</code>	IceGrid service
<code>icepatch2</code>	IcePatch2 executable
<code>libfreeze3.6-c++</code>	Freeze for C++ run-time libraries
<code>libice-c++-devel</code>	C++ header files, libraries, and Slice compiler for C++
<code>libice-java</code>	Java development kit, including JAR files and Slice compiler for Java
<code>libice3.6-c++</code>	C++ run-time libraries
<code>libicestorm3.6</code>	IceStorm service
<code>php-ice</code>	PHP extension and run time files
<code>php-ice-devel</code>	Slice compiler for PHP development

ZeroC also supplies RPMs for the following third-party packages:

RPM	Description
<code>db53</code>	Berkeley DB 5.3.28 C and C++ run time libraries
<code>db53-devel</code>	C++ development files for Berkeley DB 5.3.28
<code>db53-java</code>	Berkeley DB 5.3.28 Java run time
<code>db53-utils</code>	Berkeley DB 5.3.28 command-line utilities
<code>mcpp-devel</code>	MCCP C++ preprocessor library

The `db53` packages are supplied only for Amazon Linux, Red Hat Enterprise Linux 6 and SUSE Linux Enterprise Server. The `db53-devel` and the `mcpp-devel` RPMs are only necessary for building Ice from source.

On Red Hat Enterprise Linux 7, Berkeley DB 5.3 is available as packages `libdb-cxx`, `libdb-java` and `libdb-utils`; some of these packages are in the `rhel-7-server-optional-rpms` repository that you may need to [enable on your system](#).

## Bi-Arch Support

Recent Linux releases such as RHEL 7 are moving away from separate 64-bit and 32-bit distributions and migrating to a single 64-bit release that includes support for 32-bit packages. On these systems, all of the Ice packages listed above are provided for the `x86_64` architecture, along with a limited subset of packages for the `x86` architecture. The subset includes C++ run-time and development libraries, along with 32-bit versions of the [IceBox](#) server and [IceStorm](#) service. The 32-bit IceBox package installs the executables as `icebox32` and `icebox32++11`; the latter is used for IceBox services built in C++11 mode, as described in the C++ section below.

For development purposes, you will still need to install the 64-bit development kit packages: the 32-bit development kit packages complement these 64-bit packages.

On other systems, such as Amazon Linux and SLES 12, we only provide packages for the `x86_64` architecture.

## Installing the Linux Packages

This section describes how to install Ice binary packages for all of the supported Linux platforms.

## Installing Ice on Ubuntu

Follow the instructions below to install Ice on Ubuntu.

1. Install ZeroC's key to avoid warnings with unsigned packages:

```
sudo apt-key adv --keyserver keyserver.ubuntu.com --recv
5E6DA83306132997
```

2. Add the Ice repository to your system:

```
sudo apt-add-repository "deb
http://zeroc.com/download/Ice/3.6/ubuntu`lsb_release -rs` stable main"
```

3. Update the package list and install:

```
sudo apt-get update
sudo apt-get install zeroc-ice-all-runtime zeroc-ice-all-dev
```

Refer to the [package summary](#) if you would like to install fewer packages.

The metapackages `zeroc-ice-all-runtime` and `zeroc-ice-all-dev` reference the required Berkeley DB dependencies from the Universe repository. You need to install `db5.3-util` separately to perform admin tasks such as hot backups on your Berkeley DB databases with command-line utilities:

```
sudo apt-get install db5.3-util
```

4. Install the source package (optional):

```
sudo apt-get source zeroc-ice3.6
```

## Installing Ice on Debian 9 (stretch)

Ice is included in the Debian 9 (stretch) distribution: <https://packages.debian.org/source/stretch/zeroc-ice>.

You can install all Ice packages with:

```
sudo apt-get install zeroc-ice-all-runtime zeroc-ice-all-dev
```

Refer to the [package summary](#) if you would like to install fewer packages.

The metapackages `zeroc-ice-all-runtime` and `zeroc-ice-all-dev` reference the required Berkeley DB dependencies. You need to install `db5.3-util` separately to perform admin tasks such as hot backups on your Berkeley DB databases with command-line utilities:

```
sudo apt-get install db5.3-util
```

Debian 9 provides Ice packages for many architectures, including amd64 and armhf.

## Installing Ice on Red Hat Enterprise Linux 7

Follow the instructions below to install Ice on RHEL 7:

1. Add the Ice repositories to your system:

```
cd /etc/yum.repos.d
sudo wget https://zeroc.com/download/Ice/3.6/el7/zeroc-ice3.6.repo
```

2. Install Ice:

```
sudo yum install ice-all-runtime ice-all-devel
```

Refer to the [package summary](#) if you would like to install fewer packages.

The [yum documentation](#) provides more information about installing packages on RHEL 7.

Notes:

- Although RHEL 7 is a 64-bit operating system, we continue to support 32-bit applications by providing i686 versions of IceBox, IceStorm, C++ run-time libraries, and C++ development libraries, for example:

```
sudo yum install libzeroc-ice-dev.i686
```

- This distribution depends on the Berkeley DB packages included with RHEL 7:

```
sudo yum list 'libdb*'
```

You will need to install `libdb-utils` to perform admin tasks such as hot backups on your Berkeley DB databases with command-line utilities:

```
sudo yum install libdb-utils
```

## Installing Ice on Red Hat Enterprise Linux 6

Follow the instructions below to install Ice on RHEL 6:

1. Add the Ice repositories to your system:

```
cd /etc/yum.repos.d
sudo wget https://zeroc.com/download/Ice/3.6/el6/zeroc-ice3.6.repo
```

## 2. Install Ice:

```
sudo yum install ice-all-runtime ice-all-devel
```

Refer to the [package summary](#) if you would like to install fewer packages.

The [yum documentation](#) provides more information about installing packages on RHEL 6.

### Notes:

- This distribution depends on Berkeley DB packages included in our third-party repository:

```
sudo yum list 'db53*'
```

You will need to install `db53-utils` to perform admin tasks such as hot backups on your Berkeley DB databases with command-line utilities:

```
sudo yum install db53-utils
```

## Installing Ice on Amazon Linux

Follow the instructions below to install Ice on Amazon Linux:

### 1. Add the Ice repositories to your system:

```
cd /etc/yum.repos.d
sudo wget https://zeroc.com/download/Ice/3.6/amzn1/zeroc-ice3.6.repo
```

### 2. Install Ice:

```
sudo yum install ice-all-runtime ice-all-devel
```

Refer to the [package summary](#) if you would like to install fewer packages.

The [EC2 documentation](#) provides more information about installing packages on Amazon Linux.

### Notes:

- This distribution depends on Berkeley DB packages included in our third-party repository:

```
sudo yum list 'db53*'
```

You will need to install `db53-utils` to perform admin tasks such as hot backups on your Berkeley DB databases with command-line utilities:

```
sudo yum install db53-utils
```

## Installing Ice on SUSE Linux Enterprise Server 12

Follow the instructions below to install Ice on SLES 12:

1. Add the Ice repositories to your system:

```
sudo rpmkeys --import
https://zeroc.com/download/GPG-KEY-zeroc-release-5E6DA83306132997
wget https://zeroc.com/download/Ice/3.6/sles12/zeroc-ice3.6.repo
sudo zypper addrepo zeroc-ice3.6.repo
```

2. Install Ice:

```
sudo zypper install ice-all-runtime ice-all-devel
```

Refer to the [package summary](#) if you would like to install fewer packages.

Notes:

- This distribution depends on Berkeley DB packages included in our third-party repository:

```
sudo zypper search 'db53*'
```

You will need to install `db53-utils` to perform admin tasks such as hot backups on your Berkeley DB databases with command-line utilities:

```
sudo zypper install db53-utils
```

## Installing Ice on SUSE Linux Enterprise Server 11

Follow the instructions below to install Ice on SLES 11:

1. Add the Ice repositories to your system:

```
wget https://zeroc.com/download/Ice/3.6/sles11/zeroc-ice3.6.repo
sudo zypper addrepo zeroc-ice3.6.repo
```

2. Install Ice:

```
sudo zypper install ice-all-runtime ice-all-devel
```

Refer to the [package summary](#) if you would like to install fewer packages.

Notes:

- This distribution depends on Berkeley DB packages included in our third-party repository:

```
sudo zypper search 'db53*'
```

You will need to install `db53-utils` to perform admin tasks such as hot backups on your Berkeley DB databases with command-line utilities:

```
sudo zypper install db53-utils
```

## Setting up your Linux environment to use Ice

After installing Ice, read the relevant language-specific sections below to learn how to configure your environment and start programming with Ice.

### C++

A C++ program needs to link with at least `libIce` and `libIceUtil`, so a typical link command would look like this:

```
c++ -o myprogram myprogram.o -pthread -lIce -lIceUtil
```

Additional libraries are necessary if you are using an Ice service such as IceGrid or Glacier2.

Always use the `-pthread` option when compiling and linking your Ice applications.

### C++11 Libraries

If you build your C++ program in C++11 or C++14 mode (with `-std=c++0x`, `-std=gnu++0x`, `-std=c++11`, `-std=gnu++11`, `-std=c++14`, `-std=gnu++14`), and this mode is not your compiler's default mode, we recommend you link your application with the Ice C++11 libraries included in your binary distribution. For 32-bit programs:

```
c++ -std=c++11 -o myprogram myprogram.o -pthread -L/usr/lib/c++11 -lIce
-lIceUtil
```

For 64-bit programs:

```
c++ -std=c++11 -o myprogram myprogram.o -pthread -L/usr/lib64/c++11
-lIce -lIceUtil
```

When you build your source code with the C++11 or C++14 mode but don't use any of the extra C++ functions that Ice exposes in C++11 mode, you can either:

- link with the Ice C++11 libraries (recommended),

- or
- link with the default (C++98) Ice libraries, but only if you also compile the code generated by `slice2cpp` in C++98 mode

## Linking with Static Libraries

The Ice C++ packages always include shared libraries. On Debian 8 (jessie), the Ice C++ package also includes static libraries.

The static library `libIce.a` contains the symbols for Ice and IceUtil, and also for all Ice plug-ins (IceSSL, IceDiscovery and IceLocatorDiscovery). Other libraries (`libIceGrid.a`, `libIceStorm.a` etc.) contain symbols for applications that call IceGrid, IceStorm, etc.

Use the following command to link your application with the static Ice library (`libIce.a`):

```
c++ -o client Hello.o Client.o -Wl,-Bstatic -lIce -Wl,-Bdynamic -lcrypto
-lssl -pthread -lbz2 -ldl -lrt
```

For an application built with `--std=c++11`:

```
c++ -std=c++11 -o client Hello.o Client.o -Wl,-Bstatic
-L/usr/lib/x86_64-linux-gnu/c++11/lib -lIce -Wl,-Bdynamic -lcrypto -lssl
-pthread -lbz2 -ldl -lrt
```

When linking with the static Ice library, you need to call [register functions](#) to load Ice plug-ins.

## PHP

The Ice extension for PHP is loaded automatically when the interpreter loads the contents of the file `/etc/php.d/ice.ini` (on Red Hat Enterprise Linux and Amazon Linux) or `/etc/php5/conf.d/ice.ini` (on SUSE Linux Enterprise Server and Ubuntu). This file contains the line shown below:

```
extension=IcePHP.so
```

You can modify this file to include additional [configuration directives](#).

At run time, the PHP interpreter requires the Ice shared libraries.

You can verify that the Ice extension is installed properly by examining the output of the `php -m` command, or by calling the `phpinfo()` function from a script.

Your application will also need to include at least some of the Ice for PHP run-time source files (installed in `/usr/share/php` on RHEL, Amazon Linux, and Ubuntu, and in `/usr/share/php5` on SLES). This installation directory is included in PHP's default include path, which you can verify by executing the following command:

```
php -i | grep include_path
```

If the installation directory is listed, no further action is necessary to make the run-time source files available to your application. Otherwise,

you can modify the `include_path` setting in `php.ini` to add the installation directory:

```
include_path = /usr/share/php:...
```

Another option is to modify the include path from within your script prior to including any Ice run-time file:

```

PHP
ini_set('include_path', ini_get('include_path') . PATH_SEPARATOR .
'/usr/share/php');
require 'Ice.php'; // Load the core Ice run time definitions.
```

### SELinux Notes (for Red Hat Enterprise Linux users)

SELinux augments the traditional Unix permissions with a number of new features. In particular, SELinux can prevent the `httpd` daemon from opening network connections and reading files without the proper SELinux types.

If you suspect that your PHP application does not work due to SELinux restrictions, we recommend that you first try it with SELinux disabled. As root, run:

```
setenforce 0
```

to disable SELinux until the next reboot of your computer.

If you want to run `httpd` with the Ice extension and SELinux enabled, you must do the following:

1. Allow `httpd` to open network connections:

```
setsebool httpd_can_network_connect=1
```

You can add the `-P` option to make this setting persistent across reboots.

2. Make sure any `.ice` file used by your PHP scripts can be read by `httpd`. The enclosing directory also needs to be accessible. For example:

```
chcon -R -t httpd_sys_content_t /opt/MyApp/slice
```

For more information on SELinux in Red Hat Enterprise Linux, refer to this [Red Hat document](#).

## Using the sample programs on Linux

Sample programs for all programming languages are available in a separate [GitHub repository](#). Simply clone this repository and use its 3.6 branch:

```
git clone -b 3.6 https://github.com/zeroc-ice/ice-demos.git
cd ice-demos
```

## Starting IceGrid Admin on Linux

You can launch IceGrid Admin with the `icegridgui` command. IceGrid Admin is a Java program and requires JRE 7u6 or later.

## Startup scripts for IceGrid and Glacier2 services

All distributions include the following service configuration files:

- `/etc/icegridregistry.conf`
- `/etc/icegridnode.conf`
- `/etc/glacier2router.conf`

Distributions which use `sysvinit` or `upstart` contain the following sample scripts:

- `/etc/init.d/icegridregistry`
- `/etc/init.d/icegridnode`
- `/etc/init.d/glacier2router`

Distributions which use `systemd` contain the following services:

- `icegridregistry.service`
- `icegridnode.service`
- `glacier2router.service`

The installation also creates a user account and group for running these services (account `ice` and group `ice`), and data directories for `icegridregistry` and `icegridnode` (`/var/lib/ice/icegrid/registry` and `/var/lib/ice/icegrid/node1`).

By default, all these services are off at all runlevels. You need to manually switch on one or more runlevels, for example:

```
#
On a Red Hat Enterprise Linux 6 system, configure the icegridregistry
to start at runlevel 3 and 5:
#
sudo chkconfig --level 35 icegridregistry on

#
On a SUSE Linux Enterprise Server 11 system, configure the
icegridregistry to start at runlevel 3 and 5:
#
sudo chkconfig icegridregistry 35

#
On an Ubuntu system, configure the icegridregistry to start at the
default run levels:
#
sudo update-rc.d icegridregistry defaults

#
On systems using systemd, start icegridregistry with the multi-user
target
#
sudo systemctl enable icegridregistry.service
```

Before doing so, please review the script itself and its associated configuration file.

## Using the macOS Binary Distribution

This page provides important information for users of the Ice binary distribution for macOS.

On this page:

- [Overview of the macOS binary distribution](#)
- [Installing the macOS binary distribution](#)
- [Setting up your macOS environment to use Ice](#)
  - [C++](#)
  - [Objective-C](#)
  - [PHP](#)
  - [Berkeley DB utilities](#)
- [Using the sample programs on macOS](#)
- [Starting IceGrid Admin on macOS](#)

### Overview of the macOS binary distribution

Ice for C++, Java, Objective-C, and PHP on macOS are provided through [Homebrew](#). The `ice@3.6` formula includes the following components by default:

- Run-time libraries for C++, Objective-C and PHP
- Run-time libraries for the Freeze service in C++
- Executables for IceGrid, IceStorm, Glacier2, and IcePatch2 services
- Tools and libraries for developing Ice applications

More information about Homebrew is available at <http://brew.sh>.

By default, the `ice@3.6` formula does build any Java component - this includes Ice for Java, the Freeze service for Java, and the IceGrid Admin graphical tool.

### Installing the macOS binary distribution

Using [Homebrew](#), you can install the distribution with this command:

```
brew install zeroc-ice/tap/ice@3.6 [--with-java]
```

The `--with-java` option builds the Java components and the IceGrid Admin app. You can also install IceGrid Admin on its own by downloading [IceGrid Admin.dmg](#).

### Setting up your macOS environment to use Ice

After installing Ice, read the relevant language-specific sections below to learn how to configure your environment and start programming with Ice.

#### C++

The distribution includes libraries built with LLVM `libc++`. These libraries also support C++11 applications when compiled with the `--std=c++11` option.

When compiling Ice for C++ programs, you must pass the `-pthread` option. A typical compile command would look like this:

```
c++ -c -pthread myprogram.cpp
```

When linking a program you must link with at least `libIce` and `libIceUtil`. A typical link command would look like this:

```
c++ -o myprogram myprogram.o -lIce -lIceUtil
```

Additional libraries are necessary if you are using an Ice service such as IceGrid or Glacier2.

If you want to include Ice in your application bundle, you will need to copy the necessary Ice libraries to the `Contents/Frameworks` subdirectory of your bundle and use `@loader_path/../Frameworks` as the run path when linking the application.

Please refer to the `dyld` man page on your macOS system to learn more about `@loader_path`.

## Objective-C

When compiling Ice for Objective-C programs, you must pass the `-pthread` option. A typical compile command would look like this:

```
cc -c -pthread myprogram.m
```

When linking a program you must link with `libIceObjC`. A typical link command would look like this:

```
cc -o myprogram myprogram.o -lIceObjC -framework Foundation
```

Additional libraries are necessary if you are using an Ice service such as IceGrid or Glacier2.

If you want to include Ice in your application bundle, you will need to copy the necessary Ice libraries to the `Contents/Frameworks` subdirectory of your bundle and use `@loader_path/../Frameworks` as the run path when linking the application.

Please refer to the `dyld` man page on your macOS system to learn more about `@loader_path`.

## PHP

The macOS distribution includes the Ice extension for PHP and the Slice-to-PHP compiler (`slice2php`).

The PHP interpreter loads the Ice extension automatically when you add the following directive to `/etc/php.ini`:

```
extension=/usr/local/php/extensions/IcePHP.dylib
```

Additional configuration directives can also be added to `/etc/php.ini`.

You can verify that the Ice extension is installed properly by examining the output of the `php -m` command, or by calling the `phpinfo()` function from a script.

Your application will also need to include at least some of the Ice for PHP run-time source files (installed in `/usr/local/lib/share/php`). You can modify the `include_path` setting in `php.ini` to add the installation directory:

```
include_path = /usr/local/lib/share/php:...
```

Another option is to modify the include path from within your script prior to including any Ice run-time file:

**PHP**

```
ini_set('include_path', ini_get('include_path') . PATH_SEPARATOR .
'/usr/local/opt/ice/lib/share/php');
require 'Ice.php'; // Load the core Ice run time definitions.
```

**Berkeley DB utilities**

Berkeley DB utilities are installed in `/usr/local/opt/ice/libexec/bin`. You may add this directory to your `PATH`, or call the executables directly.

**Using the sample programs on macOS**

Sample programs for all programming languages are available in a separate [GitHub repository](#). Simply clone this repository and use its 3.6 branch:

```
git clone -b 3.6 https://github.com/zeroc-ice/ice-demos.git
cd ice-demos
```

**Starting IceGrid Admin on macOS**

You can launch IceGrid Admin with the `IceGridAdmin` application installed in your `/Applications` directory. This app is a Java program and requires JRE 7u6 or later.

## Building Ice Applications in Java

This page provides important information for Java developers.

On this page:

- [Prerequisites](#)
- [Maven Repository](#)
- [Bzip2](#)
- [Freeze and Berkeley DB](#)
- [Using the Sample Programs](#)

### Prerequisites

In order to build applications with Ice in Java, you need:

1. the Ice JAR files (`ice.jar`, `icediscovery.jar`, `icegrid.jar`, etc.)  
These JAR files are provided through Maven, as described below. The Ice binary distributions for most platforms include these JAR files as well.
2. the `slice2java` compiler  
`slice2java` is a command-line tool written in C++ and available on most platforms

Platform	Ice Package with <code>slice2java</code>	System Package?
Debian 9 (stretch)	<code>zeroc-ice-compilers</code>	yes
Ubuntu	<code>libzeroc-ice-java</code>	no
RHEL, SLES, Amazon Linux	<code>libice-java</code>	no
macOS	always installed with Ice	no
Windows	always installed with Ice	no

3. the `db.jar` file and associated Berkeley DB C library, if you are using [Freeze](#)

Platform	Package with <code>db.jar</code> 5.3	System Package?
Debian, Ubuntu	<code>libdb5.3-java</code>	yes
RHEL 7	<code>libdb-java</code>	yes
RHEL 6, SLES, Amazon Linux	<code>db53-java</code>	no
macOS	always installed with Ice	no
Windows	always installed with Ice	no

4. the [Ice Builder for Gradle](#), if you are using Gradle.

### Maven Repository

You can fetch all Ice build artifacts from the [Maven Central](#) repository. ZeroC provides the following JAR files, all in group `com.zeroc` with version `3.6.4`:

Name	Description
<code>freeze</code>	Persistent storage for Ice objects

glacier2	Generated proxy and skeleton classes plus helper classes for connecting to the Glacier2 service
ice	The Ice core classes plus the IceSSL plug-in
icebox	The IceBox server, and generated proxy and skeleton classes for connecting to IceBox
icediscovery	The IceDiscovery plug-in
icegrid	Generated proxy and skeleton classes for connecting to the IceGrid service
icelocatordiscovery	The IceLocatorDiscovery plug-in
icepatch2	Generated proxy and skeleton classes for connecting to the IcePatch2 service
icestorm	Generated proxy and skeleton classes for connecting to the IceStorm service

## Bzip2

Ice for Java supports protocol compression using the bzip2 implementation included with `ant`. Compression is automatically enabled if these classes are present in your `CLASSPATH`. You can either add `ant.jar` to your `CLASSPATH`, or download only the bzip2 classes from <http://www.kohsuke.org/bzip2>.

You can also retrieve this bzip2 JAR file from ZeroC's Maven repository located at <https://repo.zeroc.com/nexus/content/repositories/thirdparty>.

groupid	version	artifactId
org.apache.tools	1.0	bzip2

These classes are a pure Java implementation of the bzip2 algorithm and therefore add significant latency to Ice requests.

## Freeze and Berkeley DB

In order to build with Freeze for Java, you need to add both `freeze-3.6.4.jar` and the Berkeley DB JAR file (`db.jar`) to your build path.

Platform	Default directory for db.jar
Linux	<code>/usr/share/java</code>
macOS	<code>/usr/local/share/java</code>
Windows	<code>C:\Program Files (x86)\ZeroC\Ice-3.6.4\lib</code>

Then, when you run a Freeze-based application, the JVM requires that the directory containing Berkeley DB's C library be listed in its `java.library.path`. You can set `java.library.path` explicitly (with `java -Djava.library.path=...`) or through an environment variable: `LD_LIBRARY_PATH` on Linux and `PATH` on Windows.

Platform	Directory of the Berkeley DB C library
RHEL, SLES, AMZN 32-bit	<code>/usr/lib</code>
RHEL, SLES, AMZN 64-bit	<code>/usr/lib64</code>
Debian, Ubuntu i386	<code>/usr/lib/i386-linux-gnu</code>
Debian, Ubuntu x86_64	<code>/usr/lib/x86_64-linux-gnu</code>

macOS	/usr/local/opt/berkeley-db53/lib
Windows 32-bit	C:\Program Files (x86)\ZeroC\Ice-3.6.4\bin
Windows 64-bit	C:\Program Files (x86)\ZeroC\Ice-3.6.4\bin\x64

## Using the Sample Programs

Sample programs are available at the [ice-demos GitHub repository](#). You can browse this repository to see build and usage instructions for all supported programming languages. You can clone this repository with:

```
git clone -b 3.6 https://github.com/zeroc-ice/ice-demos.git
cd ice-demos
```

## Using Ice on Android

This page provides important information for users of the Ice for Java distribution.

On this page:

- [Overview of Ice on Android](#)
- [Configuring an Android Studio project](#)
- [Using the sample programs](#)

### Overview of Ice on Android

Ice is available for Android through the Ice for Java distribution. To develop an Ice application for Android you will need the following components:

- Binary distribution of Ice for your development platform (Linux, macOS, Windows)
- [Android Studio](#)
- [Ice Builder for Gradle](#)

### Configuring an Android Studio project

Android Studio uses a [Gradle](#)

-based build system. Using Ice requires modifying your project's `build.gradle`

settings file(s) to include the Ice JAR files. For convenience we recommend using the [Ice Builder for Gradle](#) plug-in to help automate the compilation of your Slice files.

The following snippets give an example of configuring the Ice and Ice Builder for Gradle sections for an Android project.

**Ice build.gradle configuration**

```

buildscript {
 repositories {
 mavenCentral()
 maven {
 url "https://plugins.gradle.org/m2/"
 }
 }
 dependencies {
 classpath
 "gradle.plugin.com.zeroc.gradle.ice-builder:slice:1.4.1"
 }
}
apply plugin: 'java'
apply plugin: 'slice'
slice {
 java {
 srcDir = '.'
 }
}
dependencies {
 compile 'com.zeroc:ice:3.6.4'
}

```

**Using the sample programs**

Sample programs are available at our [GitHub repository](#). You can browse this repository to see build and usage instructions for all supported programming languages. Simply clone this repository and use its 3.6 branch:

```

git clone -b 3.6 https://github.com/zeroc-ice/ice-demos.git
cd ice-demos

```

You can then import the directory `java/Android` into Android Studio.

## Using Ice with Yocto

On this page:

- [Overview of Ice with Yocto](#)
  - [Development Boards](#)
  - [Meta Layer](#)
- [Installing the Meta Layer](#)
- [Using the Meta Layer to install Ice](#)
- [Setting up your cross development environment to use Ice](#)
- [Using IceSSL with Platform CAs](#)
- [Using the Ice sample programs](#)

### Overview of Ice with Yocto

The Yocto Project allows you to create a custom Linux distribution for your embedded product. With ZeroC's [meta layer for Yocto](#), you can easily include Ice for C++, Ice for Python and/or the Glacier2 service in this custom Linux distribution.

### Development Boards

Ice was tested on:

Board	Yocto version
<a href="#">Freescale SABRE SD</a>	2.1 (Krogoth) with the <a href="#">Freescale Community BSP</a>
<a href="#">BeagleBone Black board (Rev C)</a>	2.1 (Krogoth)

### Meta Layer

Refer to the [README.md](#) file in the [zeroc-ice/meta-zeroc](#) repository.

### Installing the Meta Layer

Installing the meta layer for ZeroC products is simply a matter of copying the contents of the repository onto your file system. For example, assuming you are using the poky repository, download the meta layer archive from the [GitHub page](#) and extract it alongside the other directories labeled `meta-<name>`. Once this is done, source the poky environment configuration script and add the `meta-zeroc` layer to the `BBLAYERS` variable in your `bblayers.conf` file:

```
BBLAYERS ?= " \
/home/zeroc/dev/poky/meta \
/home/zeroc/dev/poky/meta-yocto \
/home/zeroc/dev/poky/meta-yocto-bsp \
/home/zeroc/dev/poky/meta-zeroc \
"
```

### Using the Meta Layer to install Ice

To include Ice in your image, add the package from the `zeroc-ice` recipe you wish to use to your `local.conf` file:

```
Install Ice for C++ dynamic libraries and Ice for Python to image
IMAGE_INSTALL_append = " zeroc-ice zeroc-ice-python"

Add the development package to the SDK
TOOLCHAIN_TARGET_TASK_append = " zeroc-ice-dev zeroc-ice-staticdev"

Add the development package to the Native SDK
TOOLCHAIN_HOST_TASK_append = " nativesdk-zeroc-ice-dev"
```

## Setting up your cross development environment to use Ice

With the variables set in `local.conf` as shown above, you can generate an SDK for your image with the following command:

### Create SDK for the core-image-minimal Image

```
bitbake core-image-minimal -c populate_sdk
```

Once complete, this SDK can be found in `tmp/deploy/sdk`. Execute the `.sh` file to install. By default your SDK will be installed into `/opt/poky/<version>/`. You can then source the cross-development environment as follows:

```
source
/opt/poky/2.1/environment-setup-cortexa9hf-vfp-neon-poky-linux-gnueabi
```

## Using IceSSL with Platform CAs

To use the `IceSSL.UsePlatformCAs` property you will need to install the `ca-certificates` package as part of your image. Since OpenSSL does not have its default `CAfile` (where IceSSL looks for the default platform CAs) set to the certificate bundle installed from `ca-certificates` you will need to set an additional IceSSL property:

```
IceSSL.CAs=/etc/ssl/certs/ca-certificates.crt
```

## Using the Ice sample programs

Sample programs are available in the `zeroc-ice/ice-demos` repository:

```
git clone -b 3.6 https://github.com/zeroc-ice/ice-demos.git
cd ice-demos
```

The Ice demos for C++ and Python are located in the `cpp` and `python` directories respectively. Review the build instructions for more information.

## Using the JavaScript Distribution

This page provides important information for users of the Ice for JavaScript distribution.

On this page:

- [Overview of the Ice for JavaScript Distribution](#)
- [Installing the Ice for JavaScript Distribution](#)
- [Using Ice for JavaScript](#)
- [Using the sample programs](#)

### Overview of the Ice for JavaScript Distribution

Ice for JavaScript is available as npm and bower packages. The following npm packages are provided for Node.js developers:

- [ice](#) - Ice for JavaScript run time
- [slice2js](#) - Slice-to-JavaScript compiler
- [gulp-ice-builder](#) - Gulp plug-in to integrate `slice2js` with the gulp build system

The following bower package is provided for developers of browser-based applications:

- [bower-ice](#) - Ice for JavaScript run time

### Installing the Ice for JavaScript Distribution

#### Node.js Applications

Install the Ice for JavaScript run time libraries using npm:

```
npm install ice --save
```

This package also includes the browser version of Ice for JavaScript in `node_modules/lib`.

You can also run `npm install ice@latest --save` to get the latest patches and bug fixes.

#### Browser Applications

To install with bower:

```
bower install ice --save
```

You can also run `bower install ice#master --save` to get the latest patches and bug fixes.

#### Slice-to-JavaScript Compiler

The Slice-to-JavaScript compiler (`slice2js`) can be installed with this command:

```
npm install slice2js --save-dev
```

This command builds the compiler from source therefore you must have a supported C++ compiler installed.

In order to use `slice2js` on the command line, use the `npm --global` option to install this package.

The `slice2js` package includes all of the standard Slice files and automatically adds the `slice` directory to the include file search path.

## Using Ice for JavaScript

The Ice manual provides a complete description of the [JavaScript mapping](#).

### Node.js Applications

You can use several top-level Ice package in your Node.js applications, as shown below:

```
JavaScript
```

```
var Ice = require('ice').Ice;
var Glacier2 = require('ice').Glacier2;
var IceStorm = require('ice').IceStorm;
var IceGrid = require('ice').IceGrid;

var communicator = Ice.initialize(process.argv);
var proxy = communicator.stringToProxy("hello:tcp -h localhost -p
10000");
```

### Browser Applications

Add the necessary `<script>` tags to your html to include the Ice for JavaScript components you require.

```
<script src="/bower_components/ice/lib/Ice.js"></script>
<script src="/bower_components/ice/lib/Glacier2.js"></script>
<script src="/bower_components/ice/lib/IceStorm.js"></script>
<script src="/bower_components/ice/lib/IceGrid.js"></script>
<script type="text/javascript">

var communicator = Ice.initialize();
var proxy = communicator.stringToProxy("hello:ws -h localhost -p
10002");
</script>
```

Minified versions are available with the `.min.js` extension.

## CDN

The Ice for JavaScript browser libraries are also available through cdnjs.

- <https://cdnjs.com/libraries/ice>

```
<script
src="https://cdnjs.cloudflare.com/ajax/libs/ice/3.6.3/Ice.min.js"></scr
ipt>
<script
src="https://cdnjs.cloudflare.com/ajax/libs/ice/3.6.3/Glacier2.min.js">
</script>
<script
src="https://cdnjs.cloudflare.com/ajax/libs/ice/3.6.3/IceStorm.min.js">
</script>
<script
src="https://cdnjs.cloudflare.com/ajax/libs/ice/3.6.3/IceGrid.min.js"><
/script>
```

A CDN is a great option for applications that do not wish to host all of their website's files themselves. Among other things, using a CDN will help to reduce bandwidth and allow caching across multiple websites.

Note however that you will still need to serve your client JavaScript files yourself.

## Slice-to-JavaScript Compiler

You can execute the Slice-to-JavaScript compiler from code as shown below:

```
JavaScript
var slice2js = require('slice2js');
slice2js.compile(["Hello.ice"]);
```

If you installed the `slice2js` package globally, you can also run `slice2js` on the command line.

Refer to the [manual](#) for a description of the arguments accepted by `slice2js`.

## Using the sample programs

The Ice sample programs are provided in a [GitHub repository](#). You can browse this repository to see build and usage instructions for all supported programming languages. Simply clone this repository and use its 3.6 branch:

```
git clone -b 3.6 https://github.com/zeroc-ice/ice-demos.git
cd ice-demos
```

## Using the Python Distribution

This page provides important information for users of the Ice for Python distribution.

On this page:

- [Overview of the Ice for Python Distribution](#)
- [Installing the Ice for Python Distribution](#)
- [Using Ice for Python](#)
- [Using the sample programs](#)

### Overview of the Ice for Python Distribution

Ice for Python is available as a collection of Python packages on the [Python Package Index](#). Each package provides the following components:

- Ice extension for Python
- Standard Slice files
- Slice-to-Python compiler (`slice2py`)

### Installing the Ice for Python Distribution

Install Ice for Python using this command:

```
pip install zeroc-ice
```

On Linux this command will build and install the source package. On macOS and Windows it installs a pre-built wheel for the following configurations:

- Python 2.7 on macOS (64 bit) and Windows (32 bit and 64 bit)
- Python 3.6 on Windows (32 bit and 64 bit)

### Using Ice for Python

The installation process automatically adds the Ice modules to Python's package directory and adds the Slice-to-Python compiler (`slice2py`) to a directory that's likely already in your executable search path. To verify that Ice is installed, execute these commands:

```
python
>>> import Ice
>>> Ice.getSliceDir()
```

The output of `getSliceDir` shows where the standard Slice files have been installed.

The Ice manual provides a complete description of the [Python mapping](#), including the options for [generating Python code](#) from Slice definitions.

### Using the sample programs

Sample programs are provided in a separate [GitHub repository](#). You can browse this repository to see build and usage instructions for all

supported programming languages. Simply clone this repository and use its 3.6 branch:

```
git clone -b 3.6 https://github.com/zeroc-ice/ice-demos.git
cd ice-demos
```

## Using the Ruby Distribution

This page provides important information for users of the Ice for Ruby distribution.

On this page:

- [Overview of the Ice for Ruby Distribution](#)
- [Installing the Ice for Ruby Distribution](#)
- [Using Ice for Ruby](#)
- [Using the sample programs](#)

### Overview of the Ice for Ruby Distribution

Ice for Ruby is available as a collection of Ruby gems. Each package provides the following components:

- Ice extension for Ruby
- Standard Slice files
- Slice-to-Ruby compiler (`slice2rb`)

### Installing the Ice for Ruby Distribution

Linux and macOS users can install Ice for Ruby using this command:

```
sudo gem install zeroc-ice
```

This gem builds Ice for Ruby from source and supports Ruby 1.8 or later.

Windows users can install a binary gem instead:

```
gem install zeroc-ice-x64-mingw (Windows 64-bit)
gem install zeroc-ice-x86-mingw (Windows 32-bit)
```

These gems require Ruby 2.4.

### Using Ice for Ruby

The installation process automatically adds the Ice modules to Ruby's package directory and adds the Slice-to-Ruby compiler (`slice2rb`) to a directory that's likely already in your executable search path. To verify that Ice is installed, execute these commands:

```
irb
irb> require 'Ice'
irb> Ice::getSliceDir()
```

The output of `getSliceDir` shows where the standard Slice files have been installed.

#### **Ruby 1.8**

Users of Ruby 1.8 must add the `-rubygems` option when starting the interpreter with `irb` or `ruby`:

```
irb -rubygems
irb> require 'Ice'
irb> Ice::getSliceDir()
```

The Ice manual provides a complete description of the [Ruby mapping](#), including the options for [generating Ruby code](#) from Slice definitions.

## Using the sample programs

Sample programs are provided in a separate [GitHub repository](#). You can browse this repository to see build and usage instructions for all supported programming languages. Simply clone this repository and use its 3.6 branch:

```
git clone -b 3.6 https://github.com/zeroc-ice/ice-demos.git
cd ice-demos
```

# Getting Started with Ice on AWS

This page explains how to get started with Ice on the Amazon Web Services (AWS) platform.

- [Select and Launch AMI](#)
- [Login](#)
- [Package Configuration](#)
  - [Red Hat Enterprise Linux](#)
  - [Ubuntu](#)

## Select and Launch AMI

Ice 3.6 is available for AWS on the following AMIs

- **ZeroC Ice for Red Hat Enterprise Linux** - Red Hat Enterprise Linux 7.2
- **ZeroC Ice for Ubuntu** - Ubuntu 14.04 (LTS)

Navigate to the [EC2 Management Console](#) and follow these steps:

1. [Select Launch Instance](#)
2. Navigate to the AWS Marketplace page for the ZeroC Ice AMI you wish to use.
3. Choose the instance type you wish to run. ZeroC Ice AMIs are available in many sizes.
4. Configure your [Security Group](#) to allow access to port 22 for SSH login, as well as any ports for any Ice servers you plan on running. Glacier2 listens (typically) on port 4064 (ssl/tls). If you plan on using Glacier then you need to add these port(s) as well.
5. Select which [Key Pair](#) to use for access to the instance once it is running.
6. Configure any remaining instance settings as desired.
7. Click [Accept Terms & Launch with 1-Click](#). Be sure to read the End-User License Agreement (EULA) beforehand.

## Login

You can log in to your instance through SSH.

```
ssh -i <keypair> -l <username> <ip address>
```

Where,

- `<keypair>` - The SSH keypair selected when you launched your instance
- `<username>` - `ec2-user` for Red Hat based instance and `ubuntu` for Ubuntu based instance
- `<ip address>` - IP address of your instance

## Package Configuration

ZeroC Ice AMIs have Ice 3.6 package repositories pre-configured. These repositories contain packages for both development and runtime.

### Red Hat Enterprise Linux

To install all development and runtime packages:

```
sudo yum install ice-all-runtime ice-all-devel
```

See [Using the Linux Binary Distributions](#) for a list of packages.

## Ubuntu

To install all development and runtime packages:

```
sudo apt-get install zeroc-ice-all-runtime zeroc-ice-all-dev
```

See [Using the Linux Binary Distributions](#) for a list of packages.

# Ice Touch Release Notes

The release notes provide information about an Ice Touch release, including descriptions of significant new features and changes as well as instructions for upgrading from an earlier release.

## Topics

- [Supported Platforms for Ice Touch 3.6.4](#)
- [New Features in Ice Touch 3.6.4](#)
- [Ice Touch Feature Set](#)
- [Upgrading your Ice Touch Application](#)
- [Using the Ice Touch Binary Distribution](#)

## Supported Platforms for Ice Touch 3.6.4

**Redirection Notice**

This page will redirect to [Supported Platforms for Ice and Ice Touch 3.6.4](#) in about one second.

## New Features in Ice Touch 3.6.4

This page outlines changes and improvements in this release that may affect the operation of your applications or have an impact on your source code.

### Changes in Ice Touch 3.6.4

- Upgraded to Ice 3.6.4.

### Changes in Ice Touch 3.6.3

- Upgraded to Ice 3.6.3.

### Changes in Ice Touch 3.6.2

- Upgraded to Ice 3.6.2.

### Changes in Ice Touch 3.6.1

- Upgraded to Ice 3.6.1.
- Added compatibility for Xcode 7, OS X El Capitan (10.11), and iOS 9:
  - Ice Touch libraries built using Xcode 7 and the iOS 9.0 SDK incorporate LLVM bitcode. Starting with Xcode 7, bitcode is required for libraries used in iOS applications.
  - You need to build Ice Touch from sources with Xcode 7 as long as the Ice Touch binary distribution is built with Xcode 6.

#### Build Ice Touch using Xcode 7

```
Select Xcode 7 beta
sudo xcode-select -s
/Applications/Xcode-beta.app/Contents/Developer/

Install Homebrew tap (only necessary if you have not done so
before)
brew tap zeroc-ice/tap

Install from source using Homebrew
brew update
brew install icetouch36 --build-from-source
```

### Changes in Ice Touch 3.6.0

- Ice Touch is now fully in-sync with Ice:
  - The Ice Touch Objective-C mapping was moved to the [ice repository](#).
  - The Ice Touch and Ice versions are now the same.
  - The preferred method to install Ice Touch is now through [Homebrew](#).
- Ice Touch is installed under `/usr/local`; it is no longer installed in `/Library/Developer`.
- Previous versions of Ice Touch included a Xcode plug-in. This plug-in has been replaced by the [Ice Builder for Xcode](#); this Ice Builder is a separate package independent of Ice Touch.

## Ice Touch Feature Set

On this page:

- [Comparing Ice Touch and Ice](#)
- [Ice Touch language mappings](#)
- [Ice Touch limitations](#)

### Comparing Ice Touch and Ice

Ice Touch 3.6.4 is based on the Ice 3.6.4 release. See the [Ice 3.6.4 Release Notes](#) for more information on Ice.

Ice Touch and Ice provide the same API and implement the same [Ice protocol](#). Here is a brief comparison of these two products:

Feature	Ice Touch	Ice
C++, Objective-C		
Java, JavaScript, PHP, Python, Ruby		
Ice transports: tcp, ssl, ws, wss, udp		
Client libraries for IceGrid, IceStorm and Glacier2		
Ice services (IceGrid, IceStorm etc.)		
Develop on macOS		
Develop with Xcode and <a href="#">Ice Builder</a>		
Target macOS		
Target iOS		
Static libraries		
Shared libraries		

### Ice Touch language mappings

Ice Touch supports the following mappings:

- [Objective-C mapping](#)
- [C++ mapping](#)

### Ice Touch limitations

Ice Touch lacks support for the `Ice::Application` and `Ice::Service` helper classes.

Ice Touch has limited support for:

- SSL

Ice Touch for macOS uses the Ice for C++ SSL protocol plug-in based on macOS Secure Transport. For iOS devices, Ice Touch SSL provides only a subset of this functionality. Ice Touch servers on iOS cannot authenticate SSL clients for instance. The [IceSSL property reference](#) provides complete details.

- UDP

On iOS, UDP requests do not transparently establish a cellular connection.

# Upgrading your Ice Touch Application

## Ice Touch backward compatibility

Ice Touch 3.6.4 is fully source and binary compatible with prior versions of Ice Touch 3.6: you do not need to recompile anything when upgrading from Ice Touch 3.6.x.

Ice Touch 3.6 is not compatible with Ice Touch 1.x. As part of your upgrade from Ice Touch 1.x to Ice Touch 3.6, you need to recompile your Slice files and rebuild your application.

## Xcode project settings

For Xcode iOS and macOS applications, you need to update the project setting "Additional SDKs" to match the location of the new Ice Touch SDK installation. You should use:

- `/usr/local/lib/IceTouch/ObjC/${PLATFORM_NAME}.sdk` for the Objective-C SDK
- `/usr/local/lib/IceTouch/Cpp/${PLATFORM_NAME}.sdk` for the C++ SDK

## Using the Ice Touch Binary Distribution

This page provides important information for users of the Ice Touch binary distribution.

On this page:

- [Overview of the Ice Touch binary distribution](#)
- [Installing the Ice Touch binary distribution](#)
- [Setting up your macOS environment to use Ice Touch](#)
- [Using the Ice Touch sample programs](#)

### Overview of the Ice Touch binary distribution

Ice Touch is provided through [Homebrew](#). The `icetouch` formula includes the following components:

- Xcode Objective-C SDKs for macOS, iPhone iOS, iPhone Simulator
- Xcode C++ SDKs for macOS, iPhone iOS, iPhone Simulator

### Installing the Ice Touch binary distribution

Using [Homebrew](#), you can install the distribution with this command:

```
brew install zeroc-ice/tap/icetouch36
```

The binaries in this distribution are 64-bit binaries for macOS and fat binaries with support for ARMv7, ARMv7s and ARM64 on iOS.

### Setting up your macOS environment to use Ice Touch

In order to use one of the Ice Touch Xcode SDKs with your Xcode project, you need to:

- add the Ice Touch SDK your *Additional SDKs*
  - C++: `/usr/local/IceTouch/Cpp/$(PLATFORM_NAME).sdk`
  - Objective-C: `/usr/local/IceTouch/ObjC/$(PLATFORM_NAME).sdk`
- link your application with at least
  - C++: `-lIce` (plus `-liconv -lbzip2` on macOS)
  - Objective-C: `-ObjC -lIceObjC -lc++` (plus `-liconv -lbzip2` on macOS)
- link your application with
  - macOS: `Security.framework`
  - iphoneos and iphonesimulator: `Security.framework CFNetwork.framework UIKit.framework`

The following optional libraries are included in the Ice Touch Xcode SDKs:

Name	Link your C++ application with	Link your Objective-C application with
Glacier2 client library	<code>-lGlacier2</code>	<code>-lGlacier2ObjC</code>
IceGrid client library	<code>-lIceGrid</code>	<code>-lIceGridObjC</code>
IceStorm client library	<code>-lIceStorm</code>	<code>-lIceStormObjC</code>

The Ice Touch Xcode SDKs include only static libraries. The `Ice` static library (`IceObjC` for Objective-C) includes the following plug-ins: `IceDiscovery`, `IceLocatorDiscovery` and `IceSSL`.

We also recommend installing the [Ice Builder for Xcode](#), which automates the compilation of Slice files to C++ and Objective-C. The builder is not included in the `ice` formula and must be installed separately with:

```
brew install zeroc-ice/tap/ice-builder-xcode
```

## Using the Ice Touch sample programs

Sample programs are available in a separate [GitHub repository](#). Simply clone this repository and use its 3.6 branch:

```
git clone -b 3.6 https://github.com/zeroc-ice/ice-demos.git
cd ice-demos
```

The Ice Touch demos are located in the `cpp/IceTouch` and `objective-c/IceTouch` directories.

# Slice API Reference

## Modules

[Ice](#) — The Ice core library.

[Freeze](#) — Freeze provides automatic persistence for Ice servants.

[Glacier2](#) — Glacier2 is a firewall solution for Ice.

[IceBox](#) — IceBox is an application server specifically for Ice applications.

[IceGrid](#) — IceGrid is a server activation and deployment tool.

[IceLocatorDiscovery](#) — IceLocatorDiscovery is an Ice plug-in that enables the discovery of IceGrid and custom locators via UDP multicast.

[IceMX](#) — The Ice Management eXtension facility.

[IcePatch2](#) — IcePatch can be used to update file hierarchies in a simple and efficient manner.

[IceSSL](#) — IceSSL provides a secure transport for Ice.

[IceStorm](#) — A messaging service with support for federation.

---

# Freeze Slice API

---

## Freeze

### Overview

#### module Freeze

Freeze provides automatic persistence for Ice servants.

### Interface Index

[BackgroundSaveEvictor](#) — A background-save evictor is an evictor that saves updates asynchronously in a background thread.

[Connection](#) — A connection to a database (database environment with Berkeley DB).

[Evictor](#) — An automatic Ice object persistence manager, based on the evictor pattern.

[EvictorIterator](#) — An iterator for the objects managed by the evictor.

[ServantInitializer](#) — A servant initializer provides the application with an opportunity to perform custom servant initialization.

[Transaction](#) — A transaction.

[TransactionalEvictor](#) — A transactional evictor is an evictor that performs every single read-write operation within its own transaction.

### Exception Index

[DatabaseException](#) — A Freeze database exception.

[DeadlockException](#) — A Freeze database deadlock exception.

[EvictorDeactivatedException](#) — This exception is raised if the evictor has been deactivated.

[IndexNotFoundException](#) — Exception raised when Freeze fails to locate an index.

[InvalidPositionException](#) — This Freeze Iterator is not on a valid position, for example this position has been erased.

[NoSuchElementException](#) — This exception is raised if there are no further elements in the iteration.

[NotFoundException](#) — A Freeze database exception, indicating that a database record could not be found.

[TransactionAlreadyInProgressException](#) — An attempt was made to start a transaction while a previous transaction has not yet been committed or rolled back.

### Structure Index

[CatalogData](#) — The catalog keeps information about Freeze Maps and Freeze evictors in a Berkeley Db environment.

[ObjectRecord](#) — ObjectRecord is the value-type for the persistent maps maintained by evictors when using Ice encoding version is 1.0.

[Statistics](#) — Evictors maintain statistics about each object, when using Ice encoding version 1.0.

### Sequence Index

[Key](#) — A database key, represented as a sequence of bytes.

[Value](#) — A database value, represented as a sequence of bytes.

## Sequences

### sequence<byte> Key

A database key, represented as a sequence of bytes.

### sequence<byte> Value

A database value, represented as a sequence of bytes.

---

## Freeze-BackgroundSaveEvictor

---

### Freeze::BackgroundSaveEvictor

#### Overview

local interface `BackgroundSaveEvictor` extends `Freeze::Evictor`

A background-save evictor is an evictor that saves updates asynchronously in a background thread.

#### Operation Index

`keep` — Lock this object in the evictor cache.  
`keepFacet` — Like `keep`, but with a facet.  
`release` — Release a lock acquired by `keep`.  
`releaseFacet` — Like `release`, but with a facet.

#### Operations

##### `void keep(Ice::Identity id)`

Lock this object in the evictor cache. This lock can be released by `release` or `remove`. `release` releases only one lock, while `remove` releases all the locks.

##### Parameters

`id` — The identity of the Ice object.

##### Exceptions

`Ice::NotRegisteredException` — Raised if this identity was not registered with the evictor.  
`Freeze::DatabaseException` — Raised if a database failure occurred.

##### See Also

- `keepFacet`
- `release`
- `remove`

##### `void keepFacet(Ice::Identity id, string facet)`

Like `keep`, but with a facet. Calling `keep(id)` is equivalent to calling `keepFacet` with an empty facet.

##### Parameters

`id` — The identity of the Ice object.  
`facet` — The facet. An empty facet means the default facet.

##### Exceptions

`Ice::NotRegisteredException` — Raised if this identity was not registered with the evictor.  
`Freeze::DatabaseException` — Raised if a database failure occurred.

##### See Also

- `keep`
- `releaseFacet`
- `removeFacet`

**void release(Ice::Identity id)**

Release a lock acquired by [keep](#). Once all the locks on an object have been released, the object is again subject to the normal eviction strategy.

**Parameters**

`id` — The identity of the Ice object.

**Exceptions**

[Ice::NotRegisteredException](#) — Raised if this object was not locked with [keep](#) or [keepFacet](#).

**See Also**

- [keepFacet](#)
- [release](#)

**void releaseFacet(Ice::Identity id, string facet)**

Like [release](#), but with a facet. Calling `release(id)` is equivalent to calling [releaseFacet](#) with an empty facet.

**Parameters**

`id` — The identity of the Ice object.

`facet` — The facet. An empty facet means the default facet.

**Exceptions**

[Ice::NotRegisteredException](#) — Raised if this object was not locked with [keep](#) or [keepFacet](#).

**See Also**

- [keep](#)
  - [releaseFacet](#)
-

## Freeze-CatalogData

---

### Freeze::CatalogData

#### Overview

#### struct CatalogData

The catalog keeps information about Freeze Maps and Freeze evictors in a Berkeley Db environment. It is used by FreezeScript.

#### Data Member Index

**evictor** — True if this entry describes an evictor database, false if it describes a map database.

**key** — The Slice type for the database key.

**value** — The Slice type for the database value.

#### Data Members

##### **bool evictor;**

True if this entry describes an evictor database, false if it describes a map database.

##### **string key;**

The Slice type for the database key.

##### **string value;**

The Slice type for the database value.

---

## Freeze-Connection

---

### Freeze::Connection

#### Overview

#### local interface Connection

A connection to a database (database environment with Berkeley DB). If you want to use a connection concurrently in multiple threads, you need to serialize access to this connection.

#### Used By

- [Freeze::Transaction::getConnection](#)

#### Operation Index

[beginTransaction](#) — Create a new transaction.

[currentTransaction](#) — Returns the transaction associated with this connection.

[removeMapIndex](#) — Remove an old unused Freeze Map index @throws [IndexNotFoundException](#) Raised if this index does not exist

[close](#) — Closes this connection.

[getCommunicator](#) — Returns the communicator associated with this connection.

[getEncoding](#) — Returns the encoding version used to encode the data.

[getName](#) — The name of the connected system (for example, the Berkeley DB environment).

#### Operations

##### **Freeze::Transaction beginTransaction()**

Create a new transaction. Only one transaction at a time can be associated with a connection.

#### *Return Value*

The new transaction.

#### *Exceptions*

[Freeze::TransactionAlreadyInProgressException](#) — Raised if a transaction is already associated with this connection.

##### **Freeze::Transaction currentTransaction()**

Returns the transaction associated with this connection.

#### *Return Value*

The current transaction if there is one, null otherwise.

##### **void removeMapIndex(string mapName, string indexName)**

Remove an old unused Freeze Map index

#### *Exceptions*

[Freeze::IndexNotFoundException](#) — Raised if this index does not exist

##### **void close()**

Closes this connection. If there is an associated transaction, it is rolled back.

**Ice::Communicator** `getCommunicator()`

Returns the communicator associated with this connection.

**Ice::EncodingVersion** `getEncoding()`

Returns the encoding version used to encode the data.

**string** `getName()`

The name of the connected system (for example, the Berkeley DB environment).

---

## Freeze-DatabaseException

---

### Freeze::DatabaseException

#### Overview

#### local exception DatabaseException

A Freeze database exception.

#### *Derived Exceptions*

- [Freeze::DeadlockException](#)
- [Freeze::NotFoundException](#)

#### *See Also*

- [Freeze::Evictor](#)
- [Freeze::Connection](#)

#### Data Member Index

[message](#) — A message describing the reason for the exception.

#### Data Members

**string message;**

A message describing the reason for the exception.

---

## Freeze-DeadlockException

---

### Freeze::DeadlockException

#### Overview

local exception `DeadlockException` extends `Freeze::DatabaseException`

A Freeze database deadlock exception. Applications can react to this exception by aborting and trying the transaction again.

#### Data Member Index

`tx` — The transaction in which the deadlock occurred.

#### Data Members

`Freeze::Transaction tx;`

The transaction in which the deadlock occurred.

---

## Freeze-Evictor

---

### Freeze::Evictor

#### Overview

#### local interface Evictor extends Ice::ServantLocator

An automatic Ice object persistence manager, based on the evictor pattern. The evictor is a servant locator implementation that stores the persistent state of its objects in a database. Any number of objects can be registered with an evictor, but only a configurable number of servants are active at a time. These active servants reside in a queue; the least recently used servant in the queue is the first to be evicted when a new servant is activated.

#### Derived Classes and Interfaces

- [Freeze::BackgroundSaveEvictor](#)
- [Freeze::TransactionalEvictor](#)

#### See Also

- [Freeze::ServantInitializer](#)

#### Operation Index

[setSize](#) — Set the size of the evictor's servant queue.  
[getSize](#) — Get the size of the evictor's servant queue.  
[add](#) — Add a servant to this evictor.  
[addFacet](#) — Like [add](#), but with a facet.  
[remove](#) — Permanently destroy an Ice object.  
[removeFacet](#) — Like [remove](#), but with a facet.  
[hasObject](#) — Returns true if the given identity is managed by the evictor with the default facet.  
[hasFacet](#) — Like [hasObject](#), but with a facet.  
[getIterator](#) — Get an iterator for the identities managed by the evictor.

#### Operations

##### void setSize(int sz)

Set the size of the evictor's servant queue. This is the maximum number of servants the evictor keeps active. Requests to set the queue size to a value smaller than zero are ignored.

#### Parameters

*sz* — The size of the servant queue. If the evictor currently holds more than *sz* servants in its queue, it evicts enough servants to match the new size. Note that this operation can block if the new queue size is smaller than the current number of servants that are servicing requests. In this case, the operation waits until a sufficient number of servants complete their requests.

#### Exceptions

[Freeze::EvictorDeactivatedException](#) — Raised if a the evictor has been deactivated.

#### See Also

- [getSize](#)

##### int getSize()

Get the size of the evictor's servant queue.

**Return Value**

The size of the servant queue.

**Exceptions**

[Freeze::EvictorDeactivatedException](#) — Raised if a the evictor has been deactivated.

**See Also**

- [setSize](#)

**Object\* add(Object servant, Ice::Identity id)**

Add a servant to this evictor. The state of the servant passed to this operation will be saved in the evictor's persistent store.

**Parameters**

`servant` — The servant to add.

`id` — The identity of the Ice object that is implemented by the servant.

**Return Value**

A proxy that matches the given identity and this evictor's object adapter.

**Exceptions**

[Ice::AlreadyRegisteredException](#) — Raised if the evictor already has an object with this identity.

[Freeze::DatabaseException](#) — Raised if a database failure occurred.

[Freeze::EvictorDeactivatedException](#) — Raised if the evictor has been deactivated.

**See Also**

- [addFacet](#)
- [remove](#)
- [removeFacet](#)

**Object\* addFacet(Object servant, Ice::Identity id, string facet)**

Like [add](#), but with a facet. Calling `add(servant, id)` is equivalent to calling [addFacet](#) with an empty facet.

**Parameters**

`servant` — The servant to add.

`id` — The identity of the Ice object that is implemented by the servant.

`facet` — The facet. An empty facet means the default facet.

**Return Value**

A proxy that matches the given identity and this evictor's object adapter.

**Exceptions**

[Ice::AlreadyRegisteredException](#) — Raised if the evictor already has an object with this identity.

[Freeze::DatabaseException](#) — Raised if a database failure occurred.

[Freeze::EvictorDeactivatedException](#) — Raised if the evictor has been deactivated.

**See Also**

- [add](#)
- [remove](#)
- [removeFacet](#)

**Object remove(Ice::Identity id)**

Permanently destroy an Ice object.

**Parameters**

`id` — The identity of the Ice object.

**Return Value**

The removed servant.

**Exceptions**

[Ice::NotRegisteredException](#) — Raised if this identity was not registered with the evictor.

[Freeze::DatabaseException](#) — Raised if a database failure occurred.

[Freeze::EvictorDeactivatedException](#) — Raised if the evictor has been deactivated.

**See Also**

- [add](#)
- [removeFacet](#)

**Object removeFacet(Ice::Identity id, string facet)**

Like `remove`, but with a facet. Calling `remove(id)` is equivalent to calling `removeFacet` with an empty facet.

**Parameters**

`id` — The identity of the Ice object.

`facet` — The facet. An empty facet means the default facet.

**Return Value**

The removed servant.

**Exceptions**

[Ice::NotRegisteredException](#) — Raised if this identity was not registered with the evictor.

[Freeze::DatabaseException](#) — Raised if a database failure occurred.

[Freeze::EvictorDeactivatedException](#) — Raised if the evictor has been deactivated.

**See Also**

- [remove](#)
- [addFacet](#)

**bool hasObject(Ice::Identity id)**

Returns true if the given identity is managed by the evictor with the default facet.

**Return Value**

true if the identity is managed by the evictor, false otherwise.

**Exceptions**

[Freeze::DatabaseException](#) — Raised if a database failure occurred.

[Freeze::EvictorDeactivatedException](#) — Raised if a the evictor has been deactivated.

**bool hasFacet(Ice::Identity id, string facet)**

Like `hasObject`, but with a facet. Calling `hasObject(id)` is equivalent to calling `hasFacet` with an empty facet.

**Return Value**

true if the identity is managed by the evictor for the given facet, false otherwise.

**Exceptions**

[Freeze::DatabaseException](#) — Raised if a database failure occurred.

[Freeze::EvictorDeactivatedException](#) — Raised if a the evictor has been deactivated.

**Freeze::EvictorIterator getIterator(string facet, int batchSize)**

Get an iterator for the identities managed by the evictor.

**Parameters**

`facet` — The facet. An empty facet means the default facet.

`batchSize` — Internally, the Iterator retrieves the identities in batches of size `batchSize`. Selecting a small `batchSize` can have an adverse effect on performance.

**Return Value**

A new iterator.

**Exceptions**

[Freeze::EvictorDeactivatedException](#) — Raised if a the evictor has been deactivated.

---

## Freeze-EvictorDeactivatedException

---

### Freeze::EvictorDeactivatedException

#### Overview

local exception `EvictorDeactivatedException`

This exception is raised if the evictor has been deactivated.

---

## Freeze-EvictorIterator

---

### Freeze::EvictorIterator

#### Overview

##### local interface EvictorIterator

An iterator for the objects managed by the evictor. Note that an EvictorIterator is not thread-safe: the application needs to serialize access to a given EvictorIterator, for example by using it in just one thread.

##### Used By

- [Freeze::Evictor::getIterator](#)

##### See Also

- [Freeze::Evictor](#)

#### Operation Index

[hasNext](#) — Determines if the iteration has more elements.

[next](#) — Obtains the next identity in the iteration.

#### Operations

##### bool hasNext()

Determines if the iteration has more elements.

##### Return Value

True if the iterator has more elements, false otherwise.

##### Exceptions

[Freeze::DatabaseException](#) — Raised if a database failure occurs while retrieving a batch of objects.

##### Ice::Identity next()

Obtains the next identity in the iteration.

##### Return Value

The next identity in the iteration.

##### Exceptions

[Freeze::NoSuchElementException](#) — Raised if there is no further elements in the iteration.

[Freeze::DatabaseException](#) — Raised if a database failure occurs while retrieving a batch of objects.

---

## Freeze-IndexNotFoundException

---

### Freeze::IndexNotFoundException

#### Overview

#### local exception IndexNotFoundException

Exception raised when Freeze fails to locate an index.

#### Data Member Index

`mapName` — The name of the map in which the index could not be found.

`indexName` — The name of the index.

#### Data Members

**string** `mapName`;

The name of the map in which the index could not be found.

**string** `indexName`;

The name of the index.

---

## Freeze-InvalidPositionException

---

### Freeze::InvalidPositionException

#### Overview

local exception InvalidPositionException

This Freeze Iterator is not on a valid position, for example this position has been erased.

---

## Freeze-NoSuchElementException

---

### Freeze::NoSuchElementException

#### Overview

local exception `NoSuchElementException`

This exception is raised if there are no further elements in the iteration.

---

## Freeze-NotFoundException

---

### Freeze::NotFound

#### Overview

local exception `NotFound` extends [Freeze::DatabaseException](#)

A Freeze database exception, indicating that a database record could not be found.

---

## Freeze-ObjectRecord

---

### Freeze::ObjectRecord

#### Overview

**struct ObjectRecord**

ObjectRecord is the value-type for the persistent maps maintained by evictors when using Ice encoding version is 1.0.

#### Data Member Index

[servant](#) — The servant implementing the object.

[stats](#) — The statistics for the object.

#### Data Members

**Object servant;**

The servant implementing the object.

**Freeze::Statistics stats;**

The statistics for the object.

---

## Freeze-ServantInitializer

---

### Freeze::ServantInitializer

#### Overview

#### local interface ServantInitializer

A servant initializer provides the application with an opportunity to perform custom servant initialization.

#### See Also

- [Freeze::Evictor](#)

#### Operation Index

[initialize](#) — Called whenever the evictor creates a new servant.

#### Operations

#### **void initialize(Ice::ObjectAdapter adapter, Ice::Identity identity, string facet, Object servant)**

Called whenever the evictor creates a new servant. This operation allows application code to perform custom servant initialization after the servant has been created by the evictor and its persistent state has been restored.

#### *Parameters*

*adapter* — The object adapter in which the evictor is installed.  
*identity* — The identity of the Ice object for which the servant was created.  
*facet* — The facet. An empty facet means the default facet.  
*servant* — The servant to initialize.

#### See Also

- [Ice::Identity](#)
-

## Freeze-Statistics

---

### Freeze::Statistics

#### Overview

#### struct Statistics

Evictors maintain statistics about each object, when using Ice encoding version 1.0.

#### Used By

- `Freeze::ObjectRecord::stats`

#### Data Member Index

`creationTime` — The time the object was created, in milliseconds since Jan 1, 1970 0:00.

`lastSaveTime` — The time the object was last saved, in milliseconds relative to `creationTime`.

`avgSaveTime` — The average time between saves, in milliseconds.

#### Data Members

##### `long creationTime;`

The time the object was created, in milliseconds since Jan 1, 1970 0:00.

##### `long lastSaveTime;`

The time the object was last saved, in milliseconds relative to `creationTime`.

##### `long avgSaveTime;`

The average time between saves, in milliseconds.

---

## Freeze-Transaction

---

### Freeze::Transaction

#### Overview

#### local interface Transaction

A transaction. If you want to use a transaction concurrently in multiple threads, you need to serialize access to this transaction.

#### *Used By*

- [Freeze::Connection::beginTransaction](#)
- [Freeze::Connection::currentTransaction](#)
- [Freeze::DeadlockException::tx](#)
- [Freeze::TransactionalEvictor::getCurrentTransaction](#)
- [Freeze::TransactionalEvictor::setCurrentTransaction](#)

#### Operation Index

[commit](#) — Commit this transaction.

[rollback](#) — Roll back this transaction.

[getConnection](#) — Get the connection associated with this Transaction

#### Operations

##### **void commit()**

Commit this transaction.

##### *Exceptions*

[Freeze::DatabaseException](#) — Raised if a database failure occurred.

##### **void rollback()**

Roll back this transaction.

##### *Exceptions*

[Freeze::DatabaseException](#) — Raised if a database failure occurred.

##### **Freeze::Connection getConnection()**

Get the connection associated with this Transaction

---

## Freeze-TransactionalEvictor

---

### Freeze::TransactionalEvictor

#### Overview

local interface `TransactionalEvictor` extends `Freeze::Evictor`

A transactional evictor is an evictor that performs every single read-write operation within its own transaction.

#### Operation Index

`getCurrentTransaction` — Get the transaction associated with the calling thread.

`setCurrentTransaction` — Associate a transaction with the calling thread.

#### Operations

##### `Freeze::Transaction` `getCurrentTransaction()`

Get the transaction associated with the calling thread.

##### *Return Value*

The transaction associated with the calling thread.

##### `void` `setCurrentTransaction(Freeze::Transaction tx)`

Associate a transaction with the calling thread.

##### *Parameters*

`tx` — The transaction to associate with the calling thread.

---

## Freeze-TransactionAlreadyInProgressException

---

### Freeze::TransactionAlreadyInProgressException

#### Overview

local exception `TransactionAlreadyInProgressException`

An attempt was made to start a transaction while a previous transaction has not yet been committed or rolled back.

---

# Glacier2 Slice API

---

## Glacier2

### Overview

#### [ "objc:prefix:GLACIER2" ] module Glacier2

Glacier2 is a firewall solution for Ice. Glacier2 authenticates and filters client requests and allows callbacks to the client in a secure fashion. In combination with IceSSL, Glacier2 provides a security solution that is both non-intrusive and easy to configure.

### Interface Index

[IdentitySet](#) — An object for managing the set of object identity constraints on a [Session](#).

[PermissionsVerifier](#) — The Glacier2 permissions verifier.

[Router](#) — The Glacier2 specialization of the [Ice::Router](#) interface.

[SSLPermissionsVerifier](#) — The SSL Glacier2 permissions verifier.

[SSLSessionManager](#) — The session manager for SSL authenticated users that is responsible for managing [Session](#) objects.

[Session](#) — A client-visible session object, which is tied to the lifecycle of a [Router](#).

[SessionControl](#) — An administrative session control object, which is tied to the lifecycle of a [Session](#).

[SessionManager](#) — The session manager for username/password authenticated users that is responsible for managing [Session](#) objects.

[StringSet](#) — An object for managing the set of identity constraints for specific parts of object identity on a [Session](#).

### Exception Index

[CannotCreateSessionException](#) — This exception is raised if an attempt to create a new session failed.

[PermissionDeniedException](#) — This exception is raised if a client is denied the ability to create a session with the router.

[SessionNotExistException](#) — This exception is raised if a client tries to destroy a session with a router, but no session exists for the client.

### Structure Index

[SSLInfo](#) — Information taken from an SSL connection used for permissions verification.

---

## Glacier2-CannotCreateSessionException

---

### Glacier2::CannotCreateSessionException

#### Overview

[ "preserve-slice" ] exception `CannotCreateSessionException`

This exception is raised if an attempt to create a new session failed.

#### *Used By*

- `Glacier2::Router::createSessionFromSecureConnection`
- `Glacier2::Router::createSession`
- `Glacier2::SSLSessionManager::create`
- `Glacier2::SessionManager::create`

#### Data Member Index

`reason` — The reason why session creation has failed.

#### Data Members

`string reason;`

The reason why session creation has failed.

---

## Glacier2-IdentitySet

---

### Glacier2::IdentitySet

#### Overview

#### interface IdentitySet

An object for managing the set of object identity constraints on a [Glacier2::Session](#).

#### See Also

- [Glacier2::Session](#)
- [Glacier2::SessionControl](#)

#### Operation Index

**add** — Add a sequence of Ice identities to this set of constraints.  
**remove** — Remove a sequence of identities from this set of constraints.  
**get** — Returns a sequence of identities describing the constraints in this set.

#### Operations

##### void add(Ice::IdentitySeq additions)

Add a sequence of Ice identities to this set of constraints. Order is not preserved and duplicates are implicitly removed.

##### Parameters

`additions` — The sequence of Ice identities to be added.

##### void remove(Ice::IdentitySeq deletions)

Remove a sequence of identities from this set of constraints. No errors are returned if an entry is not found.

##### Parameters

`deletions` — The sequence of Ice identities to be removed.

##### Ice::IdentitySeq get()

Returns a sequence of identities describing the constraints in this set.

##### Return Value

The sequence of Ice identities for this set.

---

## Glacier2-PermissionDeniedException

---

### Glacier2::PermissionDeniedException

#### Overview

[ "preserve-slice" ] exception `PermissionDeniedException`

This exception is raised if a client is denied the ability to create a session with the router.

#### *Used By*

- `Glacier2::PermissionsVerifier::checkPermissions`
- `Glacier2::Router::createSessionFromSecureConnection`
- `Glacier2::Router::createSession`
- `Glacier2::SSLPermissionsVerifier::authorize`

#### Data Member Index

`reason` — The reason why permission was denied.

#### Data Members

`string reason;`

The reason why permission was denied.

---

## Glacier2-PermissionsVerifier

---

### Glacier2::PermissionsVerifier

#### Overview

#### interface PermissionsVerifier

The Glacier2 permissions verifier. This is called through the process of establishing a session.

#### See Also

- [Glacier2::Router](#)

#### Operation Index

[checkPermissions](#) — Check whether a user has permission to access the router.

#### Operations

[ "nonmutating", "format:sliced" ] bool [checkPermissions](#)(string userId, string password, out string reason) throws [Glacier2::PermissionDeniedException](#)

Check whether a user has permission to access the router.

#### Parameters

`userId` — The user id for which to check permission.

`password` — The user's password.

`reason` — The reason why access was denied.

#### Return Value

True if access is granted, or false otherwise.

#### Exceptions

[Glacier2::PermissionDeniedException](#) — Raised if the user access is denied. This can be raised in place of returning false with a reason set in the reason out parameter.

---

## Glacier2-Router

---

### Glacier2::Router

#### Overview

interface Router extends [Ice::Router](#)

The Glacier2 specialization of the [Ice::Router](#) interface.

#### Operation Index

[getCategoryForClient](#) — This category must be used in the identities of all of the client's callback objects.

[createSession](#) — Create a per-client session with the router.

[createSessionFromSecureConnection](#) — Create a per-client session with the router.

[refreshSession](#) — Keep the calling client's session with this router alive.

[destroySession](#) — Destroy the calling client's session with this router.

[getSessionTimeout](#) — Get the value of the session timeout.

[getACMTimeout](#) — Get the value of the ACM timeout.

#### Operations

[ "nonmutating" ] string [getCategoryForClient\(\)](#)

This category must be used in the identities of all of the client's callback objects. This is necessary in order for the router to forward callback requests to the intended client. If the Glacier2 server endpoints are not set, the returned category is an empty string.

##### *Return Value*

The category.

[ "amd", "format:sliced" ] [Glacier2::Session\\*](#) [createSession\(string userId, string password\)](#) throws [Glacier2::PermissionDeniedException](#), [Glacier2::CannotCreateSessionException](#)

Create a per-client session with the router. If a [Glacier2::SessionManager](#) has been installed, a proxy to a [Glacier2::Session](#) object is returned to the client. Otherwise, null is returned and only an internal session (i.e., not visible to the client) is created. If a session proxy is returned, it must be configured to route through the router that created it. This will happen automatically if the router is configured as the client's default router at the time the session proxy is created in the client process, otherwise the client must configure the session proxy explicitly.

##### *Parameters*

`userId` — The user id for which to check the password.

`password` — The password for the given user id.

##### *Return Value*

A proxy for the newly created session, or null if no [Glacier2::SessionManager](#) has been installed.

##### *Exceptions*

[Glacier2::PermissionDeniedException](#) — Raised if the password for the given user id is not correct, or if the user is not allowed access.

[Glacier2::CannotCreateSessionException](#) — Raised if the session cannot be created.

##### *See Also*

- [Glacier2::Session](#)
- [Glacier2::SessionManager](#)

- [Glacier2::PermissionsVerifier](#)

[ "amd", "format:sliced" ] **Glacier2::Session\*** `createSessionFromSecureConnection()` throws **Glacier2::PermissionDeniedException**, **Glacier2::CannotCreateSessionException**

Create a per-client session with the router. The user is authenticated through the SSL certificates that have been associated with the connection. If a [Glacier2::SessionManager](#) has been installed, a proxy to a [Glacier2::Session](#) object is returned to the client. Otherwise, null is returned and only an internal session (i.e., not visible to the client) is created. If a session proxy is returned, it must be configured to route through the router that created it. This will happen automatically if the router is configured as the client's default router at the time the session proxy is created in the client process, otherwise the client must configure the session proxy explicitly.

**Return Value**

A proxy for the newly created session, or null if no [Glacier2::SessionManager](#) has been installed.

**Exceptions**

[Glacier2::PermissionDeniedException](#) — Raised if the user cannot be authenticated or if the user is not allowed access.  
[Glacier2::CannotCreateSessionException](#) — Raised if the session cannot be created.

**See Also**

- [Glacier2::Session](#)
- [Glacier2::SessionManager](#)
- [Glacier2::PermissionsVerifier](#)

[ "amd" ] **void** `refreshSession()` throws **Glacier2::SessionNotExistException**

Keep the calling client's session with this router alive.

**Exceptions**

[Glacier2::SessionNotExistException](#) — Raised if no session exists for the calling client.

**void** `destroySession()` throws **Glacier2::SessionNotExistException**

Destroy the calling client's session with this router.

**Exceptions**

[Glacier2::SessionNotExistException](#) — Raised if no session exists for the calling client.

[ "nonmutating" ] **long** `getSessionTimeout()`

Get the value of the session timeout. Sessions are destroyed if they see no activity for this period of time.

**Return Value**

The timeout (in seconds).

[ "nonmutating" ] **int** `getACMTimeout()`

Get the value of the ACM timeout. Clients supporting connection heartbeats can enable them instead of explicitly sending keep alives requests. NOTE: This method is only available since Ice 3.6.

**Return Value**

The timeout (in seconds).

## Glacier2-Session

---

### Glacier2::Session

#### Overview

#### interface Session

A client-visible session object, which is tied to the lifecycle of a [Glacier2::Router](#).

#### *Derived Classes and Interfaces*

- [IceGrid::AdminSession](#)
- [IceGrid::Session](#)

#### *See Also*

- [Glacier2::Router](#)
- [Glacier2::SessionManager](#)

#### Operation Index

[destroy](#) — Destroy the session.

#### Operations

##### **void destroy()**

Destroy the session. This is called automatically when the router is destroyed.

---

## Glacier2-SessionControl

---

### Glacier2::SessionControl

#### Overview

#### interface SessionControl

An administrative session control object, which is tied to the lifecycle of a [Glacier2::Session](#).

#### See Also

- [Glacier2::Session](#)

#### Operation Index

[categories](#) — Access the object that manages the allowable categories for object identities for this session.

[adapterIds](#) — Access the object that manages the allowable adapter identities for objects for this session.

[identities](#) — Access the object that manages the allowable object identities for this session.

[getSessionTimeout](#) — Get the session timeout.

[destroy](#) — Destroy the associated session.

#### Operations

##### **Glacier2::StringSet\*** [categories\(\)](#)

Access the object that manages the allowable categories for object identities for this session.

##### *Return Value*

A StringSet object.

##### **Glacier2::StringSet\*** [adapterIds\(\)](#)

Access the object that manages the allowable adapter identities for objects for this session.

##### *Return Value*

A StringSet object.

##### **Glacier2::IdentitySet\*** [identities\(\)](#)

Access the object that manages the allowable object identities for this session.

##### *Return Value*

An IdentitySet object.

##### **int** [getSessionTimeout\(\)](#)

Get the session timeout.

##### *Return Value*

The timeout.

**void destroy()**

Destroy the associated session.

---

## Glacier2-SessionManager

---

### Glacier2::SessionManager

#### Overview

#### interface SessionManager

The session manager for username/password authenticated users that is responsible for managing [Glacier2::Session](#) objects. New session objects are created by the [Glacier2::Router](#) object calling on an application-provided session manager. If no session manager is provided by the application, no client-visible sessions are passed to the client.

#### See Also

- [Glacier2::Router](#)
- [Glacier2::Session](#)

#### Operation Index

[create](#) — Create a new session.

#### Operations

[ "format:sliced" ] [Glacier2::Session\\*](#) `create(string userId, Glacier2::SessionControl\* control)` throws [Glacier2::CannotCreateSessionException](#)

Create a new session.

#### Parameters

`userId` — The user id for the session.

`control` — A proxy to the session control object.

#### Return Value

A proxy to the newly created session.

#### Exceptions

[Glacier2::CannotCreateSessionException](#) — Raised if the session cannot be created.

---

## Glacier2-SessionNotExistException

---

### Glacier2::SessionNotExistException

#### Overview

exception `SessionNotExistException`

This exception is raised if a client tries to destroy a session with a router, but no session exists for the client.

#### *Used By*

- [Glacier2::Router::destroySession](#)
- [Glacier2::Router::refreshSession](#)

#### *See Also*

- [Glacier2::Router::destroySession](#)
-

## Glacier2-SSLInfo

---

### Glacier2::SSLInfo

#### Overview

#### struct SSLInfo

Information taken from an SSL connection used for permissions verification.

#### Used By

- [Glacier2::SSLPermissionsVerifier::authorize](#)
- [Glacier2::SSLSessionManager::create](#)

#### See Also

- [Glacier2::PermissionsVerifier](#)

#### Data Member Index

[remoteHost](#) — The remote host.

[remotePort](#) — The remote port.

[localHost](#) — The router's host.

[localPort](#) — The router's port.

[cipher](#) — The negotiated cipher suite.

[certs](#) — The certificate chain.

#### Data Members

##### string remoteHost;

The remote host.

##### int remotePort;

The remote port.

##### string localHost;

The router's host.

##### int localPort;

The router's port.

##### string cipher;

The negotiated cipher suite.

##### Ice::StringSeq certs;

The certificate chain.

---

## Glacier2-SSLPermissionsVerifier

---

### Glacier2::SSLPermissionsVerifier

#### Overview

#### interface SSLPermissionsVerifier

The SSL Glacier2 permissions verifier. This is called through the process of establishing a session.

#### See Also

- [Glacier2::Router](#)

#### Operation Index

[authorize](#) — Check whether a user has permission to access the router.

#### Operations

[ "nonmutating", "format:sliced" ] bool [authorize](#)([Glacier2::SSLInfo](#) info, out string reason) throws [Glacier2::PermissionDeniedException](#)

Check whether a user has permission to access the router.

#### Parameters

*info* — The SSL information.

*reason* — The reason why access was denied.

#### Return Value

True if access is granted, or false otherwise.

#### Exceptions

[Glacier2::PermissionDeniedException](#) — Raised if the user access is denied. This can be raised in place of returning false with a reason set in the reason out parameter.

#### See Also

- [Glacier2::SSLInfo](#)
-

## Glacier2-SSLSessionManager

---

### Glacier2::SSLSessionManager

#### Overview

#### interface SSLSessionManager

The session manager for SSL authenticated users that is responsible for managing [Glacier2::Session](#) objects. New session objects are created by the [Glacier2::Router](#) object calling on an application-provided session manager. If no session manager is provided by the application, no client-visible sessions are passed to the client.

#### See Also

- [Glacier2::Router](#)
- [Glacier2::Session](#)

#### Operation Index

[create](#) — Create a new session.

#### Operations

[ "format:sliced" ] [Glacier2::Session\\*](#) [create](#)([Glacier2::SSLInfo](#) info, [Glacier2::SessionControl\\*](#) control) throws [Glacier2::CannotCreateSessionException](#)

Create a new session.

#### Parameters

`info` — The SSL info.

`control` — A proxy to the session control object.

#### Return Value

A proxy to the newly created session.

#### Exceptions

[Glacier2::CannotCreateSessionException](#) — Raised if the session cannot be created.

---

## Glacier2-StringSet

---

### Glacier2::StringSet

#### Overview

#### interface StringSet

An object for managing the set of identity constraints for specific parts of object identity on a [Glacier2::Session](#).

#### See Also

- [Glacier2::Session](#)
- [Glacier2::SessionControl](#)

#### Operation Index

**add** — Add a sequence of strings to this set of constraints.

**remove** — Remove a sequence of strings from this set of constraints.

**get** — Returns a sequence of strings describing the constraints in this set.

#### Operations

##### **void add(Ice::StringSeq additions)**

Add a sequence of strings to this set of constraints. Order is not preserved and duplicates are implicitly removed.

##### *Parameters*

`additions` — The sequence of strings to be added.

##### **void remove(Ice::StringSeq deletions)**

Remove a sequence of strings from this set of constraints. No errors are returned if an entry is not found.

##### *Parameters*

`deletions` — The sequence of strings to be removed.

##### **Ice::StringSeq get()**

Returns a sequence of strings describing the constraints in this set.

##### *Return Value*

The sequence of strings for this set.

---

# IceBox Slice API

---

## IceBox

### Overview

#### module IceBox

IceBox is an application server specifically for Ice applications. IceBox can easily run and administer Ice services that are dynamically loaded as a DLL, shared library, or Java class.

### Interface Index

[Service](#) — An application service managed by a [ServiceManager](#).

[ServiceManager](#) — Administers a set of [Service](#) instances.

[ServiceObserver](#) — An Observer interface implemented by admin clients interested in the status of services @see [ServiceManager](#)

### Exception Index

[AlreadyStartedException](#) — This exception is thrown if an attempt is made to start an already-started service.

[AlreadyStoppedException](#) — This exception is thrown if an attempt is made to stop an already-stopped service.

[FailureException](#) — This exception is a general failure notification.

[NoSuchServiceException](#) — This exception is thrown if a service name does not refer to an existing service.

---

## IceBox-AlreadyStartedException

---

### IceBox::AlreadyStartedException

#### Overview

#### exception AlreadyStartedException

This exception is thrown if an attempt is made to start an already-started service.

#### *Used By*

- IceBox::ServiceManager::startService
-

## IceBox-AlreadyStoppedException

---

### IceBox::AlreadyStoppedException

#### Overview

#### exception AlreadyStoppedException

This exception is thrown if an attempt is made to stop an already-stopped service.

#### *Used By*

- [IceBox::ServiceManager::stopService](#)
-

## IceBox-FailureException

---

### IceBox::FailureException

#### Overview

#### local exception FailureException

This exception is a general failure notification. It is thrown for errors such as a service encountering an error during initialization, or the service manager being unable to load a service executable.

#### Data Member Index

`reason` — The reason for the failure.

#### Data Members

`string reason;`

The reason for the failure.

---

## IceBox-NoSuchServiceException

---

### IceBox::NoSuchServiceException

#### Overview

#### exception NoSuchServiceException

This exception is thrown if a service name does not refer to an existing service.

#### *Used By*

- IceBox::ServiceManager::startService
  - IceBox::ServiceManager::stopService
-

## IceBox-Service

---

### IceBox::Service

#### Overview

##### local interface Service

An application service managed by a [IceBox::ServiceManager](#).

#### Operation Index

[start](#) — Start the service.

[stop](#) — Stop the service.

#### Operations

##### **void start(string name, Ice::Communicator communicator, Ice::StringSeq args)**

Start the service. The given communicator is created by the [IceBox::ServiceManager](#) for use by the service. This communicator may also be used by other services, depending on the service configuration.

*The [IceBox::ServiceManager](#) owns this communicator, and is responsible for destroying it.*

##### **Parameters**

`name` — The service's name, as determined by the configuration.

`communicator` — A communicator for use by the service.

`args` — The service arguments that were not converted into properties.

##### **Exceptions**

[IceBox::FailureException](#) — Raised if [start](#) failed.

##### **void stop()**

Stop the service.

---

## IceBox-ServiceManager

---

### IceBox::ServiceManager

#### Overview

#### interface ServiceManager

Administers a set of `IceBox::Service` instances.

#### See Also

- `IceBox::Service`

#### Operation Index

`getSliceChecksums` — Returns the checksums for the IceBox Slice definitions.  
`startService` — Start an individual service.  
`stopService` — Stop an individual service.  
`addObserver` — Registers a new observer with the ServiceManager.  
`shutdown` — Shut down all services.

#### Operations

##### [ "nonmutating" ] `Ice::SliceChecksumDict getSliceChecksums()`

Returns the checksums for the IceBox Slice definitions.

#### Return Value

A dictionary mapping Slice type ids to their checksums.

##### `void startService(string service) throws IceBox::AlreadyStartedException, IceBox::NoSuchServiceException`

Start an individual service.

#### Parameters

`service` — The service name.

##### `void stopService(string service) throws IceBox::AlreadyStoppedException, IceBox::NoSuchServiceException`

Stop an individual service.

#### Parameters

`service` — The service name.

##### `void addObserver(IceBox::ServiceObserver* observer)`

Registers a new observer with the ServiceManager.

#### Parameters

`observer` — The new observer

**void shutdown()**

Shut down all services. This causes `IceBox::Service::stop` to be invoked on all configured services.

---

## IceBox-ServiceObserver

---

### IceBox::ServiceObserver

#### Overview

#### interface ServiceObserver

An Observer interface implemented by admin clients interested in the status of services

#### See Also

- [IceBox::ServiceManager](#)

#### Operation Index

[servicesStarted](#)  
[servicesStopped](#)

#### Operations

**void servicesStarted(Ice::StringSeq services)**

**void servicesStopped(Ice::StringSeq services)**

---

# IceGrid Slice API

---

## IceGrid

### Overview

#### [ "objc:prefix:ICEGRID" ] module IceGrid

IceGrid is a server activation and deployment tool. IceGrid, simplifies the complex task of deploying applications in a heterogeneous computer network.

### Class Index

[AdaptiveLoadBalancingPolicy](#) — Adaptive load balancing policy.  
[BoxedDistributionDescriptor](#) — A "boxed" distribution descriptor.  
[BoxedString](#) — A "boxed" string.  
[CommunicatorDescriptor](#) — A communicator descriptor.  
[IceBoxDescriptor](#) — An IceBox server descriptor.  
[LoadBalancingPolicy](#) — A base class for load balancing policies.  
[OrderedLoadBalancingPolicy](#) — Ordered load balancing policy.  
[RandomLoadBalancingPolicy](#) — Random load balancing policy.  
[RoundRobinLoadBalancingPolicy](#) — Round robin load balancing policy.  
[ServerDescriptor](#) — An Ice server descriptor.  
[ServiceDescriptor](#) — An IceBox service descriptor.

### Interface Index

[AdapterObserver](#) — This interface allows applications to monitor the state of object adapters that are registered with IceGrid.  
[Admin](#) — The IceGrid administrative interface.  
[AdminSession](#) — Used by administrative clients to view, update, and receive observer updates from the IceGrid registry.  
[ApplicationObserver](#) — The database observer interface.  
[FileIterator](#) — This interface provides access to IceGrid log file contents.  
[FileParser](#) — `icegridadmin` provides a [FileParser](#) object to transform XML files into [ApplicationDescriptor](#) objects.  
[Locator](#) — The IceGrid locator interface provides access to the [Query](#) and [Registry](#) object of the IceGrid registry.  
[NodeObserver](#) — The node observer interface.  
[ObjectObserver](#) — This interface allows applications to monitor IceGrid well-known objects.  
[Query](#) — The IceGrid query interface.  
[Registry](#) — The IceGrid registry allows clients create sessions directly with the registry.  
[RegistryObserver](#) — This interface allows applications to monitor changes the state of the registry.  
[RegistryPluginFacade](#) — The [RegistryPluginFacade](#) is implemented by IceGrid and can be used by plugins and filter implementations to retrieve information from IceGrid about the well-known objects or adapters.  
[ReplicaGroupFilter](#) — The [ReplicaGroupFilter](#) is used by IceGrid to filter adapters returned to the client when it resolves a filtered replica group.  
[Session](#) — A session object is used by IceGrid clients to allocate and release objects.  
[TypeFilter](#) — The [TypeFilter](#) is used by IceGrid to filter well-known proxies returned to the client when it searches a well-known object by type.  
[UserAccountMapper](#) — A user account mapper object is used by IceGrid nodes to map session identifiers to user accounts.

### Exception Index

[AccessDeniedException](#) — This exception is raised if a registry lock wasn't acquired or is already held by a session.  
[AdapterNotExistException](#) — This exception is raised if an adapter does not exist.  
[AllocationException](#) — This exception is raised if the allocation of an object failed.  
[AllocationTimeoutException](#) — This exception is raised if the request to allocate an object times out.  
[ApplicationNotExistException](#) — This exception is raised if an application does not exist.  
[BadSignalException](#) — This exception is raised if an unknown signal was sent to to a server.  
[DeploymentException](#) — An exception for deployment errors.  
[FileNotAvailableException](#) — This exception is raised if a file is not available.

**NodeNotExistException** — This exception is raised if a node does not exist.  
**NodeUnreachableException** — This exception is raised if a node could not be reached.  
**ObjectExistsException** — This exception is raised if an object already exists.  
**ObjectNotRegisteredException** — This exception is raised if an object is not registered.  
**ObserverAlreadyRegisteredException** — This exception is raised if an observer is already registered with the registry.  
**ParseException** — This exception is raised if an error occurs during parsing.  
**PatchException** — This exception is raised if a patch failed.  
**PermissionDeniedException** — This exception is raised if a client is denied the ability to create a session with IceGrid.  
**RegistryNotExistException** — This exception is raised if a registry does not exist.  
**RegistryUnreachableException** — This exception is raised if a registry could not be reached.  
**ServerNotExistException** — This exception is raised if a server does not exist.  
**ServerStartException** — This exception is raised if a server failed to start.  
**ServerStopException** — This exception is raised if a server failed to stop.  
**ServerUnreachableException** — This exception is raised if a server could not be reached.  
**UserAccountNotFoundException** — This exception is raised if a user account for a given session identifier can't be found.

## Structure Index

**AdapterDescriptor** — An Ice object adapter descriptor.  
**AdapterDynamicInfo** — Dynamic information about the state of an adapter.  
**AdapterInfo** — Information about an adapter registered with the IceGrid registry.  
**ApplicationDescriptor** — An application descriptor.  
**ApplicationInfo** — Information about an IceGrid application.  
**ApplicationUpdateDescriptor** — An application update descriptor to describe the updates to apply to a deployed application.  
**ApplicationUpdateInfo** — Information about updates to an IceGrid application.  
**DbEnvDescriptor** — A Freeze database environment descriptor.  
**DistributionDescriptor** — A distribution descriptor defines an IcePatch2 server and the directories to retrieve from the patch server.  
**LoadInfo** — Information about the load of a node.  
**NodeDescriptor** — A node descriptor.  
**NodeDynamicInfo** — Dynamic information about the state of a node.  
**NodeInfo** — Information about an IceGrid node.  
**NodeUpdateDescriptor** — A node update descriptor to describe the updates to apply to a node of a deployed application.  
**ObjectDescriptor** — An Ice object descriptor.  
**ObjectInfo** — Information about an Ice object.  
**PropertyDescriptor** — Property descriptor.  
**PropertySetDescriptor** — A property set descriptor.  
**RegistryInfo** — Information about an IceGrid registry replica.  
**ReplicaGroupDescriptor** — A replica group descriptor.  
**ServerDynamicInfo** — Dynamic information about the state of a server.  
**ServerInfo** — Information about a server managed by an IceGrid node.  
**ServerInstanceDescriptor** — A server template instance descriptor.  
**ServiceInstanceDescriptor** — A service template instance descriptor.  
**TemplateDescriptor** — A template descriptor for server or service templates.

## Sequence Index

**AdapterDescriptorSeq** — A sequence of adapter descriptors.  
**AdapterDynamicInfoSeq** — A sequence of adapter dynamic information structures.  
**AdapterInfoSeq** — A sequence of adapter information structures.  
**ApplicationDescriptorSeq** — A sequence of application descriptors.  
**ApplicationInfoSeq** — A sequence of [ApplicationInfo](#) structures.  
**DbEnvDescriptorSeq** — A sequence of database environment descriptors.  
**NodeDynamicInfoSeq** — A sequence of node dynamic information structures.  
**NodeUpdateDescriptorSeq** — A sequence of node update descriptors.  
**ObjectDescriptorSeq** — A sequence of object descriptors.  
**ObjectInfoSeq** — A sequence of object information structures.  
**PropertyDescriptorSeq** — A sequence of property descriptors.  
**RegistryInfoSeq** — A sequence of [RegistryInfo](#) structures.  
**ReplicaGroupDescriptorSeq** — A sequence of replica groups.  
**ServerDescriptorSeq** — A sequence of server descriptors.  
**ServerDynamicInfoSeq** — A sequence of server dynamic information structures.  
**ServerInstanceDescriptorSeq** — A sequence of server instance descriptors.  
**ServiceDescriptorSeq** — A sequence of service descriptors.  
**ServiceInstanceDescriptorSeq** — A sequence of service instance descriptors.

## Dictionary Index

[NodeDescriptorDict](#) — Mapping of node name to node descriptor.  
[PropertySetDescriptorDict](#) — A mapping of property set name to property set descriptor.  
[StringObjectProxyDict](#) — A dictionary of proxies.  
[StringStringDict](#) — A mapping of string to string.  
[TemplateDescriptorDict](#) — A mapping of template identifier to template descriptor.

## Enumeration Index

[LoadSample](#) — Determines which load sampling interval to use.  
[ServerState](#) — An enumeration representing the state of the server.

## Sequences

[ "java:type:java.util.LinkedList<AdapterDescriptor>" ] [sequence<AdapterDescriptor>](#) [AdapterDescriptorSeq](#)

A sequence of adapter descriptors.

### Used By

- [CommunicatorDescriptor::adapters](#)

[ "java:type:java.util.LinkedList<AdapterDynamicInfo>" ] [sequence<AdapterDynamicInfo>](#) [AdapterDynamicInfoSeq](#)

A sequence of adapter dynamic information structures.

### Used By

- [NodeDynamicInfo::adapters](#)

[sequence<AdapterInfo>](#) [AdapterInfoSeq](#)

A sequence of adapter information structures.

### Used By

- [AdapterObserver::adapterInit](#)
- [Admin::getAdapterInfo](#)
- [RegistryPluginFacade::getAdapterInfo](#)

[ "java:type:java.util.LinkedList<ApplicationDescriptor>" ] [sequence<ApplicationDescriptor>](#) [ApplicationDescriptorSeq](#)

A sequence of application descriptors.

[ "java:type:java.util.LinkedList<ApplicationInfo>" ] [sequence<ApplicationInfo>](#) [ApplicationInfoSeq](#)

A sequence of [ApplicationInfo](#) structures.

### Used By

- [ApplicationObserver::applicationInit](#)

### [ "java:type:java.util.LinkedList<DbEnvDescriptor>" ] sequence<DbEnvDescriptor> DbEnvDescriptorSeq

A sequence of database environment descriptors.

#### Used By

- CommunicatorDescriptor::dbEnvs

### sequence<NodeDynamicInfo> NodeDynamicInfoSeq

A sequence of node dynamic information structures.

#### Used By

- NodeObserver::nodeInit

### [ "java:type:java.util.LinkedList<NodeUpdateDescriptor>" ] sequence<NodeUpdateDescriptor> NodeUpdateDescriptorSeq

A sequence of node update descriptors.

#### Used By

- ApplicationUpdateDescriptor::nodes

### [ "java:type:java.util.LinkedList<ObjectDescriptor>" ] sequence<ObjectDescriptor> ObjectDescriptorSeq

A sequence of object descriptors.

#### Used By

- AdapterDescriptor::allocatables
- AdapterDescriptor::objects
- ReplicaGroupDescriptor::objects

### sequence<ObjectInfo> ObjectInfoSeq

A sequence of object information structures.

#### Used By

- Admin::getAllObjectInfos
- Admin::getObjectInfosByType
- ObjectObserver::objectInit

### [ "java:type:java.util.LinkedList<PropertyDescriptor>" ] sequence<PropertyDescriptor> PropertyDescriptorSeq

A sequence of property descriptors.

#### Used By

- DbEnvDescriptor::properties

- `PropertySetDescriptor::properties`

### **sequence<RegistryInfo> RegistryInfoSeq**

A sequence of `RegistryInfo` structures.

#### Used By

- `RegistryObserver::registryInit`

### **[ "java:type:java.util.LinkedList<ReplicaGroupDescriptor>" ] sequence<ReplicaGroupDescriptor> ReplicaGroupDescriptorSeq**

A sequence of replica groups.

#### Used By

- `ApplicationDescriptor::replicaGroups`
- `ApplicationUpdateDescriptor::replicaGroups`

### **[ "java:type:java.util.LinkedList<ServerDescriptor>" ] sequence<ServerDescriptor> ServerDescriptorSeq**

A sequence of server descriptors.

#### Used By

- `NodeDescriptor::servers`
- `NodeUpdateDescriptor::servers`

### **[ "java:type:java.util.LinkedList<ServerDynamicInfo>" ] sequence<ServerDynamicInfo> ServerDynamicInfoSeq**

A sequence of server dynamic information structures.

#### Used By

- `NodeDynamicInfo::servers`

### **[ "java:type:java.util.LinkedList<ServerInstanceDescriptor>" ] sequence<ServerInstanceDescriptor> ServerInstanceDescriptorSeq**

A sequence of server instance descriptors.

#### Used By

- `NodeDescriptor::serverInstances`
- `NodeUpdateDescriptor::serverInstances`

### **[ "java:type:java.util.LinkedList<ServiceDescriptor>" ] sequence<ServiceDescriptor> ServiceDescriptorSeq**

A sequence of service descriptors.

## [ "java:type:java.util.LinkedList<ServiceInstanceDescriptor>" ] sequence<ServiceInstanceDescriptor> ServiceInstanceDescriptorSeq

A sequence of service instance descriptors.

### Used By

- IceBoxDescriptor::services

## Dictionaries

### dictionary<string, NodeDescriptor> NodeDescriptorDict

Mapping of node name to node descriptor.

### Used By

- ApplicationDescriptor::nodes

### dictionary<string, PropertySetDescriptor> PropertySetDescriptorDict

A mapping of property set name to property set descriptor.

### Used By

- ApplicationDescriptor::propertySets
- ApplicationUpdateDescriptor::propertySets
- NodeDescriptor::propertySets
- NodeUpdateDescriptor::propertySets
- ServerInstanceDescriptor::servicePropertySets

### dictionary<string, Object\*> StringObjectProxyDict

A dictionary of proxies.

### dictionary<string, string> StringStringDict

A mapping of string to string.

### Used By

- ApplicationDescriptor::variables
- ApplicationUpdateDescriptor::variables
- NodeDescriptor::variables
- NodeUpdateDescriptor::variables
- ServerInstanceDescriptor::parameterValues
- ServiceInstanceDescriptor::parameterValues
- TemplateDescriptor::parameterDefaults

### dictionary<string, TemplateDescriptor> TemplateDescriptorDict

A mapping of template identifier to template descriptor.

### Used By

- ApplicationDescriptor::serverTemplates
- ApplicationDescriptor::serviceTemplates
- ApplicationUpdateDescriptor::serverTemplates

- `ApplicationUpdateDescriptor::serviceTemplates`
-

## IceGrid-AccessDeniedException

---

### IceGrid::AccessDeniedException

#### Overview

#### exception AccessDeniedException

This exception is raised if a registry lock wasn't acquired or is already held by a session.

#### *Used By*

- IceGrid::Admin::addApplication
- IceGrid::Admin::instantiateServer
- IceGrid::Admin::removeApplication
- IceGrid::Admin::syncApplicationWithoutRestart
- IceGrid::Admin::syncApplication
- IceGrid::Admin::updateApplicationWithoutRestart
- IceGrid::Admin::updateApplication
- IceGrid::AdminSession::finishUpdate
- IceGrid::AdminSession::startUpdate

#### Data Member Index

`lockUserId` — The id of the user holding the lock (if any).

#### Data Members

**string** `lockUserId`;

The id of the user holding the lock (if any).

---

## IceGrid-AdapterDescriptor

---

### IceGrid::AdapterDescriptor

#### Overview

[ "cpp:comparable" ] struct AdapterDescriptor

An Ice object adapter descriptor.

#### Used By

- [IceGrid::AdapterDescriptorSeq](#)

#### Data Member Index

[name](#) — The object adapter name.

[description](#) — The description of this object adapter.

[id](#) — The object adapter id.

[replicaGroupId](#) — The replica id of this adapter.

[priority](#) — The adapter priority.

[registerProcess](#) — Flag to specify if the object adapter will register a process object.

[serverLifetime](#) — If true the lifetime of this object adapter is the same of the server lifetime.

[objects](#) — The well-known object descriptors associated with this object adapter.

[allocatables](#) — The allocatable object descriptors associated with this object adapter.

#### Data Members

**string name;**

The object adapter name.

**string description;**

The description of this object adapter.

**string id;**

The object adapter id.

**string replicaGroupId;**

The replica id of this adapter.

**string priority;**

The adapter priority. This is eventually used when the adapter is member of a replica group to sort the adapter endpoints by priority.

**bool registerProcess;**

Flag to specify if the object adapter will register a process object.

**bool serverLifetime;**

If true the lifetime of this object adapter is the same of the server lifetime. This information is used by the IceGrid node to figure out the server state: the server is active only if all its "server lifetime" adapters are active.

**IceGrid::ObjectDescriptorSeq objects;**

The well-known object descriptors associated with this object adapter.

**IceGrid::ObjectDescriptorSeq allocatables;**

The allocatable object descriptors associated with this object adapter.

---

## IceGrid-AdapterDynamicInfo

---

### IceGrid::AdapterDynamicInfo

#### Overview

#### struct AdapterDynamicInfo

Dynamic information about the state of an adapter.

#### *Used By*

- [IceGrid::AdapterDynamicInfoSeq](#)
- [IceGrid::NodeObserver::updateAdapter](#)

#### Data Member Index

[id](#) — The id of the adapter.

[proxy](#) — The direct proxy containing the adapter endpoints.

#### Data Members

**string id;**

The id of the adapter.

**Object\* proxy;**

The direct proxy containing the adapter endpoints.

---

## IceGrid-AdapterInfo

---

### IceGrid::AdapterInfo

#### Overview

[ "cpp:comparable" ] struct AdapterInfo

Information about an adapter registered with the IceGrid registry.

#### Used By

- [IceGrid::AdapterInfoSeq](#)
- [IceGrid::AdapterObserver::adapterAdded](#)
- [IceGrid::AdapterObserver::adapterUpdated](#)

#### Data Member Index

[id](#) — The id of the adapter.

[proxy](#) — A dummy direct proxy that contains the adapter endpoints.

[replicaGroupId](#) — The replica group id of the object adapter, or empty if the adapter doesn't belong to a replica group.

#### Data Members

**string id;**

The id of the adapter.

**Object\* proxy;**

A dummy direct proxy that contains the adapter endpoints.

**string replicaGroupId;**

The replica group id of the object adapter, or empty if the adapter doesn't belong to a replica group.

---

## IceGrid-AdapterNotExistException

---

### IceGrid::AdapterNotExistException

#### Overview

#### exception AdapterNotExistException

This exception is raised if an adapter does not exist.

#### *Used By*

- IceGrid::Admin::getAdapterInfo
- IceGrid::Admin::removeAdapter
- IceGrid::RegistryPluginFacade::getAdapterApplication
- IceGrid::RegistryPluginFacade::getAdapterInfo
- IceGrid::RegistryPluginFacade::getAdapterNode
- IceGrid::RegistryPluginFacade::getAdapterServer
- IceGrid::RegistryPluginFacade::getPropertyForAdapter

#### Data Member Index

`id` — The id of the object adapter.

#### Data Members

`string id;`

The id of the object adapter.

---

## IceGrid-AdapterObserver

---

### IceGrid::AdapterObserver

#### Overview

#### interface AdapterObserver

This interface allows applications to monitor the state of object adapters that are registered with IceGrid.

#### Operation Index

[adapterInit](#) — `adapterInit` is called after registration of an observer to indicate the state of the registry.

[adapterAdded](#) — The `adapterAdded` operation is called to notify an observer when a dynamically-registered adapter was added.

[adapterUpdated](#) — The `adapterUpdated` operation is called to notify an observer when a dynamically-registered adapter was updated.

[adapterRemoved](#) — The `adapterRemoved` operation is called to notify an observer when a dynamically-registered adapter was removed.

#### Operations

##### **void adapterInit(IceGrid::AdapterInfoSeq adpts)**

`adapterInit` is called after registration of an observer to indicate the state of the registry.

##### **Parameters**

`adpts` — The adapters that were dynamically registered with the registry (not through the deployment mechanism).

##### **void adapterAdded(IceGrid::AdapterInfo info)**

The `adapterAdded` operation is called to notify an observer when a dynamically-registered adapter was added.

##### **Parameters**

`info` — The details of the new adapter.

##### **void adapterUpdated(IceGrid::AdapterInfo info)**

The `adapterUpdated` operation is called to notify an observer when a dynamically-registered adapter was updated.

##### **Parameters**

`info` — The details of the updated adapter.

##### **void adapterRemoved(string id)**

The `adapterRemoved` operation is called to notify an observer when a dynamically-registered adapter was removed.

##### **Parameters**

`id` — The ID of the removed adapter.

---

## IceGrid-AdaptiveLoadBalancingPolicy

---

### IceGrid::AdaptiveLoadBalancingPolicy

#### Overview

class `AdaptiveLoadBalancingPolicy` extends `IceGrid::LoadBalancingPolicy`

Adaptive load balancing policy.

#### Data Member Index

`loadSample` — The load sample to use for the load balancing.

#### Data Members

`string loadSample;`

The load sample to use for the load balancing. The allowed values for this attribute are "1", "5" and "15", representing respectively the load average over the past minute, the past 5 minutes and the past 15 minutes.

---

## IceGrid-Admin

---

### IceGrid::Admin

#### Overview

#### interface Admin

The IceGrid administrative interface.

Allowing access to this interface is a security risk! Please see the IceGrid documentation for further information.

#### Operation Index

**addApplication** — Add an application to IceGrid.  
**syncApplication** — Synchronize a deployed application with the given application descriptor.  
**updateApplication** — Update a deployed application with the given update application descriptor.  
**syncApplicationWithoutRestart** — Synchronize a deployed application with the given application descriptor.  
**updateApplicationWithoutRestart** — Update a deployed application with the given update application descriptor only if no server restarts are necessary for the update of the application.  
**removeApplication** — Remove an application from IceGrid.  
**instantiateServer** — Instantiate a server template from an application on the given node.  
**patchApplication** — Patch the given application data.  
**getApplicationInfo** — Get an application descriptor.  
**getDefaultApplicationDescriptor** — Get the default application descriptor.  
**getAllApplicationNames** — Get all the IceGrid applications currently registered.  
**getServerInfo** — Get the server information for the server with the given id.  
**getServerState** — Get a server's state.  
**getServerPid** — Get a server's system process id.  
**getServerAdminCategory** — Get the category for server admin objects.  
**getServerAdmin** — Get a proxy to the server's admin object.  
**enableServer** — Enable or disable a server.  
**isServerEnabled** — Check if the server is enabled or disabled.  
**startServer** — Start a server and wait for its activation.  
**stopServer** — Stop a server.  
**patchServer** — Patch a server.  
**sendSignal** — Send signal to a server.  
**getAllServerIds** — Get all the server ids registered with IceGrid.  
**getAdapterInfo** — Get the adapter information for the replica group or adapter with the given id.  
**removeAdapter** — Remove the adapter with the given id.  
**getAllAdapterIds** — Get all the adapter ids registered with IceGrid.  
**addObject** — Add an object to the object registry.  
**updateObject** — Update an object in the object registry.  
**addObjectWithType** — Add an object to the object registry and explicitly specify its type.  
**removeObject** — Remove an object from the object registry.  
**getObjectInfo** — Get the object info for the object with the given identity.  
**getObjectInfosByType** — Get the object info of all the registered objects with the given type.  
**getAllObjectInfos** — Get the object info of all the registered objects whose stringified identities match the given expression.  
**pingNode** — Ping an IceGrid node to see if it is active.  
**getNodeLoad** — Get the load averages of the node.  
**getNodeInfo** — Get the node information for the node with the given name.  
**getNodeAdmin** — Get a proxy to the IceGrid node's admin object.  
**getNodeProcessorSocketCount** — Get the number of physical processor sockets for the machine running the node with the given name.  
**shutdownNode** — Shutdown an IceGrid node.  
**getNodeHostname** — Get the hostname of this node.  
**getAllNodeNames** — Get all the IceGrid nodes currently registered.  
**pingRegistry** — Ping an IceGrid registry to see if it is active.  
**getRegistryInfo** — Get the registry information for the registry with the given name.  
**getRegistryAdmin** — Get a proxy to the IceGrid registry's admin object.  
**shutdownRegistry** — Shutdown an IceGrid registry.

`getAllRegistryNames` — Get all the IceGrid registries currently registered.  
`shutdown` — Shut down the IceGrid registry.  
`getSliceChecksums` — Returns the checksums for the IceGrid Slice definitions.

## Operations

**`void addApplication(IceGrid::ApplicationDescriptor descriptor) throws IceGrid::AccessDeniedException, IceGrid::DeploymentException`**

Add an application to IceGrid.

### Parameters

`descriptor` — The application descriptor.

### Exceptions

`IceGrid::AccessDeniedException` — Raised if the session doesn't hold the exclusive lock or if another session is holding the lock.  
`IceGrid::DeploymentException` — Raised if application deployment failed.

**`void syncApplication(IceGrid::ApplicationDescriptor descriptor) throws IceGrid::AccessDeniedException, IceGrid::DeploymentException, IceGrid::ApplicationNotExistException`**

Synchronize a deployed application with the given application descriptor. This operation will replace the current descriptor with this new descriptor.

### Parameters

`descriptor` — The application descriptor.

### Exceptions

`IceGrid::AccessDeniedException` — Raised if the session doesn't hold the exclusive lock or if another session is holding the lock.  
`IceGrid::DeploymentException` — Raised if application deployment failed.  
`IceGrid::ApplicationNotExistException` — Raised if the application doesn't exist.

**`void updateApplication(IceGrid::ApplicationUpdateDescriptor descriptor) throws IceGrid::AccessDeniedException, IceGrid::DeploymentException, IceGrid::ApplicationNotExistException`**

Update a deployed application with the given update application descriptor.

### Parameters

`descriptor` — The update descriptor.

### Exceptions

`IceGrid::AccessDeniedException` — Raised if the session doesn't hold the exclusive lock or if another session is holding the lock.  
`IceGrid::DeploymentException` — Raised if application deployment failed.  
`IceGrid::ApplicationNotExistException` — Raised if the application doesn't exist.

**`void syncApplicationWithoutRestart(IceGrid::ApplicationDescriptor descriptor) throws IceGrid::AccessDeniedException, IceGrid::DeploymentException, IceGrid::ApplicationNotExistException`**

Synchronize a deployed application with the given application descriptor. This operation will replace the current descriptor with this new descriptor only if no server restarts are necessary for the update of the application. If some servers need to be restarted, the synchronization is rejected with a `DeploymentException`.

### Parameters

`descriptor` — The application descriptor.

#### **Exceptions**

`IceGrid::AccessDeniedException` — Raised if the session doesn't hold the exclusive lock or if another session is holding the lock.

`IceGrid::DeploymentException` — Raised if application deployment failed.

`IceGrid::ApplicationNotExistException` — Raised if the application doesn't exist.

**`void updateApplicationWithoutRestart(IceGrid::ApplicationUpdateDescriptor descriptor)` throws `IceGrid::AccessDeniedException`, `IceGrid::DeploymentException`, `IceGrid::ApplicationNotExistException`**

Update a deployed application with the given update application descriptor only if no server restarts are necessary for the update of the application. If some servers need to be restarted, the synchronization is rejected with a `DeploymentException`.

#### **Parameters**

`descriptor` — The update descriptor.

#### **Exceptions**

`IceGrid::AccessDeniedException` — Raised if the session doesn't hold the exclusive lock or if another session is holding the lock.

`IceGrid::DeploymentException` — Raised if application deployment failed.

`IceGrid::ApplicationNotExistException` — Raised if the application doesn't exist.

**`void removeApplication(string name)` throws `IceGrid::AccessDeniedException`, `IceGrid::DeploymentException`, `IceGrid::ApplicationNotExistException`**

Remove an application from `IceGrid`.

#### **Parameters**

`name` — The application name.

#### **Exceptions**

`IceGrid::AccessDeniedException` — Raised if the session doesn't hold the exclusive lock or if another session is holding the lock.

`IceGrid::ApplicationNotExistException` — Raised if the application doesn't exist.

**`void instantiateServer(string application, string node, IceGrid::ServerInstanceDescriptor desc)` throws `IceGrid::AccessDeniedException`, `IceGrid::ApplicationNotExistException`, `IceGrid::DeploymentException`**

Instantiate a server template from an application on the given node.

#### **Parameters**

`application` — The application name.

`node` — The name of the node where the server will be deployed.

`desc` — The descriptor of the server instance to deploy.

#### **Exceptions**

`IceGrid::AccessDeniedException` — Raised if the session doesn't hold the exclusive lock or if another session is holding the lock.

`IceGrid::DeploymentException` — Raised if server instantiation failed.

`IceGrid::ApplicationNotExistException` — Raised if the application doesn't exist.

**[ "amd" ] `void patchApplication(string name, bool shutdown)` throws `IceGrid::ApplicationNotExistException`, `IceGrid::PatchException`**

Patch the given application data.

**Parameters**

`name` — The application name.

`shutdown` — If true, the servers depending on the data to patch will be shut down if necessary.

**Exceptions**

`IceGrid::ApplicationNotExistException` — Raised if the application doesn't exist.

`IceGrid::PatchException` — Raised if the patch failed.

[ "nonmutating" ] **IceGrid::ApplicationInfo** `getApplicationInfo(string name)` throws **IceGrid::ApplicationNotExistException**

Get an application descriptor.

**Parameters**

`name` — The application name.

**Return Value**

The application descriptor.

**Exceptions**

`IceGrid::ApplicationNotExistException` — Raised if the application doesn't exist.

[ "nonmutating" ] **IceGrid::ApplicationDescriptor** `getDefaultApplicationDescriptor()` throws **IceGrid::DeploymentException**

Get the default application descriptor.

**Exceptions**

`IceGrid::DeploymentException` — Raised if the default application descriptor can't be accessed or is invalid.

[ "nonmutating" ] **Ice::StringSeq** `getAllApplicationNames()`

Get all the IceGrid applications currently registered.

**Return Value**

The application names.

[ "nonmutating" ] **IceGrid::ServerInfo** `getServerInfo(string id)` throws **IceGrid::ServerNotExistException**

Get the server information for the server with the given id.

**Parameters**

`id` — The server id.

**Return Value**

The server information.

**Exceptions**

`IceGrid::ServerNotExistException` — Raised if the server doesn't exist.

[ "nonmutating" ] **IceGrid::ServerState** `getServerState(string id)` throws **IceGrid::ServerNotExistException**, **IceGrid::NodeUnreachableException**, **IceGrid::DeploymentException**

Get a server's state.

**Parameters**

`id` — The server id.

**Return Value**

The server state.

**Exceptions**

**IceGrid::ServerNotExistException** — Raised if the server doesn't exist.

**IceGrid::NodeUnreachableException** — Raised if the node could not be reached.

**IceGrid::DeploymentException** — Raised if the server couldn't be deployed on the node.

[ "nonmutating" ] **int** `getServerPid(string id)` throws **IceGrid::ServerNotExistException**, **IceGrid::NodeUnreachableException**, **IceGrid::DeploymentException**

Get a server's system process id. The process id is operating system dependent.

**Parameters**

`id` — The server id.

**Return Value**

The server's process id.

**Exceptions**

**IceGrid::ServerNotExistException** — Raised if the server doesn't exist.

**IceGrid::NodeUnreachableException** — Raised if the node could not be reached.

**IceGrid::DeploymentException** — Raised if the server couldn't be deployed on the node.

**string** `getServerAdminCategory()`

Get the category for server admin objects. You can manufacture a server admin proxy from the admin proxy by changing its identity: use the server ID as name and the returned category as category.

**Return Value**

The category for server admin objects.

**Object\*** `getServerAdmin(string id)` throws **IceGrid::ServerNotExistException**, **IceGrid::NodeUnreachableException**, **IceGrid::DeploymentException**

Get a proxy to the server's admin object.

**Parameters**

`id` — The server id.

**Return Value**

A proxy to the server's admin object

**Exceptions**

IceGrid::ServerNotExistException — Raised if the server doesn't exist.  
 IceGrid::NodeUnreachableException — Raised if the node could not be reached.  
 IceGrid::DeploymentException — Raised if the server couldn't be deployed on the node.

**void enableServer(string id, bool enabled) throws IceGrid::ServerNotExistException, IceGrid::NodeUnreachableException, IceGrid::DeploymentException**

Enable or disable a server. A disabled server can't be started on demand or administratively. The enable state of the server is not persistent: if the node is shut down and restarted, the server will be enabled by default.

**Parameters**

id — The server id.  
 enabled — True to enable the server, false to disable it.

**Exceptions**

IceGrid::ServerNotExistException — Raised if the server doesn't exist.  
 IceGrid::NodeUnreachableException — Raised if the node could not be reached.  
 IceGrid::DeploymentException — Raised if the server couldn't be deployed on the node.

**[ "nonmutating" ] bool isServerEnabled(string id) throws IceGrid::ServerNotExistException, IceGrid::NodeUnreachableException, IceGrid::DeploymentException**

Check if the server is enabled or disabled.

**Parameters**

id — The server id.

**Exceptions**

IceGrid::ServerNotExistException — Raised if the server doesn't exist.  
 IceGrid::NodeUnreachableException — Raised if the node could not be reached.  
 IceGrid::DeploymentException — Raised if the server couldn't be deployed on the node.

**[ "amd" ] void startServer(string id) throws IceGrid::ServerNotExistException, IceGrid::ServerStartException, IceGrid::NodeUnreachableException, IceGrid::DeploymentException**

Start a server and wait for its activation.

**Parameters**

id — The server id.

**Exceptions**

IceGrid::ServerNotExistException — Raised if the server doesn't exist.  
 IceGrid::ServerStartException — Raised if the server couldn't be started.  
 IceGrid::NodeUnreachableException — Raised if the node could not be reached.  
 IceGrid::DeploymentException — Raised if the server couldn't be deployed on the node.

**[ "amd" ] void stopServer(string id) throws IceGrid::ServerNotExistException, IceGrid::ServerStopException, IceGrid::NodeUnreachableException, IceGrid::DeploymentException**

Stop a server.

**Parameters**

id — The server id.

**Exceptions**

`IceGrid::ServerNotExistException` — Raised if the server doesn't exist.  
`IceGrid::ServerStopException` — Raised if the server couldn't be stopped.  
`IceGrid::NodeUnreachableException` — Raised if the node could not be reached.  
`IceGrid::DeploymentException` — Raised if the server couldn't be deployed on the node.

[ "amd" ] **void patchServer(string id, bool shutdown) throws `IceGrid::ServerNotExistException`, `IceGrid::NodeUnreachableException`, `IceGrid::DeploymentException`, `IceGrid::PatchException`**

Patch a server.

**Parameters**

`id` — The server id.  
`shutdown` — If true, servers depending on the data to patch will be shut down if necessary.

**Exceptions**

`IceGrid::ServerNotExistException` — Raised if the server doesn't exist.  
`IceGrid::NodeUnreachableException` — Raised if the node could not be reached.  
`IceGrid::DeploymentException` — Raised if the server couldn't be deployed on the node.  
`IceGrid::PatchException` — Raised if the patch failed.

**void sendSignal(string id, string signal) throws `IceGrid::ServerNotExistException`, `IceGrid::NodeUnreachableException`, `IceGrid::DeploymentException`, `IceGrid::BadSignalException`**

Send signal to a server.

**Parameters**

`id` — The server id.  
`signal` — The signal, for example SIGTERM or 15.

**Exceptions**

`IceGrid::ServerNotExistException` — Raised if the server doesn't exist.  
`IceGrid::NodeUnreachableException` — Raised if the node could not be reached.  
`IceGrid::DeploymentException` — Raised if the server couldn't be deployed on the node.  
`IceGrid::BadSignalException` — Raised if the signal is not recognized by the target server.

[ "nonmutating" ] **`Ice::StringSeq` getAllServerIds()**

Get all the server ids registered with IceGrid.

**Return Value**

The server ids.

[ "nonmutating" ] **`IceGrid::AdapterInfoSeq` getAdapterInfo(string id) throws `IceGrid::AdapterNotExistException`**

Get the adapter information for the replica group or adapter with the given id.

**Parameters**

`id` — The adapter id.

**Return Value**

A sequence of adapter information structures. If the given id refers to an adapter, this sequence will contain only one element. If the given id

refers to a replica group, the sequence will contain the adapter information of each member of the replica group.

#### **Exceptions**

`IceGrid::AdapterNotExistException` — Raised if the adapter or replica group doesn't exist.

**`void removeAdapter(string id)` throws `IceGrid::AdapterNotExistException`, `IceGrid::DeploymentException`**

Remove the adapter with the given id.

#### **Parameters**

`id` — The adapter id.

#### **Exceptions**

`IceGrid::AdapterNotExistException` — Raised if the adapter doesn't exist.

**[ "nonmutating" ] `Ice::StringSeq getAllAdapterIds()`**

Get all the adapter ids registered with IceGrid.

#### **Return Value**

The adapter ids.

**`void addObject(Object* obj)` throws `IceGrid::ObjectExistsException`, `IceGrid::DeploymentException`**

Add an object to the object registry. IceGrid will get the object type by calling `ice_id` on the given proxy. The object must be reachable.

#### **Parameters**

`obj` — The object to be added to the registry.

#### **Exceptions**

`IceGrid::ObjectExistsException` — Raised if the object is already registered.

`IceGrid::DeploymentException` — Raised if the object can't be added. This might be raised if the invocation on the proxy to get the object type failed.

**`void updateObject(Object* obj)` throws `IceGrid::ObjectNotRegisteredException`, `IceGrid::DeploymentException`**

Update an object in the object registry. Only objects added with this interface can be updated with this operation. Objects added with deployment descriptors should be updated with the deployment mechanism.

#### **Parameters**

`obj` — The object to be updated to the registry.

#### **Exceptions**

`IceGrid::ObjectNotRegisteredException` — Raised if the object isn't registered with the registry.

`IceGrid::DeploymentException` — Raised if the object can't be updated. This might happen if the object was added with a deployment descriptor.

**`void addObjectWithType(Object* obj, string type)` throws `IceGrid::ObjectExistsException`, `IceGrid::DeploymentException`**

Add an object to the object registry and explicitly specify its type.

**Parameters**

`obj` — The object to be added to the registry.  
`type` — The object type.

**Exceptions**

`IceGrid::ObjectExistsException` — Raised if the object is already registered.

**`void removeObject(Ice::Identity id) throws IceGrid::ObjectNotRegisteredException, IceGrid::DeploymentException`**

Remove an object from the object registry. Only objects added with this interface can be removed with this operation. Objects added with deployment descriptors should be removed with the deployment mechanism.

**Parameters**

`id` — The identity of the object to be removed from the registry.

**Exceptions**

`IceGrid::ObjectNotRegisteredException` — Raised if the object isn't registered with the registry.  
`IceGrid::DeploymentException` — Raised if the object can't be removed. This might happen if the object was added with a deployment descriptor.

**[ "nonmutating" ] `IceGrid::ObjectInfo getObjectInfo(Ice::Identity id) throws IceGrid::ObjectNotRegisteredException`**

Get the object info for the object with the given identity.

**Parameters**

`id` — The identity of the object.

**Return Value**

The object info.

**Exceptions**

`IceGrid::ObjectNotRegisteredException` — Raised if the object isn't registered with the registry.

**[ "nonmutating" ] `IceGrid::ObjectInfoSeq getObjectInfosByType(string type)`**

Get the object info of all the registered objects with the given type.

**Parameters**

`type` — The type of the object.

**Return Value**

The object infos.

**[ "nonmutating" ] `IceGrid::ObjectInfoSeq getAllObjectInfos(string expr)`**

Get the object info of all the registered objects whose stringified identities match the given expression.

**Parameters**

`expr` — The expression to match against the stringified identities of registered objects. The expression may contain a trailing wildcard (\*) character.

**Return Value**

All the object infos with a stringified identity matching the given expression.

[ "nonmutating" ] **bool pingNode(string name) throws IceGrid::NodeNotExistException**

Ping an IceGrid node to see if it is active.

**Parameters**

name — The node name.

**Return Value**

true if the node ping succeeded, false otherwise.

**Exceptions**

[IceGrid::NodeNotExistException](#) — Raised if the node doesn't exist.

[ "nonmutating" ] **IceGrid::LoadInfo getNodeLoad(string name) throws IceGrid::NodeNotExistException, IceGrid::NodeUnreachableException**

Get the load averages of the node.

**Parameters**

name — The node name.

**Return Value**

The node load information.

**Exceptions**

[IceGrid::NodeNotExistException](#) — Raised if the node doesn't exist.

[IceGrid::NodeUnreachableException](#) — Raised if the node could not be reached.

[ "nonmutating" ] **IceGrid::NodeInfo getNodeInfo(string name) throws IceGrid::NodeNotExistException, IceGrid::NodeUnreachableException**

Get the node information for the node with the given name.

**Parameters**

name — The node name.

**Return Value**

The node information.

**Exceptions**

[IceGrid::NodeNotExistException](#) — Raised if the node doesn't exist.

[IceGrid::NodeUnreachableException](#) — Raised if the node could not be reached.

**Object\* getNodeAdmin(string name) throws IceGrid::NodeNotExistException, IceGrid::NodeUnreachableException**

Get a proxy to the IceGrid node's admin object.

**Parameters**

name — The IceGrid node name

**Return Value**

A proxy to the IceGrid node's admin object

**Exceptions**

`IceGrid::NodeNotExistException` — Raised if the node doesn't exist.  
`IceGrid::NodeUnreachableException` — Raised if the node could not be reached.

[ "nonmutating" ] **int** `getNodeProcessorSocketCount(string name)` throws `IceGrid::NodeNotExistException`, `IceGrid::NodeUnreachableException`

Get the number of physical processor sockets for the machine running the node with the given name. Note that this method will return 1 on operating systems where this can't be automatically determined and where the `IceGrid.Node.ProcessorSocketCount` property for the node is not set.

**Parameters**

name — The node name.

**Return Value**

The number of processor sockets or 1 if the number of sockets can't be determined.

**Exceptions**

`IceGrid::NodeNotExistException` — Raised if the node doesn't exist.  
`IceGrid::NodeUnreachableException` — Raised if the node could not be reached.

**void** `shutdownNode(string name)` throws `IceGrid::NodeNotExistException`, `IceGrid::NodeUnreachableException`

Shutdown an IceGrid node.

**Parameters**

name — The node name.

**Exceptions**

`IceGrid::NodeNotExistException` — Raised if the node doesn't exist.  
`IceGrid::NodeUnreachableException` — Raised if the node could not be reached.

[ "nonmutating" ] **string** `getNodeHostname(string name)` throws `IceGrid::NodeNotExistException`, `IceGrid::NodeUnreachableException`

Get the hostname of this node.

**Parameters**

name — The node name.

**Return Value**

The node hostname.

**Exceptions**

`IceGrid::NodeNotExistException` — Raised if the node doesn't exist.  
`IceGrid::NodeUnreachableException` — Raised if the node could not be reached.

**[ "nonmutating" ] Ice::StringSeq getAllNodeNames()**

Get all the IceGrid nodes currently registered.

**Return Value**

The node names.

**bool pingRegistry(string name) throws IceGrid::RegistryNotExistException**

Ping an IceGrid registry to see if it is active.

**Parameters**

name — The registry name.

**Return Value**

true if the registry ping succeeded, false otherwise.

**Exceptions**

[IceGrid::RegistryNotExistException](#) — Raised if the registry doesn't exist.

**IceGrid::RegistryInfo getRegistryInfo(string name) throws IceGrid::RegistryNotExistException, IceGrid::RegistryUnreachableException**

Get the registry information for the registry with the given name.

**Parameters**

name — The registry name.

**Return Value**

The registry information.

**Exceptions**

[IceGrid::RegistryNotExistException](#) — Raised if the registry doesn't exist.

[IceGrid::RegistryUnreachableException](#) — Raised if the registry could not be reached.

**Object\* getRegistryAdmin(string name) throws IceGrid::RegistryNotExistException**

Get a proxy to the IceGrid registry's admin object.

**Parameters**

name — The registry name

**Return Value**

A proxy to the IceGrid registry's admin object

**Exceptions**

[IceGrid::RegistryNotExistException](#) — Raised if the registry doesn't exist.

**void shutdownRegistry(string name) throws IceGrid::RegistryNotExistException, IceGrid::RegistryUnreachableException**

Shutdown an IceGrid registry.

**Parameters**

name — The registry name.

**Exceptions**

`IceGrid::RegistryNotExistException` — Raised if the registry doesn't exist.

`IceGrid::RegistryUnreachableException` — Raised if the registry could not be reached.

**Ice::StringSeq getAllRegistryNames()**

Get all the IceGrid registries currently registered.

**Return Value**

The registry names.

**void shutdown()**

Shut down the IceGrid registry.

**[ "nonmutating" ] Ice::SliceChecksumDict getSliceChecksums()**

Returns the checksums for the IceGrid Slice definitions.

**Return Value**

A dictionary mapping Slice type ids to their checksums.

---

## IceGrid-AdminSession

---

### IceGrid::AdminSession

#### Overview

interface `AdminSession` extends `Glacier2::Session`

Used by administrative clients to view, update, and receive observer updates from the IceGrid registry. Admin sessions are created either with the `IceGrid::Registry` object or the registry admin `Glacier2::SessionManager` object.

#### See Also

- `IceGrid::Registry`
- `Glacier2::SessionManager`

#### Operation Index

`keepAlive` — Keep the session alive.

`getAdmin` — Get the admin interface.

`getAdminCallbackTemplate` — Get a "template" proxy for admin callback objects.

`setObservers` — Set the observer proxies that receive notifications when the state of the registry or nodes changes.

`setObserversByIdentity` — Set the observer identities that receive notifications the state of the registry or nodes changes.

`startUpdate` — Acquires an exclusive lock to start updating the registry applications.

`finishUpdate` — Finish updating the registry and release the exclusive lock.

`getReplicaName` — Get the name of the registry replica hosting this session.

`openServerLog` — Open the given server log file for reading.

`openServerStdErr` — Open the given server stderr file for reading.

`openServerStdOut` — Open the given server stdout file for reading.

`openNodeStdErr` — Open the given node stderr file for reading.

`openNodeStdOut` — Open the given node stdout file for reading.

`openRegistryStdErr` — Open the given registry stderr file for reading.

`openRegistryStdOut` — Open the given registry stdout file for reading.

#### Operations

##### `void keepAlive()`

Keep the session alive. Clients should call this operation regularly to prevent the server from reaping the session.

#### See Also

- `IceGrid::Registry::getSessionTimeout`

##### [ "nonmutating" ] `IceGrid::Admin*` `getAdmin()`

Get the admin interface. The admin object returned by this operation can only be accessed by the session.

#### Return Value

The admin interface proxy.

##### `Object*` `getAdminCallbackTemplate()`

Get a "template" proxy for admin callback objects. An Admin client uses this proxy to set the category of its callback objects, and the published endpoints of the object adapter hosting the admin callback objects.

**Return Value**

A template proxy. The returned proxy is null when the Admin session was established using Glacier2.

**void setObservers(IceGrid::RegistryObserver\* registryObs, IceGrid::NodeObserver\* nodeObs, IceGrid::ApplicationObserver\* appObs, IceGrid::AdapterObserver\* adptObs, IceGrid::ObjectObserver\* objObs) throws IceGrid::ObserverAlreadyRegisteredException**

Set the observer proxies that receive notifications when the state of the registry or nodes changes.

**Parameters**

registryObs — The registry observer.  
 nodeObs — The node observer.  
 appObs — The application observer.  
 adptObs — The adapter observer.  
 objObs — The object observer.

**Exceptions**

[IceGrid::ObserverAlreadyRegisteredException](#) — Raised if an observer is already registered with this registry.

**void setObserversByIdentity(Ice::Identity registryObs, Ice::Identity nodeObs, Ice::Identity appObs, Ice::Identity adptObs, Ice::Identity objObs) throws IceGrid::ObserverAlreadyRegisteredException**

Set the observer identities that receive notifications the state of the registry or nodes changes. This operation should be used by clients that are using a bidirectional connection to communicate with the session.

**Parameters**

registryObs — The registry observer identity.  
 nodeObs — The node observer identity.  
 appObs — The application observer.  
 adptObs — The adapter observer.  
 objObs — The object observer.

**Exceptions**

[IceGrid::ObserverAlreadyRegisteredException](#) — Raised if an observer is already registered with this registry.

**int startUpdate() throws IceGrid::AccessDeniedException**

Acquires an exclusive lock to start updating the registry applications.

**Return Value**

The current serial.

**Exceptions**

[IceGrid::AccessDeniedException](#) — Raised if the exclusive lock can't be acquired. This might happen if the lock is currently acquired by another session.

**void finishUpdate() throws IceGrid::AccessDeniedException**

Finish updating the registry and release the exclusive lock.

**Exceptions**

[IceGrid::AccessDeniedException](#) — Raised if the session doesn't hold the exclusive lock.

**string getReplicaName()**

Get the name of the registry replica hosting this session.

**Return Value**

The replica name of the registry.

**IceGrid::FileIterator\* openServerLog(string id, string path, int count) throws IceGrid::FileNotAvailableException, IceGrid::ServerNotExistException, IceGrid::NodeUnreachableException, IceGrid::DeploymentException**

Open the given server log file for reading. The file can be read with the returned file iterator.

**Parameters**

`id` — The server id.

`path` — The path of the log file. A log file can be opened only if it's declared in the server or service deployment descriptor.

`count` — Specifies where to start reading the file. If negative, the file is read from the beginning. If 0 or positive, the file is read from the last `count` lines.

**Return Value**

An iterator to read the file.

**Exceptions**

`IceGrid::FileNotAvailableException` — Raised if the file can't be read.

`IceGrid::ServerNotExistException` — Raised if the server doesn't exist.

`IceGrid::NodeUnreachableException` — Raised if the node could not be reached.

`IceGrid::DeploymentException` — Raised if the server couldn't be deployed on the node.

**IceGrid::FileIterator\* openServerStdErr(string id, int count) throws IceGrid::FileNotAvailableException, IceGrid::ServerNotExistException, IceGrid::NodeUnreachableException, IceGrid::DeploymentException**

Open the given server stderr file for reading. The file can be read with the returned file iterator.

**Parameters**

`id` — The server id.

`count` — Specifies where to start reading the file. If negative, the file is read from the beginning. If 0 or positive, the file is read from the last `count` lines.

**Return Value**

An iterator to read the file.

**Exceptions**

`IceGrid::FileNotAvailableException` — Raised if the file can't be read.

`IceGrid::ServerNotExistException` — Raised if the server doesn't exist.

`IceGrid::NodeUnreachableException` — Raised if the node could not be reached.

`IceGrid::DeploymentException` — Raised if the server couldn't be deployed on the node.

**IceGrid::FileIterator\* openServerStdOut(string id, int count) throws IceGrid::FileNotAvailableException, IceGrid::ServerNotExistException, IceGrid::NodeUnreachableException, IceGrid::DeploymentException**

Open the given server stdout file for reading. The file can be read with the returned file iterator.

**Parameters**

`id` — The server id.

`count` — Specifies where to start reading the file. If negative, the file is read from the beginning. If 0 or positive, the file is read from the last `count` lines.

#### **Return Value**

An iterator to read the file.

#### **Exceptions**

`IceGrid::FileNotAvailableException` — Raised if the file can't be read.

`IceGrid::ServerNotExistException` — Raised if the server doesn't exist.

`IceGrid::NodeUnreachableException` — Raised if the node could not be reached.

`IceGrid::DeploymentException` — Raised if the server couldn't be deployed on the node.

### **IceGrid::FileIterator\* openNodeStdErr(string name, int count) throws IceGrid::FileNotAvailableException, IceGrid::NodeNotExistException, IceGrid::NodeUnreachableException**

Open the given node stderr file for reading. The file can be read with the returned file iterator.

#### **Parameters**

`name` — The node name.

`count` — Specifies where to start reading the file. If negative, the file is read from the beginning. If 0 or positive, the file is read from the last `count` lines.

#### **Return Value**

An iterator to read the file.

#### **Exceptions**

`IceGrid::FileNotAvailableException` — Raised if the file can't be read.

`IceGrid::NodeNotExistException` — Raised if the node doesn't exist.

`IceGrid::NodeUnreachableException` — Raised if the node could not be reached.

### **IceGrid::FileIterator\* openNodeStdOut(string name, int count) throws IceGrid::FileNotAvailableException, IceGrid::NodeNotExistException, IceGrid::NodeUnreachableException**

Open the given node stdout file for reading. The file can be read with the returned file iterator.

#### **Parameters**

`name` — The node name.

`count` — Specifies where to start reading the file. If negative, the file is read from the beginning. If 0 or positive, the file is read from the last `count` lines.

#### **Return Value**

An iterator to read the file.

#### **Exceptions**

`IceGrid::FileNotAvailableException` — Raised if the file can't be read.

`IceGrid::NodeNotExistException` — Raised if the node doesn't exist.

`IceGrid::NodeUnreachableException` — Raised if the node could not be reached.

### **IceGrid::FileIterator\* openRegistryStdErr(string name, int count) throws IceGrid::FileNotAvailableException, IceGrid::RegistryNotExistException, IceGrid::RegistryUnreachableException**

Open the given registry stderr file for reading. The file can be read with the returned file iterator.

**Parameters**

`name` — The registry name.

`count` — Specifies where to start reading the file. If negative, the file is read from the beginning. If 0 or positive, the file is read from the last `count` lines.

**Return Value**

An iterator to read the file.

**Exceptions**

`IceGrid::FileNotAvailableException` — Raised if the file can't be read.

`IceGrid::RegistryNotExistException` — Raised if the registry doesn't exist.

`IceGrid::RegistryUnreachableException` — Raised if the registry could not be reached.

**`IceGrid::FileIterator*` `openRegistryStdOut(string name, int count)` throws `IceGrid::FileNotAvailableException`, `IceGrid::RegistryNotExistException`, `IceGrid::RegistryUnreachableException`**

Open the given registry stdout file for reading. The file can be read with the returned file iterator.

**Parameters**

`name` — The registry name.

`count` — Specifies where to start reading the file. If negative, the file is read from the beginning. If 0 or positive, the file is read from the last `count` lines.

**Return Value**

An iterator to read the file.

**Exceptions**

`IceGrid::FileNotAvailableException` — Raised if the file can't be read.

`IceGrid::RegistryNotExistException` — Raised if the registry doesn't exist.

`IceGrid::RegistryUnreachableException` — Raised if the registry could not be reached.

---

## IceGrid-AllocationException

---

### IceGrid::AllocationException

#### Overview

#### exception AllocationException

This exception is raised if the allocation of an object failed.

#### *Derived Exceptions*

- IceGrid::AllocationTimeoutException

#### *Used By*

- IceGrid::Session::allocateObjectById
- IceGrid::Session::allocateObjectByType
- IceGrid::Session::releaseObject

#### Data Member Index

`reason` — The reason why the object couldn't be allocated.

#### Data Members

`string reason;`

The reason why the object couldn't be allocated.

---

## IceGrid-AllocationTimeoutException

---

### IceGrid::AllocationTimeoutException

#### Overview

exception `AllocationTimeoutException` extends `IceGrid::AllocationException`

This exception is raised if the request to allocate an object times out.

---

## IceGrid-ApplicationDescriptor

---

### IceGrid::ApplicationDescriptor

#### Overview

#### struct ApplicationDescriptor

An application descriptor.

#### Used By

- IceGrid::Admin::addApplication
- IceGrid::Admin::getDefaultApplicationDescriptor
- IceGrid::Admin::syncApplicationWithoutRestart
- IceGrid::Admin::syncApplication
- IceGrid::ApplicationDescriptorSeq
- IceGrid::ApplicationInfo::descriptor
- IceGrid::FileParser::parse

#### Data Member Index

[name](#) — The application name.  
[variables](#) — The variables defined in the application descriptor.  
[replicaGroups](#) — The replica groups.  
[serverTemplates](#) — The server templates.  
[serviceTemplates](#) — The service templates.  
[nodes](#) — The application nodes.  
[distrib](#) — The application distribution.  
[description](#) — The description of this application.  
[propertySets](#) — Property set descriptors.

#### Data Members

##### string name;

The application name.

##### [ "java:java.util.TreeMap<String, String>" ] IceGrid::StringStringDict variables;

The variables defined in the application descriptor.

##### IceGrid::ReplicaGroupDescriptorSeq replicaGroups;

The replica groups.

##### IceGrid::TemplateDescriptorDict serverTemplates;

The server templates.

##### IceGrid::TemplateDescriptorDict serviceTemplates;

The service templates.

**IceGrid::NodeDescriptorDict nodes;**

The application nodes.

**IceGrid::DistributionDescriptor distrib;**

The application distribution.

**string description;**

The description of this application.

**IceGrid::PropertySetDescriptorDict propertySets;**

Property set descriptors.

---

## IceGrid-ApplicationInfo

---

### IceGrid::ApplicationInfo

#### Overview

#### struct ApplicationInfo

Information about an IceGrid application.

#### Used By

- IceGrid::Admin::getApplicationInfo
- IceGrid::ApplicationInfoSeq
- IceGrid::ApplicationObserver::applicationAdded
- IceGrid::RegistryPluginFacade::getApplicationInfo

#### Data Member Index

`uuid` — Unique application identifier.  
`createTime` — The creation time.  
`createUser` — The user who created the application.  
`updateTime` — The update time.  
`updateUser` — The user who updated the application.  
`revision` — The application revision number.  
`descriptor` — The application descriptor

#### Data Members

**string uuid;**

Unique application identifier.

**long createTime;**

The creation time.

**string createUser;**

The user who created the application.

**long updateTime;**

The update time.

**string updateUser;**

The user who updated the application.

**int revision;**

The application revision number.

**IceGrid::ApplicationDescriptor** descriptor;

The application descriptor

---

## IceGrid-ApplicationNotExistException

---

### IceGrid::ApplicationNotExistException

#### Overview

#### exception ApplicationNotExistException

This exception is raised if an application does not exist.

#### *Used By*

- IceGrid::Admin::getApplicationInfo
- IceGrid::Admin::instantiateServer
- IceGrid::Admin::patchApplication
- IceGrid::Admin::removeApplication
- IceGrid::Admin::syncApplicationWithoutRestart
- IceGrid::Admin::syncApplication
- IceGrid::Admin::updateApplicationWithoutRestart
- IceGrid::Admin::updateApplication
- IceGrid::RegistryPluginFacade::getApplicationInfo

#### Data Member Index

`name` — The name of the application.

#### Data Members

`string name;`

The name of the application.

---

## IceGrid-ApplicationObserver

---

### IceGrid::ApplicationObserver

#### Overview

#### interface ApplicationObserver

The database observer interface. Observers should implement this interface to receive information about the state of the IceGrid registry database.

#### Operation Index

**applicationInit** — `applicationInit` is called after the registration of an observer to indicate the state of the registry.  
**applicationAdded** — The `applicationAdded` operation is called to notify an observer that an application was added.  
**applicationRemoved** — The `applicationRemoved` operation is called to notify an observer that an application was removed.  
**applicationUpdated** — The `applicationUpdated` operation is called to notify an observer that an application was updated.

#### Operations

##### void applicationInit(int serial, IceGrid::ApplicationInfoSeq applications)

`applicationInit` is called after the registration of an observer to indicate the state of the registry.

##### Parameters

`serial` — The current serial number of the registry database. This serial number allows observers to make sure that their internal state is synchronized with the registry.  
`applications` — The applications currently registered with the registry.

##### void applicationAdded(int serial, IceGrid::ApplicationInfo desc)

The `applicationAdded` operation is called to notify an observer that an application was added.

##### Parameters

`serial` — The new serial number of the registry database.  
`desc` — The descriptor of the new application.

##### void applicationRemoved(int serial, string name)

The `applicationRemoved` operation is called to notify an observer that an application was removed.

##### Parameters

`serial` — The new serial number of the registry database.  
`name` — The name of the application that was removed.

##### void applicationUpdated(int serial, IceGrid::ApplicationUpdateInfo desc)

The `applicationUpdated` operation is called to notify an observer that an application was updated.

##### Parameters

`serial` — The new serial number of the registry database.

`desc` — The descriptor of the update.

---

## IceGrid-ApplicationUpdateDescriptor

---

### IceGrid::ApplicationUpdateDescriptor

#### Overview

#### struct ApplicationUpdateDescriptor

An application update descriptor to describe the updates to apply to a deployed application.

#### Used By

- `IceGrid::Admin::updateApplicationWithoutRestart`
- `IceGrid::Admin::updateApplication`
- `IceGrid::ApplicationUpdateInfo::descriptor`

#### Data Member Index

`name` — The name of the application to update.  
`description` — The updated description (or null if the description wasn't updated.)  
`distrib` — The updated distribution application descriptor.  
`variables` — The variables to update.  
`removeVariables` — The variables to remove.  
`propertySets` — The property sets to update.  
`removePropertySets` — The property sets to remove.  
`replicaGroups` — The replica groups to update.  
`removeReplicaGroups` — The replica groups to remove.  
`serverTemplates` — The server templates to update.  
`removeServerTemplates` — The ids of the server template to remove.  
`serviceTemplates` — The service templates to update.  
`removeServiceTemplates` — The ids of the service template to remove.  
`nodes` — The application nodes to update.  
`removeNodes` — The nodes to remove.

#### Data Members

**string name;**

The name of the application to update.

**IceGrid::BoxedString description;**

The updated description (or null if the description wasn't updated.)

**IceGrid::BoxedDistributionDescriptor distrib;**

The updated distribution application descriptor.

**[ "java:type:java.util.TreeMap<String, String>" ] IceGrid::StringStringDict variables;**

The variables to update.

**Ice::StringSeq removeVariables;**

The variables to remove.

**IceGrid::PropertySetDescriptorDict** propertySets;

The property sets to update.

**Ice::StringSeq** removePropertySets;

The property sets to remove.

**IceGrid::ReplicaGroupDescriptorSeq** replicaGroups;

The replica groups to update.

**Ice::StringSeq** removeReplicaGroups;

The replica groups to remove.

**IceGrid::TemplateDescriptorDict** serverTemplates;

The server templates to update.

**Ice::StringSeq** removeServerTemplates;

The ids of the server template to remove.

**IceGrid::TemplateDescriptorDict** serviceTemplates;

The service templates to update.

**Ice::StringSeq** removeServiceTemplates;

The ids of the service template to remove.

**IceGrid::NodeUpdateDescriptorSeq** nodes;

The application nodes to update.

**Ice::StringSeq** removeNodes;

The nodes to remove.

---

## IceGrid-ApplicationUpdateInfo

---

### IceGrid::ApplicationUpdateInfo

#### Overview

#### struct ApplicationUpdateInfo

Information about updates to an IceGrid application.

#### Used By

- [IceGrid::ApplicationObserver::applicationUpdated](#)

#### Data Member Index

[updateTime](#) — The update time.  
[updateUser](#) — The user who updated the application.  
[revision](#) — The application revision number.  
[descriptor](#) — The update descriptor.

#### Data Members

##### long updateTime;

The update time.

##### string updateUser;

The user who updated the application.

##### int revision;

The application revision number.

##### [IceGrid::ApplicationUpdateDescriptor](#) descriptor;

The update descriptor.

---

## IceGrid-BadSignalException

---

### IceGrid::BadSignalException

#### Overview

#### exception BadSignalException

This exception is raised if an unknown signal was sent to a server.

#### *Used By*

- `IceGrid::Admin::sendSignal`

#### Data Member Index

`reason` — The details of the unknown signal.

#### Data Members

`string reason;`

The details of the unknown signal.

---

## IceGrid-BoxedDistributionDescriptor

---

### IceGrid::BoxedDistributionDescriptor

#### Overview

#### class `BoxedDistributionDescriptor`

A "boxed" distribution descriptor.

#### *Used By*

- `IceGrid::ApplicationUpdateDescriptor::distrib`

#### Data Member Index

`value` — The value of the boxed distribution descriptor.

#### Data Members

`IceGrid::DistributionDescriptor value;`

The value of the boxed distribution descriptor.

---

## IceGrid-BoxedString

---

### IceGrid::BoxedString

#### Overview

#### class BoxedString

A "boxed" string.

#### *Used By*

- IceGrid::ApplicationUpdateDescriptor::description
- IceGrid::NodeUpdateDescriptor::description
- IceGrid::NodeUpdateDescriptor::loadFactor

#### Data Member Index

value — The value of the boxed string.

#### Data Members

**string value;**

The value of the boxed string.

---

# IceGrid-CommunicatorDescriptor

---

## IceGrid::CommunicatorDescriptor

### Overview

#### class CommunicatorDescriptor

A communicator descriptor.

#### *Derived Classes and Interfaces*

- [IceGrid::ServerDescriptor](#)
- [IceGrid::ServiceDescriptor](#)

#### *Used By*

- [IceGrid::TemplateDescriptor::descriptor](#)

### Data Member Index

[adapters](#) — The object adapters.  
[propertySet](#) — The property set.  
[dbEnvs](#) — The database environments.  
[logs](#) — The path of each log file.  
[description](#) — A description of this descriptor.

### Data Members

#### **IceGrid::AdapterDescriptorSeq adapters;**

The object adapters.

#### **IceGrid::PropertySetDescriptor propertySet;**

The property set.

#### **IceGrid::DbEnvDescriptorSeq dbEnvs;**

The database environments.

#### **Ice::StringSeq logs;**

The path of each log file.

#### **string description;**

A description of this descriptor.

---

## IceGrid-DbEnvDescriptor

---

### IceGrid::DbEnvDescriptor

#### Overview

[ "cpp:comparable" ] struct DbEnvDescriptor

A Freeze database environment descriptor.

#### Used By

- IceGrid::DbEnvDescriptorSeq

#### Data Member Index

[name](#) — The name of the database environment.

[description](#) — The description of this database environment.

[dbHome](#) — The home of the database environment (i.e., the directory where the database files will be stored).

[properties](#) — The configuration properties of the database environment.

#### Data Members

**string name;**

The name of the database environment.

**string description;**

The description of this database environment.

**string dbHome;**

The home of the database environment (i.e., the directory where the database files will be stored). If empty, the node will provide a default database directory, otherwise the directory must exist.

**IceGrid::PropertyDescriptorSeq properties;**

The configuration properties of the database environment.

---

## IceGrid-DeploymentException

---

### IceGrid::DeploymentException

#### Overview

#### exception DeploymentException

An exception for deployment errors.

#### Used By

- IceGrid::Admin::addApplication
- IceGrid::Admin::addObjectWithType
- IceGrid::Admin::addObject
- IceGrid::Admin::enableServer
- IceGrid::Admin::getDefaultApplicationDescriptor
- IceGrid::Admin::getServerAdmin
- IceGrid::Admin::getServerPid
- IceGrid::Admin::getServerState
- IceGrid::Admin::instantiateServer
- IceGrid::Admin::isServerEnabled
- IceGrid::Admin::patchServer
- IceGrid::Admin::removeAdapter
- IceGrid::Admin::removeApplication
- IceGrid::Admin::removeObject
- IceGrid::Admin::sendSignal
- IceGrid::Admin::startServer
- IceGrid::Admin::stopServer
- IceGrid::Admin::syncApplicationWithoutRestart
- IceGrid::Admin::syncApplication
- IceGrid::Admin::updateApplicationWithoutRestart
- IceGrid::Admin::updateApplication
- IceGrid::Admin::updateObject
- IceGrid::AdminSession::openServerLog
- IceGrid::AdminSession::openServerStdErr
- IceGrid::AdminSession::openServerStdOut

#### Data Member Index

`reason` — The reason for the failure.

#### Data Members

`string reason;`

The reason for the failure.

---

## IceGrid-DistributionDescriptor

---

### IceGrid::DistributionDescriptor

#### Overview

[ "cpp:comparable" ] struct DistributionDescriptor

A distribution descriptor defines an IcePatch2 server and the directories to retrieve from the patch server.

#### Used By

- IceGrid::ApplicationDescriptor::distrib
- IceGrid::BoxedDistributionDescriptor::value
- IceGrid::ServerDescriptor::distrib

#### Data Member Index

[icepatch](#) — The proxy of the IcePatch2 server.

[directories](#) — The source directories.

#### Data Members

**string icepatch;**

The proxy of the IcePatch2 server.

[ "java:type:java.util.LinkedList<String>" ] **Ice::StringSeq directories;**

The source directories.

---

## IceGrid-FileIterator

---

### IceGrid::FileIterator

#### Overview

#### interface FileIterator

This interface provides access to IceGrid log file contents.

#### Operation Index

`read` — Read lines from the log file.

`destroy` — Destroy the iterator.

#### Operations

##### `bool read(int size, out Ice::StringSeq lines) throws IceGrid::FileNotAvailableException`

Read lines from the log file.

##### *Parameters*

`size` — Specifies the maximum number of bytes to be received. The server will ensure that the returned message doesn't exceed the given size.

`lines` — The lines read from the file. If there was nothing to read from the file since the last call to `read`, an empty sequence is returned. The last line of the sequence is always incomplete (and therefore no 'n' should be added when writing the last line to the to the output device).

##### *Return Value*

True if EOF is encountered.

##### *Exceptions*

`IceGrid::FileNotAvailableException` — Raised if there was a problem to read lines from the file.

##### `void destroy()`

Destroy the iterator.

---

## IceGrid-FileNotAvailableException

---

### IceGrid::FileNotAvailableException

#### Overview

#### exception FileNotAvailableException

This exception is raised if a file is not available.

#### Used By

- IceGrid::AdminSession::openNodeStdErr
- IceGrid::AdminSession::openNodeStdOut
- IceGrid::AdminSession::openRegistryStdErr
- IceGrid::AdminSession::openRegistryStdOut
- IceGrid::AdminSession::openServerLog
- IceGrid::AdminSession::openServerStdErr
- IceGrid::AdminSession::openServerStdOut
- IceGrid::FileIterator::read

#### See Also

- IceGrid::AdminSession::openServerStdOut
- IceGrid::AdminSession::openServerStdErr
- IceGrid::AdminSession::openNodeStdOut
- IceGrid::AdminSession::openNodeStdErr
- IceGrid::AdminSession::openRegistryStdOut
- IceGrid::AdminSession::openRegistryStdErr

#### Data Member Index

`reason` — The reason for the failure.

#### Data Members

`string reason;`

The reason for the failure.

---

## IceGrid-FileParser

---

### IceGrid::FileParser

#### Overview

#### interface FileParser

icegridadmin provides a `IceGrid::FileParser` object to transform XML files into `IceGrid::ApplicationDescriptor` objects.

#### Operation Index

`parse` — Parse a file.

#### Operations

**IceGrid::ApplicationDescriptor** `parse(string xmlFile, IceGrid::Admin* adminProxy)` throws **IceGrid::ParseException**

Parse a file.

##### *Parameters*

`xmlFile` — Full pathname to the file.

`adminProxy` — An Admin proxy, used only to retrieve default templates when needed. May be null.

##### *Return Value*

The application descriptor.

##### *Exceptions*

`IceGrid::ParseException` — Raised if an error occurred during parsing.

---

## IceGrid-IceBoxDescriptor

---

### IceGrid::IceBoxDescriptor

#### Overview

class `IceBoxDescriptor` extends `IceGrid::ServerDescriptor`

An IceBox server descriptor.

#### Data Member Index

`services` — The service instances.

#### Data Members

`IceGrid::ServiceInstanceDescriptorSeq` `services`;

The service instances.

---

## IceGrid-LoadBalancingPolicy

---

### IceGrid::LoadBalancingPolicy

#### Overview

#### class LoadBalancingPolicy

A base class for load balancing policies.

#### *Derived Classes and Interfaces*

- [IceGrid::AdaptiveLoadBalancingPolicy](#)
- [IceGrid::OrderedLoadBalancingPolicy](#)
- [IceGrid::RandomLoadBalancingPolicy](#)
- [IceGrid::RoundRobinLoadBalancingPolicy](#)

#### *Used By*

- [IceGrid::ReplicaGroupDescriptor::loadBalancing](#)

#### Data Member Index

[nReplicas](#) — The number of replicas that will be used to gather the endpoints of a replica group.

#### Data Members

**string nReplicas;**

The number of replicas that will be used to gather the endpoints of a replica group.

---

## IceGrid-LoadInfo

---

### IceGrid::LoadInfo

#### Overview

#### struct LoadInfo

Information about the load of a node.

#### *Used By*

- IceGrid::Admin::getNodeLoad
- IceGrid::RegistryPluginFacade::getNodeLoad

#### Data Member Index

[avg1](#) — The load average over the past minute.

[avg5](#) — The load average over the past 5 minutes.

[avg15](#) — The load average over the past 15 minutes.

#### Data Members

##### **float avg1;**

The load average over the past minute.

##### **float avg5;**

The load average over the past 5 minutes.

##### **float avg15;**

The load average over the past 15 minutes.

---

## IceGrid-LoadSample

---

### IceGrid::LoadSample

#### Overview

#### enum LoadSample

Determines which load sampling interval to use.

#### *Used By*

- [Query::findObjectByTypeOnLeastLoadedNode](#)

#### Enumerator Index

[LoadSample1](#) — Sample every minute.

[LoadSample5](#) — Sample every five minutes.

[LoadSample15](#) — Sample every fifteen minutes.

#### Enumerators

##### LoadSample1

Sample every minute.

##### LoadSample5

Sample every five minutes.

##### LoadSample15

Sample every fifteen minutes.

---

## IceGrid-Locator

---

### IceGrid::Locator

#### Overview

interface `Locator` extends `Ice::Locator`

The IceGrid locator interface provides access to the `IceGrid::Query` and `IceGrid::Registry` object of the IceGrid registry.

#### See Also

- `IceGrid::Query`
- `IceGrid::Registry`

#### Operation Index

`getLocalRegistry` — Get the proxy of the registry object hosted by this IceGrid registry.

`getLocalQuery` — Get the proxy of the query object hosted by this IceGrid registry.

#### Operations

##### `IceGrid::Registry*` `getLocalRegistry()`

Get the proxy of the registry object hosted by this IceGrid registry.

##### *Return Value*

The proxy of the registry object.

##### `IceGrid::Query*` `getLocalQuery()`

Get the proxy of the query object hosted by this IceGrid registry.

##### *Return Value*

The proxy of the query object.

---

## IceGrid-NodeDescriptor

---

### IceGrid::NodeDescriptor

#### Overview

#### struct NodeDescriptor

A node descriptor.

#### Used By

- [IceGrid::NodeDescriptorDict](#)

#### Data Member Index

[variables](#) — The variables defined for the node.  
[serverInstances](#) — The server instances.  
[servers](#) — Servers (which are not template instances).  
[loadFactor](#) — Load factor of the node.  
[description](#) — The description of this node.  
[propertySets](#) — Property set descriptors.

#### Data Members

[ "java:type:java.util.TreeMap<String, String>" ] [IceGrid::StringStringDict](#) variables;

The variables defined for the node.

[IceGrid::ServerInstanceDescriptorSeq](#) serverInstances;

The server instances.

[IceGrid::ServerDescriptorSeq](#) servers;

Servers (which are not template instances).

**string** loadFactor;

Load factor of the node.

**string** description;

The description of this node.

[IceGrid::PropertySetDescriptorDict](#) propertySets;

Property set descriptors.

---

## IceGrid-NodeDynamicInfo

---

### IceGrid::NodeDynamicInfo

#### Overview

#### struct NodeDynamicInfo

Dynamic information about the state of a node.

#### Used By

- [IceGrid::NodeDynamicInfoSeq](#)
- [IceGrid::NodeObserver::nodeUp](#)

#### Data Member Index

[info](#) — Some static information about the node.

[servers](#) — The dynamic information of the servers deployed on this node.

[adapters](#) — The dynamic information of the adapters deployed on this node.

#### Data Members

##### **IceGrid::NodeInfo** info;

Some static information about the node.

##### **IceGrid::ServerDynamicInfoSeq** servers;

The dynamic information of the servers deployed on this node.

##### **IceGrid::AdapterDynamicInfoSeq** adapters;

The dynamic information of the adapters deployed on this node.

---

## IceGrid-NodeInfo

---

### IceGrid::NodeInfo

#### Overview

#### struct NodeInfo

Information about an IceGrid node.

#### Used By

- IceGrid::Admin::getNodeInfo
- IceGrid::NodeDynamicInfo::info
- IceGrid::RegistryPluginFacade::getNodeInfo

#### Data Member Index

`name` — The name of the node.

`os` — The operating system name.

`hostname` — The network name of the host running this node (as defined in `uname()`).

`release` — The operation system release level (as defined in `uname()`).

`version` — The operation system version (as defined in `uname()`).

`machine` — The machine hardware type (as defined in `uname()`).

`nProcessors` — The number of processor threads on the node.

`dataDir` — The path to the node data directory.

#### Data Members

##### **string name;**

The name of the node.

##### **string os;**

The operating system name.

##### **string hostname;**

The network name of the host running this node (as defined in `uname()`).

##### **string release;**

The operation system release level (as defined in `uname()`).

##### **string version;**

The operation system version (as defined in `uname()`).

##### **string machine;**

The machine hardware type (as defined in `uname()`).

**int nProcessors;**

The number of processor threads on the node. For example, nProcessors is 8 on a computer with a single quad-core processor and two HT threads per core.

**string dataDir;**

The path to the node data directory.

---

## IceGrid-NodeNotExistException

---

### IceGrid::NodeNotExistException

#### Overview

#### exception NodeNotExistException

This exception is raised if a node does not exist.

#### *Used By*

- IceGrid::Admin::getNodeAdmin
- IceGrid::Admin::getNodeHostname
- IceGrid::Admin::getNodeInfo
- IceGrid::Admin::getNodeLoad
- IceGrid::Admin::getNodeProcessorSocketCount
- IceGrid::Admin::pingNode
- IceGrid::Admin::shutdownNode
- IceGrid::AdminSession::openNodeStdErr
- IceGrid::AdminSession::openNodeStdOut
- IceGrid::RegistryPluginFacade::getNodeInfo
- IceGrid::RegistryPluginFacade::getNodeLoad

#### Data Member Index

name — The node name.

#### Data Members

string name;

The node name.

---

## IceGrid-NodeObserver

---

### IceGrid::NodeObserver

#### Overview

#### interface NodeObserver

The node observer interface. Observers should implement this interface to receive information about the state of the IceGrid nodes.

#### Operation Index

**nodeInit** — The `nodeInit` operation indicates the current state of nodes.

**nodeUp** — The `nodeUp` operation is called to notify an observer that a node came up.

**nodeDown** — The `nodeDown` operation is called to notify an observer that a node went down.

**updateServer** — The `updateServer` operation is called to notify an observer that the state of a server changed.

**updateAdapter** — The `updateAdapter` operation is called to notify an observer that the state of an adapter changed.

#### Operations

##### **void nodeInit(IceGrid::NodeDynamicInfoSeq nodes)**

The `nodeInit` operation indicates the current state of nodes. It is called after the registration of an observer.

##### *Parameters*

`nodes` — The current state of the nodes.

##### **void nodeUp(IceGrid::NodeDynamicInfo node)**

The `nodeUp` operation is called to notify an observer that a node came up.

##### *Parameters*

`node` — The node state.

##### **void nodeDown(string name)**

The `nodeDown` operation is called to notify an observer that a node went down.

##### *Parameters*

`name` — The node name.

##### **void updateServer(string node, IceGrid::ServerDynamicInfo updatedInfo)**

The `updateServer` operation is called to notify an observer that the state of a server changed.

##### *Parameters*

`node` — The node hosting the server.

`updatedInfo` — The new server state.

##### **void updateAdapter(string node, IceGrid::AdapterDynamicInfo updatedInfo)**

The `updateAdapter` operation is called to notify an observer that the state of an adapter changed.

**Parameters**

`node` — The node hosting the adapter.

`updatedInfo` — The new adapter state.

---

## IceGrid-NodeUnreachableException

---

### IceGrid::NodeUnreachableException

#### Overview

#### exception NodeUnreachableException

This exception is raised if a node could not be reached.

#### Used By

- IceGrid::Admin::enableServer
- IceGrid::Admin::getNodeAdmin
- IceGrid::Admin::getNodeHostname
- IceGrid::Admin::getNodeInfo
- IceGrid::Admin::getNodeLoad
- IceGrid::Admin::getNodeProcessorSocketCount
- IceGrid::Admin::getServerAdmin
- IceGrid::Admin::getServerPid
- IceGrid::Admin::getServerState
- IceGrid::Admin::isServerEnabled
- IceGrid::Admin::patchServer
- IceGrid::Admin::sendSignal
- IceGrid::Admin::shutdownNode
- IceGrid::Admin::startServer
- IceGrid::Admin::stopServer
- IceGrid::AdminSession::openNodeStdErr
- IceGrid::AdminSession::openNodeStdOut
- IceGrid::AdminSession::openServerLog
- IceGrid::AdminSession::openServerStdErr
- IceGrid::AdminSession::openServerStdOut
- IceGrid::RegistryPluginFacade::getNodeInfo
- IceGrid::RegistryPluginFacade::getNodeLoad

#### Data Member Index

**name** — The name of the node that is not reachable.

**reason** — The reason why the node couldn't be reached.

#### Data Members

**string name;**

The name of the node that is not reachable.

**string reason;**

The reason why the node couldn't be reached.

---

## IceGrid-NodeUpdateDescriptor

---

### IceGrid::NodeUpdateDescriptor

#### Overview

#### struct NodeUpdateDescriptor

A node update descriptor to describe the updates to apply to a node of a deployed application.

#### Used By

- [IceGrid::NodeUpdateDescriptorSeq](#)

#### Data Member Index

[name](#) — The name of the node to update.  
[description](#) — The updated description (or null if the description wasn't updated.)  
[variables](#) — The variables to update.  
[removeVariables](#) — The variables to remove.  
[propertySets](#) — The property sets to update.  
[removePropertySets](#) — The property sets to remove.  
[serverInstances](#) — The server instances to update.  
[servers](#) — The servers which are not template instances to update.  
[removeServers](#) — The ids of the servers to remove.  
[loadFactor](#) — The updated load factor of the node (or null if the load factor was not updated).

#### Data Members

**string name;**

The name of the node to update.

**IceGrid::BoxedString description;**

The updated description (or null if the description wasn't updated.)

**[ "java:type:java.util.TreeMap<String, String>" ] IceGrid::StringStringDict variables;**

The variables to update.

**Ice::StringSeq removeVariables;**

The variables to remove.

**IceGrid::PropertySetDescriptorDict propertySets;**

The property sets to update.

**Ice::StringSeq removePropertySets;**

The property sets to remove.

**IceGrid::ServerInstanceDescriptorSeq** serverInstances;

The server instances to update.

**IceGrid::ServerDescriptorSeq** servers;

The servers which are not template instances to update.

**Ice::StringSeq** removeServers;

The ids of the servers to remove.

**IceGrid::BoxedString** loadFactor;

The updated load factor of the node (or null if the load factor was not updated).

---

## IceGrid-ObjectDescriptor

---

### IceGrid::ObjectDescriptor

#### Overview

#### struct ObjectDescriptor

An Ice object descriptor.

#### Used By

- [IceGrid::ObjectDescriptorSeq](#)

#### Data Member Index

[id](#) — The identity of the object.

[type](#) — The object type.

[proxyOptions](#) — Proxy options to use with the proxy created for this Ice object.

#### Data Members

##### **Ice::Identity** id;

The identity of the object.

##### **string** type;

The object type.

##### **string** proxyOptions;

Proxy options to use with the proxy created for this Ice object. If empty, the proxy will be created with the proxy options specified on the object adapter or replica group.

---

## IceGrid-ObjectExistsException

---

### IceGrid::ObjectExistsException

#### Overview

exception `ObjectExistsException`

This exception is raised if an object already exists.

#### *Used By*

- `IceGrid::Admin::addObjectWithType`
- `IceGrid::Admin::addObject`

#### Data Member Index

`id` — The identity of the object.

#### Data Members

**Ice::Identity** `id`;

The identity of the object.

---

## IceGrid-ObjectInfo

---

### IceGrid::ObjectInfo

#### Overview

[ "cpp:comparable" ] struct ObjectInfo

Information about an Ice object.

#### *Used By*

- IceGrid::Admin::getObjectInfo
- IceGrid::ObjectInfoSeq
- IceGrid::ObjectObserver::objectAdded
- IceGrid::ObjectObserver::objectUpdated
- IceGrid::RegistryPluginFacade::getObjectInfo

#### Data Member Index

`proxy` — The proxy of the object.

`type` — The type of the object.

#### Data Members

`Object* proxy;`

The proxy of the object.

`string type;`

The type of the object.

---

## IceGrid-ObjectNotRegisteredException

---

### IceGrid::ObjectNotRegisteredException

#### Overview

exception `ObjectNotRegisteredException`

This exception is raised if an object is not registered.

#### *Used By*

- `IceGrid::Admin::getObjectInfo`
- `IceGrid::Admin::removeObject`
- `IceGrid::Admin::updateObject`
- `IceGrid::RegistryPluginFacade::getObjectInfo`
- `IceGrid::Session::allocateObjectById`
- `IceGrid::Session::releaseObject`

#### Data Member Index

`id` — The identity of the object.

#### Data Members

**Ice::Identity** `id`;

The identity of the object.

---

## IceGrid-ObjectObserver

---

### IceGrid::ObjectObserver

#### Overview

#### interface ObjectObserver

This interface allows applications to monitor IceGrid well-known objects.

#### Operation Index

`objectInit` — `objectInit` is called after the registration of an observer to indicate the state of the registry.

`objectAdded` — The `objectAdded` operation is called to notify an observer when an object was added to the `IceGrid::Admin` interface.

`objectUpdated` — `objectUpdated` is called to notify an observer when an object registered with the `IceGrid::Admin` interface was updated.

`objectRemoved` — `objectRemoved` is called to notify an observer when an object registered with the `IceGrid::Admin` interface was removed.

#### Operations

##### `void objectInit(IceGrid::ObjectInfoSeq objects)`

`objectInit` is called after the registration of an observer to indicate the state of the registry.

##### *Parameters*

`objects` — The objects registered with the `IceGrid::Admin` interface (not through the deployment mechanism).

##### `void objectAdded(IceGrid::ObjectInfo info)`

The `objectAdded` operation is called to notify an observer when an object was added to the `IceGrid::Admin` interface.

##### *Parameters*

`info` — The details of the added object.

##### `void objectUpdated(IceGrid::ObjectInfo info)`

`objectUpdated` is called to notify an observer when an object registered with the `IceGrid::Admin` interface was updated.

##### *Parameters*

`info` — The details of the updated object.

##### `void objectRemoved(Ice::Identity id)`

`objectRemoved` is called to notify an observer when an object registered with the `IceGrid::Admin` interface was removed.

##### *Parameters*

`id` — The identity of the removed object.

---

## IceGrid-ObserverAlreadyRegisteredException

---

### IceGrid::ObserverAlreadyRegisteredException

#### Overview

#### exception ObserverAlreadyRegisteredException

This exception is raised if an observer is already registered with the registry.

#### *Used By*

- `IceGrid::AdminSession::setObserversByIdentity`
- `IceGrid::AdminSession::setObservers`

#### *See Also*

- `IceGrid::AdminSession::setObservers`
- `IceGrid::AdminSession::setObserversByIdentity`

#### Data Member Index

`id` — The identity of the observer.

#### Data Members

**Ice::Identity** `id`;

The identity of the observer.

---

## IceGrid-OrderedLoadBalancingPolicy

---

### IceGrid::OrderedLoadBalancingPolicy

#### Overview

class `OrderedLoadBalancingPolicy` extends `IceGrid::LoadBalancingPolicy`

Ordered load balancing policy.

---

## IceGrid-ParseException

---

### IceGrid::ParseException

#### Overview

#### exception ParseException

This exception is raised if an error occurs during parsing.

#### *Used By*

- [IceGrid::FileParser::parse](#)

#### Data Member Index

[reason](#) — The reason for the failure.

#### Data Members

**string** reason;

The reason for the failure.

---

## IceGrid-PatchException

---

### IceGrid::PatchException

#### Overview

#### exception PatchException

This exception is raised if a patch failed.

#### *Used By*

- IceGrid::Admin::patchApplication
- IceGrid::Admin::patchServer

#### Data Member Index

[reasons](#) — The reasons why the patch failed.

#### Data Members

**Ice::StringSeq** reasons;

The reasons why the patch failed.

---

## IceGrid-PermissionDeniedException

---

### IceGrid::PermissionDeniedException

#### Overview

#### exception PermissionDeniedException

This exception is raised if a client is denied the ability to create a session with IceGrid.

#### *Used By*

- IceGrid::Registry::createAdminSessionFromSecureConnection
- IceGrid::Registry::createAdminSession
- IceGrid::Registry::createSessionFromSecureConnection
- IceGrid::Registry::createSession

#### Data Member Index

`reason` — The reason why permission was denied.

#### Data Members

`string reason;`

The reason why permission was denied.

---

## IceGrid-PropertyDescriptor

---

### IceGrid::PropertyDescriptor

#### Overview

**struct** PropertyDescriptor

Property descriptor.

#### *Used By*

- IceGrid::PropertyDescriptorSeq

#### Data Member Index

[name](#) — The name of the property.

[value](#) — The value of the property.

#### Data Members

**string** name;

The name of the property.

**string** value;

The value of the property.

---

## IceGrid-PropertySetDescriptor

---

### IceGrid::PropertySetDescriptor

#### Overview

[ "cpp:comparable" ] struct PropertySetDescriptor

A property set descriptor.

#### Used By

- IceGrid::CommunicatorDescriptor::propertySet
- IceGrid::PropertySetDescriptorDict
- IceGrid::ServerInstanceDescriptor::propertySet
- IceGrid::ServiceInstanceDescriptor::propertySet

#### Data Member Index

[references](#) — References to named property sets.

[properties](#) — The property set properties.

#### Data Members

**Ice::StringSeq** [references](#);

References to named property sets.

**IceGrid::PropertyDescriptorSeq** [properties](#);

The property set properties.

---

## IceGrid-Query

---

### IceGrid::Query

#### Overview

#### interface Query

The IceGrid query interface. This interface is accessible to Ice clients who wish to look up well-known objects.

#### Operation Index

`findObjectById` — Find a well-known object by identity.

`findObjectByType` — Find a well-known object by type.

`findObjectByTypeOnLeastLoadedNode` — Find a well-known object by type on the least-loaded node.

`findAllObjectsByType` — Find all the well-known objects with the given type.

`findAllReplicas` — Find all the object replicas associated with the given proxy.

#### Operations

##### [ "nonmutating" ] Object\* findObjectById(Ice::Identity id)

Find a well-known object by identity.

##### Parameters

`id` — The identity.

##### Return Value

The proxy or null if no such object has been found.

##### [ "nonmutating" ] Object\* findObjectByType(string type)

Find a well-known object by type. If there are several objects registered for the given type, the object is randomly selected.

##### Parameters

`type` — The object type.

##### Return Value

The proxy or null, if no such object has been found.

##### [ "nonmutating" ] Object\* findObjectByTypeOnLeastLoadedNode(string type, IceGrid::LoadSample sample)

Find a well-known object by type on the least-loaded node. If the registry does not know which node hosts the object (for example, because the object was registered with a direct proxy), the registry assumes the object is hosted on a node that has a load average of 1.0.

##### Parameters

`type` — The object type.

`sample` — The sampling interval.

##### Return Value

The proxy or null, if no such object has been found.

**[ "nonmutating" ] Ice::ObjectProxySeq findAllObjectsByType(string type)**

Find all the well-known objects with the given type.

**Parameters**

`type` — The object type.

**Return Value**

The proxies or an empty sequence, if no such objects have been found.

**Ice::ObjectProxySeq findAllReplicas(Object\* proxy)**

Find all the object replicas associated with the given proxy. If the given proxy is not an indirect proxy from a replica group, an empty sequence is returned.

**Parameters**

`proxy` — The object proxy.

**Return Value**

The proxies of each object replica or an empty sequence, if the given proxy is not from a replica group.

---

## IceGrid-RandomLoadBalancingPolicy

---

### IceGrid::RandomLoadBalancingPolicy

#### Overview

class `RandomLoadBalancingPolicy` extends `IceGrid::LoadBalancingPolicy`

Random load balancing policy.

---

## IceGrid-Registry

---

### IceGrid::Registry

#### Overview

#### interface Registry

The IceGrid registry allows clients create sessions directly with the registry.

#### See Also

- [IceGrid::Session](#)
- [IceGrid::AdminSession](#)

#### Operation Index

[createSession](#) — Create a client session.

[createAdminSession](#) — Create an administrative session.

[createSessionFromSecureConnection](#) — Create a client session from a secure connection.

[createAdminSessionFromSecureConnection](#) — Create an administrative session from a secure connection.

[getSessionTimeout](#) — Get the session timeout.

[getACMTimeout](#) — Get the value of the ACM timeout.

#### Operations

##### **IceGrid::Session\*** [createSession\(string userId, string password\)](#) throws **IceGrid::PermissionDeniedException**

Create a client session.

#### Parameters

`userId` — The user id.

`password` — The password for the given user id.

#### Return Value

A proxy for the newly created session.

#### Exceptions

**IceGrid::PermissionDeniedException** — Raised if the password for the given user id is not correct, or if the user is not allowed access.

#### See Also

- [IceGrid::Session](#)
- [Glacier2::PermissionsVerifier](#)

##### **IceGrid::AdminSession\*** [createAdminSession\(string userId, string password\)](#) throws **IceGrid::PermissionDeniedException**

Create an administrative session.

#### Parameters

`userId` — The user id.

`password` — The password for the given user id.

**Return Value**

A proxy for the newly created session.

**Exceptions**

[IceGrid::PermissionDeniedException](#) — Raised if the password for the given user id is not correct, or if the user is not allowed access.

**See Also**

- [IceGrid::Session](#)
- [Glacier2::PermissionsVerifier](#)

**IceGrid::Session\* createSessionFromSecureConnection() throws IceGrid::PermissionDeniedException**

Create a client session from a secure connection.

**Return Value**

A proxy for the newly created session.

**Exceptions**

[IceGrid::PermissionDeniedException](#) — Raised if the password for the given user id is not correct, or if the user is not allowed access.

**See Also**

- [IceGrid::Session](#)
- [Glacier2::SSLPermissionsVerifier](#)

**IceGrid::AdminSession\* createAdminSessionFromSecureConnection() throws IceGrid::PermissionDeniedException**

Create an administrative session from a secure connection.

**Return Value**

A proxy for the newly created session.

**Exceptions**

[IceGrid::PermissionDeniedException](#) — Raised if the password for the given user id is not correct, or if the user is not allowed access.

**See Also**

- [IceGrid::Session](#)
- [Glacier2::SSLPermissionsVerifier](#)

**[ "nonmutating" ] int getSessionTimeout()**

Get the session timeout. If a client or administrative client doesn't call the session `keepAlive` method in the time interval defined by this timeout, IceGrid might reap the session.

**Return Value**

The timeout (in seconds).

**See Also**

- [IceGrid::Session::keepAlive](#)
- [IceGrid::AdminSession::keepAlive](#)

**[ "nonmutating" ] int getACMTimeout()**

Get the value of the ACM timeout. Clients supporting ACM connection heartbeats can enable them instead of explicitly sending keep alives requests. NOTE: This method is only available since Ice 3.6.

***Return Value***

The timeout (in seconds).

---

## IceGrid-RegistryInfo

---

### IceGrid::RegistryInfo

#### Overview

#### struct RegistryInfo

Information about an IceGrid registry replica.

#### *Used By*

- IceGrid::Admin::getRegistryInfo
- IceGrid::RegistryInfoSeq
- IceGrid::RegistryObserver::registryUp

#### Data Member Index

`name` — The name of the registry.

`hostname` — The network name of the host running this registry (as defined in `uname()`).

#### Data Members

**string name;**

The name of the registry.

**string hostname;**

The network name of the host running this registry (as defined in `uname()`).

---

## IceGrid-RegistryNotExistException

---

### IceGrid::RegistryNotExistException

#### Overview

exception RegistryNotExistException

This exception is raised if a registry does not exist.

#### *Used By*

- IceGrid::Admin::getRegistryAdmin
- IceGrid::Admin::getRegistryInfo
- IceGrid::Admin::pingRegistry
- IceGrid::Admin::shutdownRegistry
- IceGrid::AdminSession::openRegistryStdErr
- IceGrid::AdminSession::openRegistryStdOut

#### Data Member Index

`name` — The registry name.

#### Data Members

`string name;`

The registry name.

---

## IceGrid-RegistryObserver

---

### IceGrid::RegistryObserver

#### Overview

#### interface RegistryObserver

This interface allows applications to monitor changes the state of the registry.

#### Operation Index

**registryInit** — The `registryInit` operation is called after registration of an observer to indicate the state of the registries.

**registryUp** — The `nodeUp` operation is called to notify an observer that a node came up.

**registryDown** — The `nodeDown` operation is called to notify an observer that a node went down.

#### Operations

##### **void registryInit(IceGrid::RegistryInfoSeq registries)**

The `registryInit` operation is called after registration of an observer to indicate the state of the registries.

##### *Parameters*

`registries` — The current state of the registries.

##### **void registryUp(IceGrid::RegistryInfo node)**

The `nodeUp` operation is called to notify an observer that a node came up.

##### *Parameters*

`node` — The node state.

##### **void registryDown(string name)**

The `nodeDown` operation is called to notify an observer that a node went down.

##### *Parameters*

`name` — The node name.

---

## IceGrid-RegistryPluginFacade

---

### IceGrid::RegistryPluginFacade

#### Overview

#### local interface RegistryPluginFacade

The RegistryPluginFacade is implemented by IceGrid and can be used by plugins and filter implementations to retrieve information from IceGrid about the well-known objects or adapters. It's also used to register/unregister replica group and type filters.

#### Operation Index

[getApplicationInfo](#) — Get an application descriptor.  
[getServerInfo](#) — Get the server information for the server with the given id.  
[getAdapterServer](#) — Get the ID of the server to which the given adapter belongs.  
[getAdapterApplication](#) — Get the name of the application to which the given adapter belongs.  
[getAdapterNode](#) — Get the name of the node to which the given adapter belongs.  
[getAdapterInfo](#) — Get the adapter information for the replica group or adapter with the given id.  
[getObjectInfo](#) — Get the object info for the object with the given identity.  
[getNodeInfo](#) — Get the node information for the node with the given name.  
[getNodeLoad](#) — Get the load averages of the node.  
[getPropertyForAdapter](#) — Get the property value for the given property and adapter.  
[addReplicaGroupFilter](#) — Add a replica group filter.  
[removeReplicaGroupFilter](#) — Remove a replica group filter.  
[addTypeFilter](#) — Add a type filter.  
[removeTypeFilter](#) — Remove a type filter.

#### Operations

[ "nonmutating" ] **IceGrid::ApplicationInfo** [getApplicationInfo\(string name\)](#) throws **IceGrid::ApplicationNotExistException**

Get an application descriptor.

##### Parameters

`name` — The application name.

##### Return Value

The application descriptor.

##### Exceptions

**IceGrid::ApplicationNotExistException** — Raised if the application doesn't exist.

[ "nonmutating" ] **IceGrid::ServerInfo** [getServerInfo\(string id\)](#) throws **IceGrid::ServerNotExistException**

Get the server information for the server with the given id.

##### Parameters

`id` — The server id.

##### Return Value

The server information.

**Exceptions**

`IceGrid::ServerNotExistException` — Raised if the server doesn't exist.

[ "nonmutating" ] **string** `getAdapterServer(string adapterId)` throws `IceGrid::AdapterNotExistException`

Get the ID of the server to which the given adapter belongs.

**Parameters**

`adapterId` — The adapter ID.

**Return Value**

The server ID or the empty string if the given identifier is not associated to an object adapter defined with an application descriptor.

**Exceptions**

`IceGrid::AdapterNotExistException` — Raised if the adapter doesn't exist.

[ "nonmutating" ] **string** `getAdapterApplication(string adapterId)` throws `IceGrid::AdapterNotExistException`

Get the name of the application to which the given adapter belongs.

**Parameters**

`adapterId` — The adapter ID.

**Return Value**

The application name or the empty string if the given identifier is not associated to a replica group or object adapter defined with an application descriptor.

**Exceptions**

`IceGrid::AdapterNotExistException` — Raised if the adapter doesn't exist.

[ "nonmutating" ] **string** `getAdapterNode(string adapterId)` throws `IceGrid::AdapterNotExistException`

Get the name of the node to which the given adapter belongs.

**Parameters**

`adapterId` — The adapter ID.

**Return Value**

The node name or the empty string if the given identifier is not associated to an object adapter defined with an application descriptor.

**Exceptions**

`IceGrid::AdapterNotExistException` — Raised if the adapter doesn't exist.

[ "nonmutating" ] **IceGrid::AdapterInfoSeq** `getAdapterInfo(string id)` throws `IceGrid::AdapterNotExistException`

Get the adapter information for the replica group or adapter with the given id.

**Parameters**

`id` — The adapter id.

**Return Value**

A sequence of adapter information structures. If the given `id` refers to an adapter, this sequence will contain only one element. If the given `id` refers to a replica group, the sequence will contain the adapter information of each member of the replica group.

**Exceptions**

`IceGrid::AdapterNotExistException` — Raised if the adapter or replica group doesn't exist.

[ "nonmutating" ] **IceGrid::ObjectInfo getObjectInfo(Ice::Identity id) throws IceGrid::ObjectNotRegisteredException**

Get the object info for the object with the given identity.

**Parameters**

`id` — The identity of the object.

**Return Value**

The object info.

**Exceptions**

`IceGrid::ObjectNotRegisteredException` — Raised if the object isn't registered with the registry.

[ "nonmutating" ] **IceGrid::NodeInfo getNodeInfo(string name) throws IceGrid::NodeNotExistException, IceGrid::NodeUnreachableException**

Get the node information for the node with the given name.

**Parameters**

`name` — The node name.

**Return Value**

The node information.

**Exceptions**

`IceGrid::NodeNotExistException` — Raised if the node doesn't exist.

`IceGrid::NodeUnreachableException` — Raised if the node could not be reached.

[ "nonmutating" ] **IceGrid::LoadInfo getNodeLoad(string name) throws IceGrid::NodeNotExistException, IceGrid::NodeUnreachableException**

Get the load averages of the node.

**Parameters**

`name` — The node name.

**Return Value**

The node load information.

**Exceptions**

`IceGrid::NodeNotExistException` — Raised if the node doesn't exist.

`IceGrid::NodeUnreachableException` — Raised if the node could not be reached.

[ "nonmutating" ] string getPropertyForAdapter(string adapterId, string name) throws **IceGrid::AdapterNotExistException**

Get the property value for the given property and adapter. The property is looked up in the server or service descriptor where the adapter is defined.

**Parameters**

`adapterId` — The adapter ID  
`name` — The name of the property.

**Return Value**

The property value.

void addReplicaGroupFilter(string id, **IceGrid::ReplicaGroupFilter** filter)

Add a replica group filter.

**Parameters**

`id` — The identifier of the filter. This identifier must match the value of the "filter" attribute specified in the replica group descriptor. To filter dynamically registered replica groups, you should use the empty filter id.  
`filter` — The filter implementation.

bool removeReplicaGroupFilter(string id, **IceGrid::ReplicaGroupFilter** filter)

Remove a replica group filter.

**Parameters**

`id` — The identifier of the filter.  
`filter` — The filter implementation.

**Return Value**

True if the filter was removed, false otherwise.

void addTypeFilter(string type, **IceGrid::TypeFilter** filter)

Add a type filter.

**Parameters**

`type` — The type to register this filter with.  
`filter` — The filter implementation.

bool removeTypeFilter(string type, **IceGrid::TypeFilter** filter)

Remove a type filter.

**Parameters**

`type` — The type to register this filter with.  
`filter` — The filter implementation.

**Return Value**

True if the filter was removed, false otherwise.

## IceGrid-RegistryUnreachableException

---

### IceGrid::RegistryUnreachableException

#### Overview

#### exception RegistryUnreachableException

This exception is raised if a registry could not be reached.

#### *Used By*

- IceGrid::Admin::getRegistryInfo
- IceGrid::Admin::shutdownRegistry
- IceGrid::AdminSession::openRegistryStdErr
- IceGrid::AdminSession::openRegistryStdOut

#### Data Member Index

`name` — The name of the registry that is not reachable.

`reason` — The reason why the registry couldn't be reached.

#### Data Members

**string name;**

The name of the registry that is not reachable.

**string reason;**

The reason why the registry couldn't be reached.

---

## IceGrid-ReplicaGroupDescriptor

---

### IceGrid::ReplicaGroupDescriptor

#### Overview

#### struct ReplicaGroupDescriptor

A replica group descriptor.

#### Used By

- [IceGrid::ReplicaGroupDescriptorSeq](#)

#### Data Member Index

[id](#) — The id of the replica group.  
[loadBalancing](#) — The load balancing policy.  
[proxyOptions](#) — Default options for proxies created for the replica group.  
[objects](#) — The object descriptors associated with this object adapter.  
[description](#) — The description of this replica group.  
[filter](#) — The filter to use for this replica group.

#### Data Members

##### string id;

The id of the replica group.

##### [IceGrid::LoadBalancingPolicy](#) loadBalancing;

The load balancing policy.

##### string proxyOptions;

Default options for proxies created for the replica group.

##### [IceGrid::ObjectDescriptorSeq](#) objects;

The object descriptors associated with this object adapter.

##### string description;

The description of this replica group.

##### string filter;

The filter to use for this replica group.

---

## IceGrid-ReplicaGroupFilter

---

### IceGrid::ReplicaGroupFilter

#### Overview

#### local interface ReplicaGroupFilter

The ReplicaGroupFilter is used by IceGrid to filter adapters returned to the client when it resolves a filtered replica group. IceGrid provides the list of available adapters. The implementation of this method can use the provided context and connection to filter and return the filtered set of adapters.

#### Used By

- IceGrid::RegistryPluginFacade::addReplicaGroupFilter
- IceGrid::RegistryPluginFacade::removeReplicaGroupFilter

#### Operation Index

`filter` — Filter the the given set of adapters.

#### Operations

**Ice::StringSeq** `filter`(string replicaGroupId, Ice::StringSeq adapterIds, Ice::Connection con, Ice::Context ctx)

Filter the the given set of adapters.

#### Parameters

`replicaGroupId` — The replica group ID.

`adapterIds` — The adapter IDs to filter.

`con` — The connection from the Ice client which is resolving the replica group endpoints.

`ctx` — The context from the Ice client which is resolving the replica group endpoints.

#### Return Value

The filtered adapter IDs.

---

## IceGrid-RoundRobinLoadBalancingPolicy

---

### IceGrid::RoundRobinLoadBalancingPolicy

#### Overview

class RoundRobinLoadBalancingPolicy extends [IceGrid::LoadBalancingPolicy](#)

Round robin load balancing policy.

---

## IceGrid-ServerDescriptor

---

### IceGrid::ServerDescriptor

#### Overview

class `ServerDescriptor` extends `IceGrid::CommunicatorDescriptor`

An Ice server descriptor.

#### Derived Classes and Interfaces

- `IceGrid::IceBoxDescriptor`

#### Used By

- `IceGrid::ServerDescriptorSeq`
- `IceGrid::ServerInfo::descriptor`

#### Data Member Index

`id` — The server id.

`exe` — The path of the server executable.

`iceVersion` — The Ice version used by this server.

`pwd` — The path to the server working directory.

`options` — The command line options to pass to the server executable.

`envs` — The server environment variables.

`activation` — The server activation mode (possible values are "on-demand" or "manual").

`activationTimeout` — The activation timeout (an integer value representing the number of seconds to wait for activation).

`deactivationTimeout` — The deactivation timeout (an integer value representing the number of seconds to wait for deactivation).

`applicationDistrib` — Specifies if the server depends on the application distribution.

`distrib` — The distribution descriptor.

`allocatable` — Specifies if the server is allocatable.

`user` — The user account used to run the server.

#### Data Members

**string** `id`;

The server id.

**string** `exe`;

The path of the server executable.

**string** `iceVersion`;

The Ice version used by this server. This is only required if backward compatibility with servers using old Ice versions is needed (otherwise the registry will assume the server is using the same Ice version). For example "3.1.1", "3.2", "3.3.0".

**string** `pwd`;

The path to the server working directory.

[ "java:type:java.util.LinkedList<String>" ] **Ice::StringSeq** `options`;

The command line options to pass to the server executable.

```
["java:type:java.util.LinkedList<String>"] Ice::StringSeq envs;
```

The server environment variables.

**string activation;**

The server activation mode (possible values are "on-demand" or "manual").

**string activationTimeout;**

The activation timeout (an integer value representing the number of seconds to wait for activation).

**string deactivationTimeout;**

The deactivation timeout (an integer value representing the number of seconds to wait for deactivation).

**bool applicationDistrib;**

Specifies if the server depends on the application distribution.

**IceGrid::DistributionDescriptor distrib;**

The distribution descriptor.

**bool allocatable;**

Specifies if the server is allocatable.

**string user;**

The user account used to run the server.

---

## IceGrid-ServerDynamicInfo

---

### IceGrid::ServerDynamicInfo

#### Overview

#### struct ServerDynamicInfo

Dynamic information about the state of a server.

#### Used By

- [IceGrid::NodeObserver::updateServer](#)
- [IceGrid::ServerDynamicInfoSeq](#)

#### Data Member Index

[id](#) — The id of the server.

[state](#) — The state of the server.

[pid](#) — The process id of the server.

[enabled](#) — Indicates whether the server is enabled.

#### Data Members

**string id;**

The id of the server.

**IceGrid::ServerState state;**

The state of the server.

**int pid;**

The process id of the server.

**bool enabled;**

Indicates whether the server is enabled.

---

## IceGrid-ServerInfo

---

### IceGrid::ServerInfo

#### Overview

#### struct ServerInfo

Information about a server managed by an IceGrid node.

#### Used By

- `IceGrid::Admin::getServerInfo`
- `IceGrid::RegistryPluginFacade::getServerInfo`

#### Data Member Index

`application` — The server application.

`uuid` — The application uuid.

`revision` — The application revision.

`node` — The server node.

`descriptor` — The server descriptor.

`sessionId` — The id of the session which allocated the server.

#### Data Members

##### `string application;`

The server application.

##### `string uuid;`

The application uuid.

##### `int revision;`

The application revision.

##### `string node;`

The server node.

##### `IceGrid::ServerDescriptor descriptor;`

The server descriptor.

##### `string sessionId;`

The id of the session which allocated the server.

---

## IceGrid-ServerInstanceDescriptor

---

### IceGrid::ServerInstanceDescriptor

#### Overview

[ "cpp:comparable" ] struct ServerInstanceDescriptor

A server template instance descriptor.

#### Used By

- [IceGrid::Admin::instantiateServer](#)
- [IceGrid::ServerInstanceDescriptorSeq](#)

#### Data Member Index

[template](#) — The template used by this instance.  
[parameterValues](#) — The template parameter values.  
[propertySet](#) — The property set.  
[servicePropertySets](#) — The services property sets.

#### Data Members

**string** [template](#);

The template used by this instance.

**IceGrid::StringStringDict** [parameterValues](#);

The template parameter values.

**IceGrid::PropertySetDescriptor** [propertySet](#);

The property set.

**IceGrid::PropertySetDescriptorDict** [servicePropertySets](#);

The services property sets. It's only valid to set these property sets if the template is an IceBox server template.

---

## IceGrid-ServerNotExistException

---

### IceGrid::ServerNotExistException

#### Overview

#### exception ServerNotExistException

This exception is raised if a server does not exist.

#### Used By

- IceGrid::Admin::enableServer
- IceGrid::Admin::getServerAdmin
- IceGrid::Admin::getServerInfo
- IceGrid::Admin::getServerPid
- IceGrid::Admin::getServerState
- IceGrid::Admin::isServerEnabled
- IceGrid::Admin::patchServer
- IceGrid::Admin::sendSignal
- IceGrid::Admin::startServer
- IceGrid::Admin::stopServer
- IceGrid::AdminSession::openServerLog
- IceGrid::AdminSession::openServerStdErr
- IceGrid::AdminSession::openServerStdOut
- IceGrid::RegistryPluginFacade::getServerInfo

#### Data Member Index

`id` — The identifier of the server.

#### Data Members

`string id;`

The identifier of the server.

---

## IceGrid-ServerStartException

---

### IceGrid::ServerStartException

#### Overview

exception `ServerStartException`

This exception is raised if a server failed to start.

#### *Used By*

- `IceGrid::Admin::startServer`

#### Data Member Index

`id` — The identifier of the server.

`reason` — The reason for the failure.

#### Data Members

`string id;`

The identifier of the server.

`string reason;`

The reason for the failure.

---

## IceGrid-ServerState

---

### IceGrid::ServerState

#### Overview

#### enum ServerState

An enumeration representing the state of the server.

#### Used By

- [Admin::getServerState](#)
- [ServerDynamicInfo::state](#)

#### Enumerator Index

[Inactive](#) — The server is not running.

[Activating](#) — The server is being activated and will change to the active state when the registered server object adapters are activated or to the activation timed out state if the activation timeout expires.

[ActivationTimedOut](#) — The activation timed out state indicates that the server activation timed out.

[Active](#) — The server is running.

[Deactivating](#) — The server is being deactivated.

[Destroying](#) — The server is being destroyed.

[Destroyed](#) — The server is destroyed.

#### Enumerators

##### Inactive

The server is not running.

##### Activating

The server is being activated and will change to the active state when the registered server object adapters are activated or to the activation timed out state if the activation timeout expires.

##### ActivationTimedOut

The activation timed out state indicates that the server activation timed out.

##### Active

The server is running.

##### Deactivating

The server is being deactivated.

##### Destroying

The server is being destroyed.

## Destroyed

The server is destroyed.

---

## IceGrid-ServerStopException

---

### IceGrid::ServerStopException

#### Overview

exception `ServerStopException`

This exception is raised if a server failed to stop.

#### *Used By*

- `IceGrid::Admin::stopServer`

#### Data Member Index

`id` — The identifier of the server.

`reason` — The reason for the failure.

#### Data Members

`string id;`

The identifier of the server.

`string reason;`

The reason for the failure.

---

## IceGrid-ServerUnreachableException

---

### IceGrid::ServerUnreachableException

#### Overview

exception `ServerUnreachableException`

This exception is raised if a server could not be reached.

#### Data Member Index

`name` — The id of the server that is not reachable.

`reason` — The reason why the server couldn't be reached.

#### Data Members

**string name;**

The id of the server that is not reachable.

**string reason;**

The reason why the server couldn't be reached.

---

## IceGrid-ServiceDescriptor

---

### IceGrid::ServiceDescriptor

#### Overview

class `ServiceDescriptor` extends `IceGrid::CommunicatorDescriptor`

An IceBox service descriptor.

#### Used By

- `IceGrid::ServiceDescriptorSeq`
- `IceGrid::ServiceInstanceDescriptor::descriptor`

#### Data Member Index

`name` — The service name.

`entry` — The entry point of the IceBox service.

#### Data Members

`string name;`

The service name.

`string entry;`

The entry point of the IceBox service.

---

## IceGrid-ServiceInstanceDescriptor

---

### IceGrid::ServiceInstanceDescriptor

#### Overview

#### struct ServiceInstanceDescriptor

A service template instance descriptor.

#### Used By

- [IceGrid::ServiceInstanceDescriptorSeq](#)

#### Data Member Index

[template](#) — The template used by this instance.

[parameterValues](#) — The template parameter values.

[descriptor](#) — The service definition if the instance isn't a template instance (i.e.: if the template attribute is empty).

[propertySet](#) — The property set.

#### Data Members

##### string template;

The template used by this instance.

##### IceGrid::StringStringDict parameterValues;

The template parameter values.

##### IceGrid::ServiceDescriptor descriptor;

The service definition if the instance isn't a template instance (i.e.: if the template attribute is empty).

##### IceGrid::PropertySetDescriptor propertySet;

The property set.

---

## IceGrid-Session

---

### IceGrid::Session

#### Overview

interface `Session` extends `Glacier2::Session`

A session object is used by IceGrid clients to allocate and release objects. Client sessions are either created with the `IceGrid::Registry` object or the registry client `Glacier2::SessionManager` object.

#### See Also

- `IceGrid::Registry`
- `Glacier2::SessionManager`

#### Operation Index

`keepAlive` — Keep the session alive.

`allocateObjectById` — Allocate an object.

`allocateObjectByType` — Allocate an object with the given type.

`releaseObject` — Release an object that was allocated using `allocateObjectById` or `allocateObjectByType`.

`setAllocationTimeout` — Set the allocation timeout.

#### Operations

##### `void keepAlive()`

Keep the session alive. Clients should call this operation regularly to prevent the server from reaping the session.

#### See Also

- `IceGrid::Registry::getSessionTimeout`

[ "amd" ] `Object*` `allocateObjectById(Ice::Identity id)` throws `IceGrid::ObjectNotRegisteredException`, `IceGrid::AllocationException`

Allocate an object. Depending on the allocation timeout, this operation might hang until the object is available or until the timeout is reached.

#### Parameters

`id` — The identity of the object to allocate.

#### Return Value

The proxy of the allocated object.

#### Exceptions

`IceGrid::ObjectNotRegisteredException` — Raised if the object with the given identity is not registered with the registry.

`IceGrid::AllocationException` — Raised if the object can't be allocated.

#### See Also

- `setAllocationTimeout`
- `releaseObject`

**[ "amd" ] Object\* allocateObjectByType(string type) throws IceGrid::AllocationException**

Allocate an object with the given type. Depending on the allocation timeout, this operation can block until an object becomes available or until the timeout is reached.

**Parameters**

`type` — The type of the object.

**Return Value**

The proxy of the allocated object.

**Exceptions**

[IceGrid::ObjectNotRegisteredException](#) — Raised if no objects with the given type can be allocated.

[IceGrid::AllocationException](#) — Raised if the object could not be allocated.

**See Also**

- [setAllocationTimeout](#)
- [releaseObject](#)

**void releaseObject(Ice::Identity id) throws IceGrid::ObjectNotRegisteredException, IceGrid::AllocationException**

Release an object that was allocated using `allocateObjectById` or `allocateObjectByType`.

**Parameters**

`id` — The identity of the object to release.

**Exceptions**

[IceGrid::ObjectNotRegisteredException](#) — Raised if the object with the given identity is not registered with the registry.

[IceGrid::AllocationException](#) — Raised if the given object can't be released. This might happen if the object isn't allocatable or isn't allocated by the session.

**void setAllocationTimeout(int timeout)**

Set the allocation timeout. If no objects are available for an allocation request, a call to `allocateObjectById` or `allocateObjectByType` will block for the duration of this timeout.

**Parameters**

`timeout` — The timeout in milliseconds.

---

## IceGrid-TemplateDescriptor

---

### IceGrid::TemplateDescriptor

#### Overview

#### struct TemplateDescriptor

A template descriptor for server or service templates.

#### Used By

- [IceGrid::TemplateDescriptorDict](#)

#### Data Member Index

[descriptor](#) — The template.

[parameters](#) — The parameters required to instantiate the template.

[parameterDefaults](#) — The parameters default values.

#### Data Members

##### [IceGrid::CommunicatorDescriptor](#) descriptor;

The template.

##### [ "java:type:java.util.LinkedList<String>" ] [Ice::StringSeq](#) parameters;

The parameters required to instantiate the template.

##### [IceGrid::StringStringDict](#) parameterDefaults;

The parameters default values.

---

## IceGrid-TypeFilter

---

### IceGrid::TypeFilter

#### Overview

#### local interface TypeFilter

The TypeFilter is used by IceGrid to filter well-known proxies returned to the client when it searches a well-known object by type. IceGrid provides the list of available proxies. The implementation of this method can use the provided context and connection to filter and return the filtered set of proxies.

#### Used By

- IceGrid::RegistryPluginFacade::addTypeFilter
- IceGrid::RegistryPluginFacade::removeTypeFilter

#### Operation Index

`filter` — Filter the the given set of proxies.

#### Operations

**Ice::ObjectProxySeq filter(string type, Ice::ObjectProxySeq proxies, Ice::Connection con, Ice::Context ctx)**

Filter the the given set of proxies.

#### Parameters

`type` — The type.

`proxies` — The proxies to filter.

`con` — The connection from the Ice client which is looking up well-known objects by type.

`ctx` — The context from the Ice client which is looking up well-known objects by type.

#### Return Value

The filtered proxies.

---

## IceGrid-UserAccountMapper

---

### IceGrid::UserAccountMapper

#### Overview

#### interface `UserAccountMapper`

A user account mapper object is used by IceGrid nodes to map session identifiers to user accounts.

#### Operation Index

`getUserAccount` — Get the name of the user account for the given user.

#### Operations

##### `string getUserAccount(string user)` throws `IceGrid::UserAccountNotFoundException`

Get the name of the user account for the given user. This is used by IceGrid nodes to figure out the user account to use to run servers.

##### *Parameters*

`user` — The value of the server descriptor's `user` attribute. If this attribute is not defined, and the server's activation mode is `session`, the default value of `user` is the session identifier.

##### *Return Value*

The user account name.

##### *Exceptions*

`IceGrid::UserAccountNotFoundException` — Raised if no user account is found for the given user.

---

## IceGrid-UserAccountNotFoundException

---

### IceGrid::UserAccountNotFoundException

#### Overview

#### exception UserAccountNotFoundException

This exception is raised if a user account for a given session identifier can't be found.

#### *Used By*

- `IceGrid::UserAccountMapper::getUserAccount`
-

# IceLocatorDiscovery Slice API

---

## IceLocatorDiscovery

### Overview

#### module IceLocatorDiscovery

IceLocatorDiscovery is an Ice plug-in that enables the discovery of IceGrid and custom locators via UDP multicast.

### Interface Index

[Lookup](#) — The Ice lookup interface is implemented by Ice locator implementations and can be used by clients to find available Ice locators on the network.

[LookupReply](#) — The Ice lookup reply interface must be implemented by clients which are searching for Ice locators.

---

## IceLocatorDiscovery-Lookup

---

### IceLocatorDiscovery::Lookup

#### Overview

#### interface Lookup

The Ice lookup interface is implemented by Ice locator implementations and can be used by clients to find available Ice locators on the network. Ice locator implementations provide a well-known 'Ice/LocatorLookup' object accessible through UDP multicast. Clients typically make a multicast findLocator request to find the locator proxy.

#### See Also

- [Ice::Locator](#)
- [IceLocatorDiscovery::LookupReply](#)

#### Operation Index

[findLocator](#) — Find a locator proxy with the given instance name.

#### Operations

**void findLocator(string instanceName, [IceLocatorDiscovery::LookupReply\\*](#) reply)**

Find a locator proxy with the given instance name.

#### Parameters

*instanceName* — Restrict the search to Ice registries configured with the given instance name. If empty, all the available registries will reply.

*reply* — The reply object to use to send the reply.

---

## IceLocatorDiscovery-LookupReply

---

### IceLocatorDiscovery::LookupReply

#### Overview

#### interface LookupReply

The Ice lookup reply interface must be implemented by clients which are searching for Ice locators. Ice locator implementations invoke on this interface to provide their locator proxy.

#### See Also

- [Ice::Locator](#)
- [IceLocatorDiscovery::Lookup](#)

#### Operation Index

`foundLocator` — This method is called by the implementation of the Lookup interface to reply to a `findLocator` request.

#### Operations

`void foundLocator(Ice::Locator* prx)`

This method is called by the implementation of the Lookup interface to reply to a `findLocator` request.

#### Parameters

`prx` — The proxy of the locator.

---

# IceMX Slice API

---

## IceMX

### Overview

[ "objc:prefix:ICEMX" ] module IceMX

The Ice Management eXtension facility. It provides the [MetricsAdmin](#) interface for management clients to retrieve metrics from Ice applications.

### Class Index

[ChildInvocationMetrics](#) — Provides information on child invocations.  
[CollocatedMetrics](#) — Provides information on invocations that are collocated.  
[ConnectionMetrics](#) — Provides information on the data sent and received over Ice connections.  
[DispatchMetrics](#) — Provides information on servant dispatch.  
[InvocationMetrics](#) — Provide measurements for proxy invocations.  
[Metrics](#) — The base class for metrics.  
[RemoteMetrics](#) — Provides information on invocations that are specifically sent over Ice connections.  
[SessionMetrics](#) — Provides information on Glacier2 sessions.  
[SubscriberMetrics](#) — Provides information on IceStorm subscribers.  
[ThreadMetrics](#) — Provides information on the number of threads currently in use and their activity.  
[TopicMetrics](#) — Provides information on IceStorm topics.

### Interface Index

[MetricsAdmin](#) — The metrics administrative facet interface.

### Exception Index

[UnknownMetricsView](#) — Raised if a metrics view cannot be found.

### Structure Index

[MetricsFailures](#) — A structure to keep track of failures associated with a given metrics.

### Sequence Index

[MetricsFailuresSeq](#) — A sequence of [MetricsFailures](#).  
[MetricsMap](#) — A metrics map is a sequence of metrics.

### Dictionary Index

[MetricsView](#) — A metrics view is a dictionary of metrics map.  
[StringIntDict](#) — A dictionary of strings to integers.

### Sequences

**sequence<[MetricsFailures](#)> [MetricsFailuresSeq](#)**

A sequence of [MetricsFailures](#).

**Used By**

- [MetricsAdmin::getMapMetricsFailures](#)

**sequence<Metrics> MetricsMap**

A metrics map is a sequence of metrics. We use a sequence here instead of a map because the ID of the metrics is already included in the Metrics class and using sequences of metrics objects is more efficient than using dictionaries since lookup is not necessary.

**Used By**

- [InvocationMetrics::collocated](#)
- [InvocationMetrics::remotes](#)
- [MetricsView](#)

**Dictionaries****dictionary<string, MetricsMap> MetricsView**

A metrics view is a dictionary of metrics map. The key of the dictionary is the name of the metrics map.

**Used By**

- [MetricsAdmin::getMetricsView](#)

**dictionary<string, int> StringIntDict**

A dictionary of strings to integers.

**Used By**

- [MetricsFailures::failures](#)
-

## IceMX-ChildInvocationMetrics

---

### IceMX::ChildInvocationMetrics

#### Overview

class `ChildInvocationMetrics` extends `IceMX::Metrics`

Provides information on child invocations. A child invocation is either remote (sent over an Ice connection) or collocated. An invocation can have multiple child invocation if it is retried. Child invocation metrics are embedded within `IceMX::InvocationMetrics`.

#### *Derived Classes and Interfaces*

- `IceMX::CollocatedMetrics`
- `IceMX::RemoteMetrics`

#### Data Member Index

`size` — The size of the invocation.

`replySize` — The size of the invocation reply.

#### Data Members

**long size;**

The size of the invocation. This corresponds to the size of the marshalled input parameters.

**long replySize;**

The size of the invocation reply. This corresponds to the size of the marshalled output and return parameters.

---

## IceMX-CollocatedMetrics

---

### IceMX::CollocatedMetrics

#### Overview

class CollocatedMetrics extends [IceMX::ChildInvocationMetrics](#)

Provides information on invocations that are collocated. Collocated metrics are embedded within [IceMX::InvocationMetrics](#).

---

## IceMX-ConnectionMetrics

---

### IceMX::ConnectionMetrics

#### Overview

class `ConnectionMetrics` extends `IceMX::Metrics`

Provides information on the data sent and received over Ice connections.

#### Data Member Index

`receivedBytes` — The number of bytes received by the connection.

`sentBytes` — The number of bytes sent by the connection.

#### Data Members

**long** `receivedBytes`;

The number of bytes received by the connection.

**long** `sentBytes`;

The number of bytes sent by the connection.

---

## IceMX-DispatchMetrics

---

### IceMX::DispatchMetrics

#### Overview

class `DispatchMetrics` extends `IceMX::Metrics`

Provides information on servant dispatch.

#### Data Member Index

`userException` — The number of dispatch that failed with a user exception.

`size` — The size of the dispatch.

`replySize` — The size of the dispatch reply.

#### Data Members

`int userException;`

The number of dispatch that failed with a user exception.

`long size;`

The size of the dispatch. This corresponds to the size of the marshalled input parameters.

`long replySize;`

The size of the dispatch reply. This corresponds to the size of the marshalled output and return parameters.

---

## IceMX-InvocationMetrics

---

### IceMX::InvocationMetrics

#### Overview

class `InvocationMetrics` extends `IceMX::Metrics`

Provide measurements for proxy invocations. Proxy invocations can either be sent over the wire or be collocated.

#### Data Member Index

`retry` — The number of retries for the invocation(s).  
`userException` — The number of invocations that failed with a user exception.  
`remotes` — The remote invocation metrics map.  
`collocated` — The collocated invocation metrics map.

#### Data Members

`int retry;`

The number of retries for the invocation(s).

`int userException;`

The number of invocations that failed with a user exception.

`IceMX::MetricsMap remotes;`

The remote invocation metrics map.

*See Also*

- [IceMX::RemoteMetrics](#)

`IceMX::MetricsMap collocated;`

The collocated invocation metrics map.

*See Also*

- [IceMX::CollocatedMetrics](#)
-

## IceMX-Metrics

---

### IceMX::Metrics

#### Overview

#### class Metrics

The base class for metrics. A metrics object represents a collection of measurements associated to a given a system.

#### *Derived Classes and Interfaces*

- [IceMX::ChildInvocationMetrics](#)
- [IceMX::ConnectionMetrics](#)
- [IceMX::DispatchMetrics](#)
- [IceMX::InvocationMetrics](#)
- [IceMX::SessionMetrics](#)
- [IceMX::SubscriberMetrics](#)
- [IceMX::ThreadMetrics](#)
- [IceMX::TopicMetrics](#)

#### *Used By*

- [IceMX::MetricsMap](#)

#### Data Member Index

[id](#) — The metrics identifier.

[total](#) — The total number of objects that were observed by this metrics.

[current](#) — The current number of objects observed by this metrics.

[totalLifetime](#) — The sum of the lifetime of each observed objects.

[failures](#) — The number of failures observed.

#### Data Members

**string id;**

The metrics identifier.

**long total;**

The total number of objects that were observed by this metrics.

**int current;**

The current number of objects observed by this metrics.

**long totalLifetime;**

The sum of the lifetime of each observed objects. This does not include the lifetime of objects which are currently observed.

**int failures;**

The number of failures observed.

---

## IceMX-MetricsAdmin

---

### IceMX::MetricsAdmin

#### Overview

[ "format:sliced" ] interface `MetricsAdmin`

The metrics administrative facet interface. This interface allows remote administrative clients to access metrics of an application that enabled the Ice administrative facility and configured some metrics views.

#### Operation Index

`getMetricsViewNames` — Get the names of enabled and disabled metrics.  
`enableMetricsView` — Enables a metrics view.  
`disableMetricsView` — Disable a metrics view.  
`getMetricsView` — Get the metrics objects for the given metrics view.  
`getMapMetricsFailures` — Get the metrics failures associated with the given view and map.  
`getMetricsFailures` — Get the metrics failure associated for the given metrics.

#### Operations

**`Ice::StringSeq getMetricsViewNames(out Ice::StringSeq disabledViews)`**

Get the names of enabled and disabled metrics.

##### *Parameters*

`disabledViews` — The names of the disabled views.

##### *Return Value*

The name of the enabled views.

**`void enableMetricsView(string name) throws IceMX::UnknownMetricsView`**

Enables a metrics view.

##### *Parameters*

`name` — The metrics view name.

##### *Exceptions*

`IceMX::UnknownMetricsView` — Raised if the metrics view cannot be found.

**`void disableMetricsView(string name) throws IceMX::UnknownMetricsView`**

Disable a metrics view.

##### *Parameters*

`name` — The metrics view name.

##### *Exceptions*

`IceMX::UnknownMetricsView` — Raised if the metrics view cannot be found.

**IceMX::MetricsView** `getMetricsView(string view, out long timestamp)` throws **IceMX::UnknownMetricsView**

Get the metrics objects for the given metrics view. This returns a dictionary of metric maps for each metrics class configured with the view. The timestamp allows the client to compute averages which are not dependent of the invocation latency for this operation.

**Parameters**

`view` — The name of the metrics view.

`timestamp` — The local time of the process when the metrics object were retrieved.

**Return Value**

The metrics view data.

**Exceptions**

**IceMX::UnknownMetricsView** — Raised if the metrics view cannot be found.

**IceMX::MetricsFailuresSeq** `getMapMetricsFailures(string view, string map)` throws **IceMX::UnknownMetricsView**

Get the metrics failures associated with the given view and map.

**Parameters**

`view` — The name of the metrics view.

`map` — The name of the metrics map.

**Return Value**

The metrics failures associated with the map.

**Exceptions**

**IceMX::UnknownMetricsView** — Raised if the metrics view cannot be found.

**IceMX::MetricsFailures** `getMetricsFailures(string view, string map, string id)` throws **IceMX::UnknownMetricsView**

Get the metrics failure associated for the given metrics.

**Parameters**

`view` — The name of the metrics view.

`map` — The name of the metrics map.

`id` — The ID of the metrics.

**Return Value**

The metrics failures associated with the metrics.

**Exceptions**

**IceMX::UnknownMetricsView** — Raised if the metrics view cannot be found.

## IceMX-MetricsFailures

---

### IceMX::MetricsFailures

#### Overview

#### struct MetricsFailures

A structure to keep track of failures associated with a given metrics.

#### Used By

- [IceMX::MetricsAdmin::getMetricsFailures](#)
- [IceMX::MetricsFailuresSeq](#)

#### Data Member Index

[id](#) — The identifier of the metrics object associated to the failures.

[failures](#) — The failures observed for this metrics.

#### Data Members

**string id;**

The identifier of the metrics object associated to the failures.

**[IceMX::StringIntDict failures;](#)**

The failures observed for this metrics.

---

## IceMX-RemoteMetrics

---

### IceMX::RemoteMetrics

#### Overview

`class RemoteMetrics` extends `IceMX::ChildInvocationMetrics`

Provides information on invocations that are specifically sent over Ice connections. Remote metrics are embedded within `IceMX::InvocationMetrics`.

---

## IceMX-SessionMetrics

---

### IceMX::SessionMetrics

#### Overview

class `SessionMetrics` extends `IceMX::Metrics`

Provides information on Glacier2 sessions.

#### Data Member Index

`forwardedClient` — Number of client requests forwarded.  
`forwardedServer` — Number of server requests forwarded.  
`routingTableSize` — The size of the routing table.  
`queuedClient` — Number of client requests queued.  
`queuedServer` — Number of server requests queued.  
`overriddenClient` — Number of client requests overridden.  
`overriddenServer` — Number of server requests overridden.

#### Data Members

**int** `forwardedClient`;

Number of client requests forwarded.

**int** `forwardedServer`;

Number of server requests forwarded.

**int** `routingTableSize`;

The size of the routing table.

**int** `queuedClient`;

Number of client requests queued.

**int** `queuedServer`;

Number of server requests queued.

**int** `overriddenClient`;

Number of client requests overridden.

**int** `overriddenServer`;

Number of server requests overridden.

---

## IceMX-SubscriberMetrics

---

### IceMX::SubscriberMetrics

#### Overview

class `SubscriberMetrics` extends `IceMX::Metrics`

Provides information on IceStorm subscribers.

#### Data Member Index

`queued` — Number of queued events.  
`outstanding` — Number of outstanding events.  
`delivered` — Number of forwarded events.

#### Data Members

**int** `queued`;

Number of queued events.

**int** `outstanding`;

Number of outstanding events.

**long** `delivered`;

Number of forwarded events.

---

## IceMX-ThreadMetrics

---

### IceMX::ThreadMetrics

#### Overview

class `ThreadMetrics` extends `IceMX::Metrics`

Provides information on the number of threads currently in use and their activity.

#### Data Member Index

`inUseForIO` — The number of threads which are currently performing socket read or writes.

`inUseForUser` — The number of threads which are currently calling user code (servant dispatch, AMI callbacks, etc).

`inUseForOther` — The number of threads which are currently performing other activities.

#### Data Members

`int inUseForIO;`

The number of threads which are currently performing socket read or writes.

`int inUseForUser;`

The number of threads which are currently calling user code (servant dispatch, AMI callbacks, etc).

`int inUseForOther;`

The number of threads which are currently performing other activities. These are all other that are not counted with `inUseForUser` or `inUseForIO`, such as DNS lookups, garbage collection).

---

## IceMX-TopicMetrics

---

### IceMX::TopicMetrics

#### Overview

class `TopicMetrics` extends `IceMX::Metrics`

Provides information on IceStorm topics.

#### Data Member Index

`published` — Number of events published on the topic by publishers.

`forwarded` — Number of events forwarded on the topic by IceStorm topic links.

#### Data Members

##### `long published;`

Number of events published on the topic by publishers.

##### `long forwarded;`

Number of events forwarded on the topic by IceStorm topic links.

---

## IceMX-UnknownMetricsView

---

### IceMX::UnknownMetricsView

#### Overview

#### exception UnknownMetricsView

Raised if a metrics view cannot be found.

#### *Used By*

- IceMX::MetricsAdmin::disableMetricsView
  - IceMX::MetricsAdmin::enableMetricsView
  - IceMX::MetricsAdmin::getMapMetricsFailures
  - IceMX::MetricsAdmin::getMetricsFailures
  - IceMX::MetricsAdmin::getMetricsView
-

# IcePatch2 Slice API

---

## IcePatch2

### Overview

[ "objc:prefix:ICEPATCH2" ] module IcePatch2

IcePatch can be used to update file hierarchies in a simple and efficient manner. Checksums ensure file integrity, and data is compressed before downloading.

### Interface Index

[FileServer](#) — The interface that provides access to files.

### Exception Index

[FileAccessException](#) — This exception is raised if a file's contents cannot be read.

[FileSizeRangeException](#) — This exception is raised if an operation tries to use a file whose size is larger than 2.1 GB.

[PartitionOutOfRangeException](#) — A `partition` argument for was not in the range 0-255.

### Structure Index

[FileInfo](#) — Basic information about a single file.

[LargeFileInfo](#) — Basic information about a single file.

### Sequence Index

[ByteSeqSeq](#) — A sequence of byte sequences.

[FileInfoSeq](#) — A sequence with information about many files.

[LargeFileInfoSeq](#) — A sequence with information about many files.

### Sequences

#### `sequence<Ice::ByteSeq> ByteSeqSeq`

A sequence of byte sequences. Each element is the checksum for a partition.

##### Used By

- [FileServer::getChecksumSeq](#)

#### `sequence<FileInfo> FileInfoSeq`

A sequence with information about many files.

##### Used By

- [FileServer::getFileInfoSeq](#)

#### `sequence<LargeFileInfo> LargeFileInfoSeq`

A sequence with information about many files.

**Used By**

- `FileServer::getLargeFileInfoSeq`
-

## IcePatch2-FileAccessException

---

### IcePatch2::FileAccessException

#### Overview

exception `FileAccessException`

This exception is raised if a file's contents cannot be read.

#### *Derived Exceptions*

- `IcePatch2::FileSizeRangeException`

#### *Used By*

- `IcePatch2::FileServer::getFileCompressed`
- `IcePatch2::FileServer::getLargeFileCompressed`

#### Data Member Index

`reason` — An explanation of the reason for the failure.

#### Data Members

`string reason;`

An explanation of the reason for the failure.

---

## IcePatch2-FileInfo

---

### IcePatch2::FileInfo

#### Overview

#### struct FileInfo

Basic information about a single file.

#### Used By

- `IcePatch2::FileInfoSeq`

#### Data Member Index

`path` — The pathname.

`checksum` — The SHA-1 checksum of the file.

`size` — The size of the compressed file in number of bytes.

`executable` — The executable flag.

#### Data Members

##### string path;

The pathname.

##### Ice::ByteSeq checksum;

The SHA-1 checksum of the file.

##### int size;

The size of the compressed file in number of bytes.

##### bool executable;

The executable flag.

---

## IcePatch2-FileServer

---

### IcePatch2::FileServer

#### Overview

#### interface FileServer

The interface that provides access to files.

#### Operation Index

[getFileInfoSeq](#) — Return file information for the specified partition. (*Deprecated*)

[getLargeFileInfoSeq](#) — Returns file information for the specified partition.

[getChecksumSeq](#) — Return the checksums for all partitions.

[getChecksum](#) — Return the master checksum for all partitions.

[getFileCompressed](#) — Read the specified file. (*Deprecated*)

[getLargeFileCompressed](#) — Read the specified file.

#### Operations

[ "nonmutating" ] [IcePatch2::FileInfoSeq](#) [getFileInfoSeq\(int partition\)](#) throws [IcePatch2::PartitionOutOfRangeException](#), [IcePatch2::FileSizeRangeException](#)

Return file information for the specified partition.

*This operation is deprecated and only present for compatibility with old Ice clients (older than version 3.6).*

*getFileInfoSeq() is deprecated, use getLargeFileInfoSeq() instead.*

##### Parameters

`partition` — The partition number in the range 0-255.

##### Return Value

A sequence containing information about the files in the specified partition.

##### Exceptions

[IcePatch2::PartitionOutOfRangeException](#) — If the partition number is out of range.

[IcePatch2::FileSizeRangeException](#) — If a file is larger than 2.1GB.

[ "nonmutating" ] [IcePatch2::LargeFileInfoSeq](#) [getLargeFileInfoSeq\(int partition\)](#) throws [IcePatch2::PartitionOutOfRangeException](#)

Returns file information for the specified partition.

##### Parameters

`partition` — The partition number in the range 0-255.

##### Return Value

A sequence containing information about the files in the specified partition.

##### Exceptions

`IcePatch2::PartitionOutOfRangeException` — If the partition number is out of range.

#### [ "nonmutating" ] `IcePatch2::ByteSeqSeq getChecksumSeq()`

Return the checksums for all partitions.

##### *Return Value*

A sequence containing 256 checksums. Partitions with a checksum that differs from the previous checksum for the same partition contain updated files. Partitions with a checksum that is identical to the previous checksum do not contain updated files.

#### [ "nonmutating" ] `Ice::ByteSeq getChecksum()`

Return the master checksum for all partitions. If this checksum is the same as for a previous run, the entire file set is up-to-date.

##### *Return Value*

The master checksum for the file set.

#### [ "amd", "nonmutating", "cpp:array" ] `Ice::ByteSeq getFileCompressed(string path, int pos, int num)` throws `IcePatch2::FileAccessException`, `IcePatch2::FileSizeRangeException`

Read the specified file. This operation may only return fewer bytes than requested in case there was an end-of-file condition.

*This operation is deprecated and only present for compatibility with old Ice clients (older than version 3.6).*

*getFileCompressed() is deprecated, use getLargeFileCompressed() instead.*

##### *Parameters*

`path` — The pathname (relative to the data directory) for the file to be read.

`pos` — The file offset at which to begin reading.

`num` — The number of bytes to be read.

##### *Return Value*

A sequence containing the compressed file contents.

##### *Exceptions*

`IcePatch2::FileAccessException` — If an error occurred while trying to read the file.

`IcePatch2::FileSizeRangeException` — If a file is larger than 2.1GB.

#### [ "amd", "nonmutating", "cpp:array" ] `Ice::ByteSeq getLargeFileCompressed(string path, long pos, int num)` throws `IcePatch2::FileAccessException`

Read the specified file. This operation may only return fewer bytes than requested in case there was an end-of-file condition.

##### *Parameters*

`path` — The pathname (relative to the data directory) for the file to be read.

`pos` — The file offset at which to begin reading.

`num` — The number of bytes to be read.

##### *Return Value*

A sequence containing the compressed file contents.

##### *Exceptions*

`IcePatch2::FileAccessException` — If an error occurred while trying to read the file.

## IcePatch2-FileSizeRangeException

---

### IcePatch2::FileSizeRangeException

#### Overview

exception `FileSizeRangeException` extends `IcePatch2::FileAccessException`

This exception is raised if an operation tries to use a file whose size is larger than 2.1 GB. Use the "large" versions of the operations instead.

#### *Used By*

- `IcePatch2::FileServer::getFileCompressed`
  - `IcePatch2::FileServer::getFileInfoSeq`
-

## IcePatch2-LargeFileInfo

---

### IcePatch2::LargeFileInfo

#### Overview

#### struct LargeFileInfo

Basic information about a single file.

#### Used By

- [IcePatch2::LargeFileInfoSeq](#)

#### Data Member Index

[path](#) — The pathname.

[checksum](#) — The SHA-1 checksum of the file.

[size](#) — The size of the compressed file in number of bytes.

[executable](#) — The executable flag.

#### Data Members

##### string path;

The pathname.

##### Ice::ByteSeq checksum;

The SHA-1 checksum of the file.

##### long size;

The size of the compressed file in number of bytes.

##### bool executable;

The executable flag.

---

## IcePatch2-PartitionOutOfRangeException

---

### IcePatch2::PartitionOutOfRangeException

#### Overview

exception `PartitionOutOfRangeException`

A `partition` argument for was not in the range 0-255.

#### Used By

- `IcePatch2::FileServer::getFileInfoSeq`
  - `IcePatch2::FileServer::getLargeFileInfoSeq`
-

# Ice Slice API

---

## Ice

### Overview

#### [ "objc:prefix:ICE" ] module Ice

The Ice core library. Among many other features, the Ice core library manages all the communication tasks using an efficient protocol (including protocol compression and support for both TCP and UDP), provides a thread pool for multi-threaded servers, and additional functionality that supports high scalability.

### Module Index

**Instrumentation** — The Instrumentation local interfaces enable observing a number of Ice core internal components (threads, connections, etc).

### Class Index

**ConnectionInfo** — Base class providing access to the connection details.  
**EndpointInfo** — Base class providing access to the endpoint details.  
**IPConnectionInfo** — Provides access to the connection details of an IP connection  
**IPEndpointInfo** — Provides access to the address details of a IP endpoint.  
**OpaqueEndpointInfo** — Provides access to the details of an opaque endpoint.  
**TCPConnectionInfo** — Provides access to the connection details of a TCP connection  
**TCPEndpointInfo** — Provides access to a TCP endpoint information.  
**UDPConnectionInfo** — Provides access to the connection details of a UDP connection  
**UDPEndpointInfo** — Provides access to an UDP endpoint information.  
**WSConnectionInfo** — Provides access to the connection details of a WebSocket connection  
**WSEndpointInfo** — Provides access to a WebSocket endpoint information.

### Interface Index

**Communicator** — The central object in Ice.  
**Connection** — The user-level interface to a connection.  
**ConnectionCallback** — An application can implement this interface to receive notifications when a connection closes or receives a heartbeat message.  
**Endpoint** — The user-level interface to an endpoint.  
**ImplicitContext** — An interface to associate implicit contexts with communicators.  
**Locator** — The Ice locator interface.  
**LocatorFinder** — This interface should be implemented by services implementing the Ice::Locator interface.  
**LocatorRegistry** — The Ice locator registry interface.  
**Logger** — The Ice message logger.  
**LoggerAdmin** — The interface of the admin object that allows an Ice application the attach its **RemoteLogger** to the **Logger** of this admin object's Ice communicator.  
**ObjectAdapter** — The object adapter provides an up-call interface from the Ice run time to the implementation of Ice objects.  
**ObjectFactory** — A factory for objects.  
**Plugin** — A communicator plug-in.  
**PluginManager** — Each communicator has a plug-in manager to administer the set of plug-ins.  
**Process** — An administrative interface for process management.  
**Properties** — A property set used to configure Ice and Ice applications.  
**PropertiesAdmin** — The PropertiesAdmin interface provides remote access to the properties of a communicator.  
**RemoteLogger** — The Ice remote logger interface.  
**Router** — The Ice router interface.  
**RouterFinder** — This interface should be implemented by services implementing the Ice::Router interface.  
**ServantLocator** — A servant locator is called by an object adapter to locate a servant that is not found in its active servant map.

## Exception Index

- AdapterAlreadyActiveException** — This exception is raised if a server tries to set endpoints for an adapter that is already active.
- AdapterNotFoundException** — This exception is raised if an adapter cannot be found.
- AlreadyRegisteredException** — An attempt was made to register something more than once with the Ice run time.
- BadMagicException** — This exception indicates that a message did not start with the expected magic number ('I', 'c', 'e', 'P').
- CloneNotImplementedException** — An attempt was made to clone a class that does not support cloning.
- CloseConnectionException** — This exception indicates that the connection has been gracefully shut down by the server.
- CloseTimeoutException** — This exception indicates a connection closure timeout condition.
- CollocationOptimizationException** — This exception is raised if a feature is requested that is not supported with collocation optimization. (*Deprecated*)
- CommunicatorDestroyedException** — This exception is raised if the [Communicator](#) has been destroyed.
- CompressionException** — This exception indicates a problem with compressing or uncompressing data.
- ConnectFailedException** — This exception indicates connection failures.
- ConnectTimeoutException** — This exception indicates a connection establishment timeout condition.
- ConnectionLostException** — This exception indicates a lost connection.
- ConnectionNotValidatedException** — This exception is raised if a message is received over a connection that is not yet validated.
- ConnectionRefusedException** — This exception indicates a connection failure for which the server host actively refuses a connection.
- ConnectionTimeoutException** — This exception indicates that a connection has been shut down because it has been idle for some time.
- DNSException** — This exception indicates a DNS problem.
- DatagramLimitException** — A datagram exceeds the configured size.
- EncapsulationException** — This exception indicates a malformed data encapsulation.
- EndpointParseException** — This exception is raised if there was an error while parsing an endpoint.
- EndpointSelectionTypeParseException** — This exception is raised if there was an error while parsing an endpoint selection type.
- FacetNotExistException** — This exception is raised if no facet with the given name exists, but at least one facet with the given identity exists.
- FeatureNotSupportedException** — This exception is raised if an unsupported feature is used.
- FileException** — This exception indicates file errors.
- FixedProxyException** — This exception indicates that an attempt has been made to change the connection properties of a fixed proxy.
- ForcedCloseConnectionException** — This exception is raised by an operation call if the application forcefully closes the connection `Connecton::close`.
- IdentityParseException** — This exception is raised if there was an error while parsing a stringified identity.
- IllegalIdentityException** — This exception is raised if an illegal identity is encountered.
- IllegalMessageSizeException** — This exception indicates that a message size is less than the minimum required size.
- IllegalServantException** — This exception is raised to reject an illegal servant (typically a null servant)
- InitializationException** — This exception is raised when a failure occurs during initialization.
- InvalidReplicaGroupIdException** — This exception is raised if the replica group provided by the server is invalid.
- InvocationCanceledException** — This exception indicates that an asynchronous invocation failed because it was canceled explicitly by the user using the `Ice::AsyncResult::cancel` method.
- InvocationTimeoutException** — This exception indicates that an invocation failed because it timed out.
- MarshalException** — This exception is raised for errors during marshaling or unmarshaling data.
- MemoryLimitException** — This exception is raised when Ice receives a request or reply message whose size exceeds the limit specified by the `Ice.MessageSizeMax` property.
- NoEndpointException** — This exception is raised if no suitable endpoint is available.
- NoObjectFactoryException** — This exception is raised if no suitable object factory was found during unmarshaling of a `Slice` class instance.
- NotRegisteredException** — An attempt was made to find or deregister something that is not registered with the Ice run time or Ice locator.
- ObjectAdapterDeactivatedException** — This exception is raised if an attempt is made to use a deactivated [ObjectAdapter](#).
- ObjectAdapterIdInUseException** — This exception is raised if an [ObjectAdapter](#) cannot be activated.
- ObjectNotExistException** — This exception is raised if an object does not exist on the server, that is, if no facets with the given identity exist.
- ObjectNotFoundException** — This exception is raised if an object cannot be found.
- OperationInterruptedException** — This exception indicates a request was interrupted.
- OperationNotExistException** — This exception is raised if an operation for a given object does not exist on the server.
- PluginInitializationException** — This exception indicates that a failure occurred while initializing a plug-in.
- ProtocolException** — A generic exception base for all kinds of protocol error conditions.
- ProxyParseException** — This exception is raised if there was an error while parsing a stringified proxy.
- ProxyUnmarshalException** — This exception is raised if inconsistent data is received while unmarshaling a proxy.
- RemoteLoggerAlreadyAttachedException** — An exception thrown by [LoggerAdmin::attachRemoteLogger](#) to report that the provided [RemoteLogger](#) was previously attached to this [LoggerAdmin](#).
- RequestFailedException** — This exception is raised if a request failed.
- ResponseSentException** — Indicates that the response to a request has already been sent; re-dispatching such a request is not possible.
- SecurityException** — This exception indicates a failure in a security subsystem, such as the IceSSL plug-in.
- ServerNotFoundException** — This exception is raised if a server cannot be found.
- SocketException** — This exception indicates socket errors.
- StringConversionException** — This exception is raised when a string conversion to or from UTF-8 fails during marshaling or unmarshaling.
- SyscallException** — This exception is raised if a system error occurred in the server or client process.
- TimeoutException** — This exception indicates a timeout condition.
- TwowayOnlyException** — The operation can only be invoked with a twoway request.
- UnexpectedObjectException** — This exception is raised if the type of an unmarshaled `Slice` class instance does not match its expected type.
- UnknownException** — This exception is raised if an operation call on a server raises an unknown exception.

[UnknownLocalException](#) — This exception is raised if an operation call on a server raises a local exception.

[UnknownMessageException](#) — This exception indicates that an unknown protocol message has been received.

[UnknownReplyStatusException](#) — This exception indicates that an unknown reply status has been received.

[UnknownRequestIdException](#) — This exception indicates that a response for an unknown request ID has been received.

[UnknownUserException](#) — An operation raised an incorrect user exception.

[UnmarshalOutOfBoundsException](#) — This exception is raised if an out-of-bounds condition occurs during unmarshaling.

[UnsupportedEncodingException](#) — This exception indicates an unsupported data encoding version.

[UnsupportedProtocolException](#) — This exception indicates an unsupported protocol version.

[VersionMismatchException](#) — This exception is raised if the Ice library version does not match the version in the Ice header files.

[VersionParseException](#) — This exception is raised if there was an error while parsing a version.

## Structure Index

### ACM

[Current](#) — Information about the current method invocation for servers.

[EncodingVersion](#) — A version structure for the encoding version.

[Identity](#) — The identity of an Ice object.

[LogMessage](#) — A complete log message.

[ProtocolVersion](#) — A version structure for the protocol version.

## Sequence Index

[BoolSeq](#) — A sequence of bools.

[ByteSeq](#) — A sequence of bytes.

[DoubleSeq](#) — A sequence of doubles.

[EndpointSeq](#) — A sequence of endpoints.

[FloatSeq](#) — A sequence of floats.

[IdentitySeq](#) — A sequence of identities.

[IntSeq](#) — A sequence of ints.

[LogMessageSeq](#) — A sequence of [LogMessage](#).

[LogMessageTypeSeq](#) — A sequence of [LogMessageType](#)

[LongSeq](#) — A sequence of longs.

[ObjectProxySeq](#) — A sequence of object proxies.

[ObjectSeq](#) — A sequence of objects.

[ShortSeq](#) — A sequence of shorts.

[StringSeq](#) — A sequence of strings.

## Dictionary Index

[Context](#) — A request context.

[FacetMap](#) — A mapping from facet name to servant.

[HeaderDict](#)

[ObjectDict](#) — A mapping between identities and Ice objects.

[PropertyDict](#) — A simple collection of properties, represented as a dictionary of key/value pairs.

[SliceChecksumDict](#) — A mapping from type IDs to Slice checksums.

## Constant Index

[SSLEndpointType](#) — Uniquely identifies SSL endpoints.

[TCPEndpointType](#) — Uniquely identifies TCP endpoints.

[UDPEndpointType](#) — Uniquely identifies UDP endpoints.

[WSEndpointType](#) — Uniquely identifies TCP-based WebSocket endpoints.

[WSSSEndpointType](#) — Uniquely identifies SSL-based WebSocket endpoints.

## Enumeration Index

[ACMClose](#)

[ACMHeartbeat](#)

[EndpointSelectionType](#) — Determines the order in which the Ice run time uses the endpoints in a proxy when establishing a connection.

[LogMessageType](#) — An enumeration representing the different types of log messages.

[OperationMode](#) — The [OperationMode](#) determines the retry behavior an invocation in case of a (potentially) recoverable error.

## Sequences

### sequence<bool> BoolSeq

A sequence of bools.

### sequence<byte> ByteSeq

A sequence of bytes.

#### Used By

- BadMagicException::badMagic
- IcePatch2::ByteSeqSeq
- IcePatch2::FileInfo::checksum
- IcePatch2::FileServer::getChecksum
- IcePatch2::FileServer::getFileCompressed
- IcePatch2::FileServer::getLargeFileCompressed
- IcePatch2::LargeFileInfo::checksum
- OpaqueEndpointInfo::rawBytes

### sequence<double> DoubleSeq

A sequence of doubles.

### local sequence<Endpoint> EndpointSeq

A sequence of endpoints.

#### Used By

- ObjectAdapter::getEndpoints
- ObjectAdapter::getPublishedEndpoints

### sequence<float> FloatSeq

A sequence of floats.

### sequence<Identity> IdentitySeq

A sequence of identities.

#### Used By

- Glacier2::IdentitySet::add
- Glacier2::IdentitySet::get
- Glacier2::IdentitySet::remove
- IceStorm::Topic::getSubscribers

### sequence<int> IntSeq

A sequence of ints.

### [ "cpp:type:std::list<LogMessage>" ] sequence<LogMessage> LogMessageSeq

A sequence of LogMessage.

**Used By**

- `LoggerAdmin::getLog`
- `RemoteLogger::init`

**sequence<LogMessageType> LogMessageTypeSeq**

A sequence of `LogMessageType`

**Used By**

- `LoggerAdmin::attachRemoteLogger`
- `LoggerAdmin::getLog`

**sequence<long> LongSeq**

A sequence of longs.

**sequence<Object\*> ObjectProxySeq**

A sequence of object proxies.

**Used By**

- `IceGrid::Query::findAllObjectsByType`
- `IceGrid::Query::findAllReplicas`
- `IceGrid::TypeFilter::filter`
- `Router::addProxies`

**sequence<Object> ObjectSeq**

A sequence of objects.

**sequence<short> ShortSeq**

A sequence of shorts.

**sequence<string> StringSeq**

A sequence of strings.

**Used By**

- `Glacier2::SSLInfo::certs`
- `Glacier2::StringSet::add`
- `Glacier2::StringSet::get`
- `Glacier2::StringSet::remove`
- `IceBox::Service::start`
- `IceBox::ServiceObserver::servicesStarted`
- `IceBox::ServiceObserver::servicesStopped`
- `IceGrid::Admin::getAllAdapterIds`
- `IceGrid::Admin::getAllApplicationNames`
- `IceGrid::Admin::getAllNodeNames`
- `IceGrid::Admin::getAllRegistryNames`
- `IceGrid::Admin::getAllServerIds`
- `IceGrid::ApplicationUpdateDescriptor::removeNodes`
- `IceGrid::ApplicationUpdateDescriptor::removePropertySets`
- `IceGrid::ApplicationUpdateDescriptor::removeReplicaGroups`

- IceGrid::ApplicationUpdateDescriptor::removeServerTemplates
- IceGrid::ApplicationUpdateDescriptor::removeServiceTemplates
- IceGrid::ApplicationUpdateDescriptor::removeVariables
- IceGrid::CommunicatorDescriptor::logs
- IceGrid::DistributionDescriptor::directories
- IceGrid::FileIterator::read
- IceGrid::NodeUpdateDescriptor::removePropertySets
- IceGrid::NodeUpdateDescriptor::removeServers
- IceGrid::NodeUpdateDescriptor::removeVariables
- IceGrid::PatchException::reasons
- IceGrid::PropertySetDescriptor::references
- IceGrid::ReplicaGroupFilter::filter
- IceGrid::ServerDescriptor::envs
- IceGrid::ServerDescriptor::options
- IceGrid::TemplateDescriptor::parameters
- IceMX::MetricsAdmin::getMetricsViewNames
- IceSSL::ConnectionInfo::certs
- LoggerAdmin::attachRemoteLogger
- LoggerAdmin::getLog
- PluginManager::getPlugins
- Properties::getCommandLineOptions
- Properties::getPropertyAsListWithDefault
- Properties::getPropertyAsList
- Properties::parseCommandLineOptions
- Properties::parseIceCommandLineOptions

## Dictionaries

### dictionary<string, string> Context

A request context. `Context` is used to transmit metadata about a request from the server to the client, such as Quality-of-Service (QoS) parameters. Each operation on the client has a `Context` as its implicit final parameter.

#### Used By

- Current::ctx
- IceGrid::ReplicaGroupFilter::filter
- IceGrid::TypeFilter::filter
- ImplicitContext::getContext
- ImplicitContext::setContext
- Instrumentation::CommunicatorObserver::getInvocationObserver

### local dictionary<string, Object> FacetMap

A mapping from facet name to servant.

#### Used By

- Communicator::findAllAdminFacets
- ObjectAdapter::findAllFacets
- ObjectAdapter::removeAllFacets

### dictionary<string, string> HeaderDict

#### Used By

- IceSSL::WSSConnectionInfo::headers
- WSSConnectionInfo::headers

### local dictionary<Identity, Object> ObjectDict

A mapping between identities and Ice objects.

### **dictionary<string, string> PropertyDict**

A simple collection of properties, represented as a dictionary of key/value pairs. Both key and value are strings.

#### **Used By**

- [Communicator::proxyToProperty](#)
- [Properties::getPropertiesForPrefix](#)
- [PropertiesAdmin::getPropertiesForPrefix](#)
- [PropertiesAdmin::setProperties](#)

#### **See Also**

- [Properties::getPropertiesForPrefix](#)

### **dictionary<string, string> SliceChecksumDict**

A mapping from type IDs to Slice checksums. The dictionary allows verification at run time that client and server use matching Slice definitions.

#### **Used By**

- [IceBox::ServiceManager::getSliceChecksums](#)
- [IceGrid::Admin::getSliceChecksums](#)
- [IceStorm::TopicManager::getSliceChecksums](#)

## **Constants**

**const short SSLEndpointType = 2;**

Uniquely identifies SSL endpoints.

**const short TCPEndpointType = 1;**

Uniquely identifies TCP endpoints.

**const short UDPEndpointType = 3;**

Uniquely identifies UDP endpoints.

**const short WSEndpointType = 4;**

Uniquely identifies TCP-based WebSocket endpoints.

**const short WSSSLEndpointType = 5;**

Uniquely identifies SSL-based WebSocket endpoints.

## Ice-AdapterAlreadyActiveException

---

### Ice::AdapterAlreadyActiveException

#### Overview

#### exception AdapterAlreadyActiveException

This exception is raised if a server tries to set endpoints for an adapter that is already active.

#### *Used By*

- `Ice::LocatorRegistry::setAdapterDirectProxy`
  - `Ice::LocatorRegistry::setReplicatedAdapterDirectProxy`
-

## Ice-AdapterNotFoundException

---

### Ice::AdapterNotFoundException

#### Overview

#### exception AdapterNotFoundException

This exception is raised if an adapter cannot be found.

#### *Used By*

- Ice::Locator::findAdapterById
  - Ice::LocatorRegistry::setAdapterDirectProxy
  - Ice::LocatorRegistry::setReplicatedAdapterDirectProxy
-

## Ice-AlreadyRegisteredException

---

### Ice::AlreadyRegisteredException

#### Overview

#### local exception AlreadyRegisteredException

An attempt was made to register something more than once with the Ice run time. This exception is raised if an attempt is made to register a servant, servant locator, facet, object factory, plug-in, object adapter, object, or user exception factory more than once for the same ID.

#### Data Member Index

**kindOfObject** — The kind of object that is registered already: "servant", "servant locator", "object factory", "plug-in", "object adapter", "object", or "user exception factory".

**id** — The ID (or name) of the object that is registered already.

#### Data Members

**string kindOfObject;**

The kind of object that is registered already: "servant", "servant locator", "object factory", "plug-in", "object adapter", "object", or "user exception factory".

**string id;**

The ID (or name) of the object that is registered already.

---

## Ice-BadMagicException

---

### Ice::BadMagicException

#### Overview

local exception `BadMagicException` extends `Ice::ProtocolException`

This exception indicates that a message did not start with the expected magic number ('I', 'c', 'e', 'P').

#### Data Member Index

`badMagic` — A sequence containing the first four bytes of the incorrect message.

#### Data Members

`Ice::ByteSeq badMagic;`

A sequence containing the first four bytes of the incorrect message.

---

## Ice-CloneNotImplementedException

---

### Ice::CloneNotImplementedException

#### Overview

#### local exception CloneNotImplementedException

An attempt was made to clone a class that does not support cloning. This exception is raised if `ice_clone` is called on a class that is derived from an abstract Slice class (that is, a class containing operations), and the derived class does not provide an implementation of the `ice_clone` operation (C++ only).

---

## Ice-CloseConnectionException

---

### Ice::CloseConnectionException

#### Overview

local exception `CloseConnectionException` extends `Ice::ProtocolException`

This exception indicates that the connection has been gracefully shut down by the server. The operation call that caused this exception has not been executed by the server. In most cases you will not get this exception, because the client will automatically retry the operation call in case the server shut down the connection. However, if upon retry the server shuts down the connection again, and the retry limit has been reached, then this exception is propagated to the application code.

---

## Ice-CloseTimeoutException

---

### Ice::CloseTimeoutException

#### Overview

local exception `CloseTimeoutException` extends `Ice::TimeoutException`

This exception indicates a connection closure timeout condition.

---

## Ice-CollocationOptimizationException

---

### Ice::CollocationOptimizationException

#### Overview

#### local exception CollocationOptimizationException

This exception is raised if a feature is requested that is not supported with collocation optimization.

*this exception isn't used anymore by the Ice runtime*

---

# Ice-Communicator

---

## Ice::Communicator

### Overview

[ "clr:implements:\_System.IDisposable" ] local interface **Communicator**

The central object in Ice. One or more communicators can be instantiated for an Ice application. Communicator instantiation is language-specific, and not specified in Slice code.

#### Used By

- [Freeze::Connection::getCommunicator](#)
- [Ice::ObjectAdapter::getCommunicator](#)
- [IceBox::Service::start](#)

#### See Also

- [Ice::Logger](#)
- [Ice::ObjectAdapter](#)
- [Ice::Properties](#)
- [Ice::ObjectFactory](#)

### Operation Index

[destroy](#) — Destroy the communicator.

[shutdown](#) — Shuts down this communicator's server functionality, which includes the deactivation of all object adapters.

[waitForShutdown](#) — Wait until the application has called [shutdown](#) (or [destroy](#)).

[isShutdown](#) — Check whether communicator has been shut down.

[stringToProxy](#) — Convert a stringified proxy into a proxy.

[proxyToString](#) — Convert a proxy into a string.

[propertyToProxy](#) — Convert a set of proxy properties into a proxy.

[proxyToProperty](#) — Convert a proxy to a set of proxy properties.

[stringToIdentity](#) — Convert a string into an identity.

[identityToString](#) — Convert an identity into a string.

[createObjectAdapter](#) — Create a new object adapter.

[createObjectAdapterWithEndpoints](#) — Create a new object adapter with endpoints.

[createObjectAdapterWithRouter](#) — Create a new object adapter with a router.

[addObjectFactory](#) — Add an object factory to this communicator.

[findObjectFactory](#) — Find an object factory registered with this communicator.

[getImplicitContext](#) — Get the implicit context associated with this communicator.

[getProperties](#) — Get the properties for this communicator.

[getLogger](#) — Get the logger for this communicator.

[getObserver](#) — Get the observer resolver object for this communicator.

[getDefaultRouter](#) — Get the default router this communicator.

[setDefaultRouter](#) — Set a default router for this communicator.

[getDefaultLocator](#) — Get the default locator this communicator.

[setDefaultLocator](#) — Set a default Ice locator for this communicator.

[getPluginManager](#) — Get the plug-in manager for this communicator.

[flushBatchRequests](#) — Flush any pending batch requests for this communicator.

[createAdmin](#) — Add the Admin object with all its facets to the provided object adapter.

[getAdmin](#) — Get a proxy to the main facet of the Admin object.

[addAdminFacet](#) — Add a new facet to the Admin object.

[removeAdminFacet](#) — Remove the following facet to the Admin object.

[findAdminFacet](#) — Returns a facet of the Admin object.

[findAllAdminFacets](#) — Returns a map of all facets of the Admin object.

### Operations

**void destroy()**

Destroy the communicator. This operation calls [shutdown](#) implicitly. Calling [destroy](#) cleans up memory, and shuts down this communicator's client functionality and destroys all object adapters. Subsequent calls to [destroy](#) are ignored.

**See Also**

- [shutdown](#)
- [Ice::ObjectAdapter::destroy](#)

**void shutdown()**

Shuts down this communicator's server functionality, which includes the deactivation of all object adapters. (Attempts to use a deactivated object adapter raise [Ice::ObjectAdapterDeactivatedException](#).) Subsequent calls to [shutdown](#) are ignored.

*After [shutdown](#) returns, no new requests are processed. However, requests that have been started before [shutdown](#) was called might still be active. You can use [waitForShutdown](#) to wait for the completion of all requests.*

**See Also**

- [destroy](#)
- [waitForShutdown](#)
- [Ice::ObjectAdapter::deactivate](#)

**void waitForShutdown()**

Wait until the application has called [shutdown](#) (or [destroy](#)). On the server side, this operation blocks the calling thread until all currently-executing operations have completed. On the client side, the operation simply block until another thread has called [shutdown](#) or [destroy](#).

A typical use of this operation is to call it from the main thread, which then waits until some other thread calls [shutdown](#). After shut-down is complete, the main thread returns and can do some cleanup work before it finally calls [destroy](#) to shut down the client functionality, and then exits the application.

**See Also**

- [shutdown](#)
- [destroy](#)
- [Ice::ObjectAdapter::waitForDeactivate](#)

**bool isShutdown()**

Check whether communicator has been shut down.

**Return Value**

True if the communicator has been shut down; false otherwise.

**See Also**

- [shutdown](#)

**Object\* stringToProxy(string str)**

Convert a stringified proxy into a proxy. For example, `MyCategory/MyObject:tcp -h some_host -p 10000` creates a proxy that refers to the Ice object having an identity with a name "MyObject" and a category "MyCategory", with the server running on host "some\_host", port 10000. If the stringified proxy does not parse correctly, the operation throws one of [Ice::ProxyParseException](#), [Ice::EndpointParseException](#), or [Ice::IdentityParseException](#). An appendix in the Ice manual provides a detailed description of the syntax supported by stringified proxies.

**Parameters**

`str` — The stringified proxy to convert into a proxy.

**Return Value**

The proxy, or nil if `str` is an empty string.

**See Also**

- [proxyToString](#)

**string proxyToString(Object\* obj)**

Convert a proxy into a string.

**Parameters**

`obj` — The proxy to convert into a stringified proxy.

**Return Value**

The stringified proxy, or an empty string if `obj` is nil.

**See Also**

- [stringToProxy](#)

**Object\* propertyToProxy(string property)**

Convert a set of proxy properties into a proxy. The "base" name supplied in the `property` argument refers to a property containing a stringified proxy, such as `MyProxy=id:tcp -h localhost -p 10000`. Additional properties configure local settings for the proxy, such as `MyProxy.PreferSecure=1`. The "Properties" appendix in the Ice manual describes each of the supported proxy properties.

**Parameters**

`property` — The base property name.

**Return Value**

The proxy.

**Ice::PropertyDict proxyToProperty(Object\* proxy, string property)**

Convert a proxy to a set of proxy properties.

**Parameters**

`proxy` — The proxy.

`property` — The base property name.

**Return Value**

The property set.

**Ice::Identity stringToIdentity(string str)**

Convert a string into an identity. If the string does not parse correctly, the operation throws `Ice::IdentityParseException`.

**Parameters**

`str` — The string to convert into an identity.

**Return Value**

The identity.

**See Also**

- [identityToString](#)

**string identityToString(Ice::Identity ident)**

Convert an identity into a string.

**Parameters**

`ident` — The identity to convert into a string.

**Return Value**

The "stringified" identity.

**See Also**

- [stringToIdentity](#)

**Ice::ObjectAdapter createObjectAdapter(string name)**

Create a new object adapter. The endpoints for the object adapter are taken from the property `name.Endpoints`.

It is legal to create an object adapter with the empty string as its name. Such an object adapter is accessible via bidirectional connections or by collocated invocations that originate from the same communicator as is used by the adapter.

Attempts to create a named object adapter for which no configuration can be found raise `Ice::InitializationException`.

**Parameters**

`name` — The object adapter name.

**Return Value**

The new object adapter.

**See Also**

- [createObjectAdapterWithEndpoints](#)
- [Ice::ObjectAdapter](#)
- [Ice::Properties](#)

**Ice::ObjectAdapter createObjectAdapterWithEndpoints(string name, string endpoints)**

Create a new object adapter with endpoints. This operation sets the property `name.Endpoints`, and then calls [createObjectAdapter](#). It is provided as a convenience function.

Calling this operation with an empty name will result in a UUID being generated for the name.

**Parameters**

`name` — The object adapter name.

`endpoints` — The endpoints for the object adapter.

**Return Value**

The new object adapter.

**See Also**

- [createObjectAdapter](#)
- [Ice::ObjectAdapter](#)
- [Ice::Properties](#)

### **Ice::ObjectAdapter** createObjectAdapterWithRouter(string name, **Ice::Router**\* rtr)

Create a new object adapter with a router. This operation creates a routed object adapter.

Calling this operation with an empty name will result in a UUID being generated for the name.

#### *Parameters*

`name` — The object adapter name.

`rtr` — The router.

#### *Return Value*

The new object adapter.

#### *See Also*

- [createObjectAdapter](#)
- [Ice::ObjectAdapter](#)
- [Ice::Properties](#)

### **void** addObjectFactory(**Ice::ObjectFactory** factory, string id)

Add an object factory to this communicator. Installing a factory with an id for which a factory is already registered throws [Ice::AlreadyRegisteredException](#).

When unmarshaling an Ice object, the Ice run time reads the most-derived type id off the wire and attempts to create an instance of the type using a factory. If no instance is created, either because no factory was found, or because all factories returned nil, the behavior of the Ice run time depends on the format with which the object was marshaled:

If the object uses the "sliced" format, Ice ascends the class hierarchy until it finds a type that is recognized by a factory, or it reaches the least-derived type. If no factory is found that can create an instance, the run time throws [Ice::NoObjectFactoryException](#).

If the object uses the "compact" format, Ice immediately raises [Ice::NoObjectFactoryException](#).

The following order is used to locate a factory for a type:

1. The Ice run-time looks for a factory registered specifically for the type.
2. If no instance has been created, the Ice run-time looks for the default factory, which is registered with an empty type id.
3. If no instance has been created by any of the preceding steps, the Ice run-time looks for a factory that may have been statically generated by the language mapping for non-abstract classes.

#### *Parameters*

`factory` — The factory to add.

`id` — The type id for which the factory can create instances, or an empty string for the default factory.

#### *See Also*

- [findObjectFactory](#)
- [Ice::ObjectFactory](#)

### **Ice::ObjectFactory** findObjectFactory(string id)

Find an object factory registered with this communicator.

#### *Parameters*

`id` — The type id for which the factory can create instances, or an empty string for the default factory.

**Return Value**

The object factory, or null if no object factory was found for the given id.

**See Also**

- [addObjectFactory](#)
- [Ice::ObjectFactory](#)

**Ice::ImplicitContext getImplicitContext()**

Get the implicit context associated with this communicator.

**Return Value**

The implicit context associated with this communicator; returns null when the property Ice.ImplicitContext is not set or is set to None.

**Ice::Properties getProperties()**

Get the properties for this communicator.

**Return Value**

This communicator's properties.

**See Also**

- [Ice::Properties](#)

**Ice::Logger getLogger()**

Get the logger for this communicator.

**Return Value**

This communicator's logger.

**See Also**

- [Ice::Logger](#)

**Ice::Instrumentation::CommunicatorObserver getObserver()**

Get the observer resolver object for this communicator.

**Return Value**

This communicator's observer resolver object.

**Ice::Router\* getDefaultRouter()**

Get the default router this communicator.

**Return Value**

The default router for this communicator.

**See Also**

- [setDefaultRouter](#)
- [Ice::Router](#)

**void setDefaultRouter(Ice::Router\* rtr)**

Set a default router for this communicator. All newly created proxies will use this default router. To disable the default router, null can be used. Note that this operation has no effect on existing proxies.

*You can also set a router for an individual proxy by calling the operation `ice_router` on the proxy.*

**Parameters**

`rtr` — The default router to use for this communicator.

**See Also**

- [getDefaultRouter](#)
- [createObjectAdapterWithRouter](#)
- [Ice::Router](#)

**Ice::Locator\* getDefaultLocator()**

Get the default locator this communicator.

**Return Value**

The default locator for this communicator.

**See Also**

- [setDefaultLocator](#)
- [Ice::Locator](#)

**void setDefaultLocator(Ice::Locator\* loc)**

Set a default Ice locator for this communicator. All newly created proxy and object adapters will use this default locator. To disable the default locator, null can be used. Note that this operation has no effect on existing proxies or object adapters.

*You can also set a locator for an individual proxy by calling the operation `ice_locator` on the proxy, or for an object adapter by calling the operation `Ice::ObjectAdapter::setLocator` on the object adapter.*

**Parameters**

`loc` — The default locator to use for this communicator.

**See Also**

- [getDefaultLocator](#)
- [Ice::Locator](#)
- [Ice::ObjectAdapter::setLocator](#)

**Ice::PluginManager getPluginManager()**

Get the plug-in manager for this communicator.

**Return Value**

This communicator's plug-in manager.

**See Also**

- [Ice::PluginManager](#)

**[ "async" ] void flushBatchRequests()**

Flush any pending batch requests for this communicator. This means all batch requests invoked on fixed proxies for all connections associated with the communicator. Any errors that occur while flushing a connection are ignored.

### Object\* createAdmin(Ice::ObjectAdapter adminAdapter, Ice::Identity adminId)

Add the Admin object with all its facets to the provided object adapter. If Ice.Admin.ServerId is set and the provided object adapter has a Ice::Locator, createAdmin registers the Admin's Process facet with the Ice::Locator's Ice::LocatorRegistry.

createAdmin call only be called once; subsequent calls raise Ice::InitializationException.

#### Parameters

adminAdapter — The object adapter used to host the Admin object; if null and Ice.Admin.Endpoints is set, create, activate and use the Ice.Admin object adapter.

adminId — The identity of the Admin object.

#### Return Value

A proxy to the main ("") facet of the Admin object. Never returns a null proxy.

#### See Also

- [getAdmin](#)
- [Ice::LocatorRegistry::setServerProcessProxy](#)

### Object\* getAdmin()

Get a proxy to the main facet of the Admin object. getAdmin also creates the Admin object and creates and activates the Ice.Admin object adapter to host this Admin object if Ice.Admin.Endpoints is set. The identity of the Admin object created by getAdmin is **UNRECOGNIZED MARKUP: value/admin**, or **UNRECOGNIZED MARKUP: UUID/admin** when Ice.Admin.InstanceName is not set.

If Ice.Admin.DelayCreation is 0 or not set, getAdmin is called by the communicator initialization, after initialization of all plugins.

#### Return Value

A proxy to the main ("") facet of the Admin object, or a null proxy if no Admin object is configured.

#### See Also

- [createAdmin](#)

### void addAdminFacet(Object servant, string facet)

Add a new facet to the Admin object. Adding a servant with a facet that is already registered throws Ice::AlreadyRegisteredException.

#### Parameters

servant — The servant that implements the new Admin facet.

facet — The name of the new Admin facet.

### Object removeAdminFacet(string facet)

Remove the following facet to the Admin object. Removing a facet that was not previously registered throws Ice::NotRegisteredException.

#### Parameters

facet — The name of the Admin facet.

#### Return Value

The servant associated with this Admin facet.

### Object `findAdminFacet(string facet)`

Returns a facet of the Admin object.

#### *Parameters*

`facet` — The name of the Admin facet.

#### *Return Value*

The servant associated with this Admin facet, or null if no facet is registered with the given name.

### **Ice::FacetMap** `findAllAdminFacets()`

Returns a map of all facets of the Admin object.

#### *Return Value*

A collection containing all the facet names and servants of the Admin object.

#### *See Also*

- [findAdminFacet](#)
-

## Ice-CommunicatorDestroyedException

---

### Ice::CommunicatorDestroyedException

#### Overview

#### local exception `CommunicatorDestroyedException`

This exception is raised if the [Ice::Communicator](#) has been destroyed.

#### See Also

- [Ice::Communicator::destroy](#)
-

## Ice-CompressionException

---

### Ice::CompressionException

#### Overview

local exception `CompressionException` extends `Ice::ProtocolException`

This exception indicates a problem with compressing or uncompressing data.

---

## Ice-ConnectFailedException

---

### Ice::ConnectFailedException

#### Overview

local exception `ConnectFailedException` extends `Ice::SocketException`

This exception indicates connection failures.

#### *Derived Exceptions*

- `Ice::ConnectionRefusedException`
-

## Ice-Connection

---

### Ice::Connection

#### Overview

#### local interface Connection

The user-level interface to a connection.

#### Used By

- [Ice::ConnectionCallback::closed](#)
- [Ice::ConnectionCallback::heartbeat](#)
- [Ice::Current::con](#)
- [IceGrid::ReplicaGroupFilter::filter](#)
- [IceGrid::TypeFilter::filter](#)

#### Operation Index

[close](#) — Close a connection, either gracefully or forcefully.

[createProxy](#) — Create a special proxy that always uses this connection.

[setAdapter](#) — Explicitly set an object adapter that dispatches requests that are received over this connection.

[getAdapter](#) — Get the object adapter that dispatches requests for this connection.

[getEndpoint](#) — Get the endpoint from which the connection was created.

[flushBatchRequests](#) — Flush any pending batch requests for this connection.

[setCallback](#) — Set callback on the connection.

[setACM](#) — Set the active connection management parameters.

[getACM](#) — Get the ACM parameters.

[type](#) — Return the connection type.

[timeout](#) — Get the timeout for the connection.

[toString](#) — Return a description of the connection as human readable text, suitable for logging or error messages.

[getInfo](#) — Returns the connection information.

[setBufferSize](#) — Set the connection buffer receive/send size.

#### Operations

##### void close(bool force)

Close a connection, either gracefully or forcefully. If a connection is closed forcefully, it closes immediately, without sending the relevant close connection protocol messages to the peer and waiting for the peer to acknowledge these protocol messages.

#### Parameters

`force` — If true, close forcefully. Otherwise the connection is closed gracefully.

##### Object\* createProxy(Ice::Identity id)

Create a special proxy that always uses this connection. This can be used for callbacks from a server to a client if the server cannot directly establish a connection to the client, for example because of firewalls. In this case, the server would create a proxy using an already established connection from the client.

#### Parameters

`id` — The identity for which a proxy is to be created.

#### Return Value

A proxy that matches the given identity and uses this connection.

**See Also**

- [setAdapter](#)

**void setAdapter(Ice::ObjectAdapter adapter)**

Explicitly set an object adapter that dispatches requests that are received over this connection. A client can invoke an operation on a server using a proxy, and then set an object adapter for the outgoing connection that is used by the proxy in order to receive callbacks. This is useful if the server cannot establish a connection back to the client, for example because of firewalls.

**Parameters**

`adapter` — The object adapter that should be used by this connection to dispatch requests. The object adapter must be activated. When the object adapter is deactivated, it is automatically removed from the connection.

**See Also**

- [createProxy](#)
- [setAdapter](#)

**Ice::ObjectAdapter getAdapter()**

Get the object adapter that dispatches requests for this connection.

**Return Value**

The object adapter that dispatches requests for the connection, or null if no adapter is set.

**See Also**

- [setAdapter](#)

**Ice::Endpoint getEndpoint()**

Get the endpoint from which the connection was created.

**Return Value**

The endpoint from which the connection was created.

**[ "async" ] void flushBatchRequests()**

Flush any pending batch requests for this connection. This means all batch requests invoked on fixed proxies associated with the connection.

**void setCallback(Ice::ConnectionCallback callback)**

Set callback on the connection. The callback is called by the connection when it's closed. The callback is called from the Ice thread pool associated with the connection.

**Parameters**

`callback` — The connection callback object.

**[ "java:optional" ] void setACM(int timeout, Ice::ACMClose close, Ice::ACMHeartbeat heartbeat)**

Set the active connection management parameters.

**Parameters**

`timeout` — The timeout value in milliseconds.  
`close` — The close condition  
`heartbeat` — The heartbeat condition

**Ice::ACM getACM()**

Get the ACM parameters.

**Return Value**

The ACM parameters.

**string type()**

Return the connection type. This corresponds to the endpoint type, i.e., "tcp", "udp", etc.

**Return Value**

The type of the connection.

**int timeout()**

Get the timeout for the connection.

**Return Value**

The connection's timeout.

**string toString()**

Return a description of the connection as human readable text, suitable for logging or error messages.

**Return Value**

The description of the connection as human readable text.

**Ice::ConnectionInfo getInfo()**

Returns the connection information.

**Return Value**

The connection information.

**void setBufferSize(int rcvSize, int sndSize)**

Set the connection buffer receive/send size.

**Parameters**

`rcvSize` — The connection receive buffer size.  
`sndSize` — The connection send buffer size.

## Ice-ConnectionCallback

---

### Ice::ConnectionCallback

#### Overview

#### local interface ConnectionCallback

An application can implement this interface to receive notifications when a connection closes or receives a heartbeat message.

#### Used By

- [Ice::Connection::setCallback](#)

#### See Also

- [Ice::Connection::setCallback](#)

#### Operation Index

[heartbeat](#) — This method is called by the the connection when a heartbeat is received from the peer.

[closed](#) — This method is called by the the connection when the connection is closed.

#### Operations

##### `void heartbeat(Ice::Connection con)`

This method is called by the the connection when a heartbeat is received from the peer.

##### `void closed(Ice::Connection con)`

This method is called by the the connection when the connection is closed.

---

## Ice-ConnectionInfo

---

### Ice::ConnectionInfo

#### Overview

#### local class ConnectionInfo

Base class providing access to the connection details. \*

#### Derived Classes and Interfaces

- Ice::IPConnectionInfo

#### Used By

- Ice::Connection::getInfo
- Ice::Instrumentation::CommunicatorObserver::getConnectionObserver
- Ice::Instrumentation::InvocationObserver::getRemoteObserver

#### Data Member Index

[incoming](#) — Whether or not the connection is an incoming or outgoing connection.  
[adapterName](#) — The name of the adapter associated with the connection.  
[connectionId](#) — The connection id.  
[rcvSize](#) — The connection buffer receive size.  
[sndSize](#) — The connection buffer send size.

#### Data Members

##### **bool incoming;**

Whether or not the connection is an incoming or outgoing connection.

##### **string adapterName;**

The name of the adapter associated with the connection.

##### **string connectionId;**

The connection id.

##### **int rcvSize;**

The connection buffer receive size.

##### **int sndSize;**

The connection buffer send size.

---

## Ice-ConnectionLostException

---

### Ice::ConnectionLostException

#### Overview

local exception `ConnectionLostException` extends `Ice::SocketException`

This exception indicates a lost connection.

---

## Ice-ConnectionNotValidatedException

---

### Ice::ConnectionNotValidatedException

#### Overview

local exception `ConnectionNotValidatedException` extends `Ice::ProtocolException`

This exception is raised if a message is received over a connection that is not yet validated.

---

## Ice-ConnectionRefusedException

---

### Ice::ConnectionRefusedException

#### Overview

local exception `ConnectionRefusedException` extends `Ice::ConnectFailedException`

This exception indicates a connection failure for which the server host actively refuses a connection.

---

## Ice-ConnectionTimeoutException

---

### Ice::ConnectionTimeoutException

#### Overview

local exception `ConnectionTimeoutException` extends `Ice::TimeoutException`

This exception indicates that a connection has been shut down because it has been idle for some time.

---

## Ice-ConnectTimeoutException

---

### Ice::ConnectTimeoutException

#### Overview

local exception `ConnectTimeoutException` extends `Ice::TimeoutException`

This exception indicates a connection establishment timeout condition.

---

## Ice-Current

---

### Ice::Current

#### Overview

#### local struct Current

Information about the current method invocation for servers. Each operation on the server has a `Current` as its implicit final parameter. `Current` is mostly used for Ice services. Most applications ignore this parameter.

#### Used By

- `Ice::Instrumentation::CommunicatorObserver::getDispatchObserver`
- `Ice::ServantLocator::finished`
- `Ice::ServantLocator::locate`

#### Data Member Index

`adapter` — The object adapter.

`con` — Information about the connection over which the current method invocation was received.

`id` — The Ice object identity.

`facet` — The facet.

`operation` — The operation name.

`mode` — The mode of the operation.

`ctx` — The request context, as received from the client.

`requestId` — The request id unless oneway (0) or collocated (-1).

`encoding` — The encoding version used to encode the input and output parameters.

#### Data Members

##### **Ice::ObjectAdapter** adapter;

The object adapter.

##### **Ice::Connection** con;

Information about the connection over which the current method invocation was received. If the invocation is direct due to collocation optimization, this value is set to null.

##### **Ice::Identity** id;

The Ice object identity.

##### **string** facet;

The facet.

##### **string** operation;

The operation name.

##### **Ice::OperationMode** mode;

The mode of the operation.

**Ice::Context** *ctx*;

The request context, as received from the client.

**int** *requestId*;

The request id unless oneway (0) or collocated (-1).

**Ice::EncodingVersion** *encoding*;

The encoding version used to encode the input and output parameters.

---

## Ice-DatagramLimitException

---

### Ice::DatagramLimitException

#### Overview

local exception `DatagramLimitException` extends `Ice::ProtocolException`

A datagram exceeds the configured size. This exception is raised if a datagram exceeds the configured send or receive buffer size, or exceeds the maximum payload size of a UDP packet (65507 bytes).

---

## Ice-DNSException

---

### Ice::DNSException

#### Overview

#### local exception DNSException

This exception indicates a DNS problem. For details on the cause, [error](#) should be inspected.

#### Data Member Index

[error](#) — The error number describing the DNS problem.

[host](#) — The host name that could not be resolved.

#### Data Members

**int error;**

The error number describing the DNS problem. For C++ and Unix, this is equivalent to `h_errno`. For C++ and Windows, this is the value returned by `WSAGetLastError()`.

**string host;**

The host name that could not be resolved.

---

## Ice-EncapsulationException

---

### Ice::EncapsulationException

#### Overview

local exception EncapsulationException extends [Ice::MarshalException](#)

This exception indicates a malformed data encapsulation.

---

## Ice-EncodingVersion

---

### Ice::EncodingVersion

#### Overview

#### struct EncodingVersion

A version structure for the encoding version.

#### *Used By*

- Freeze::Connection::getEncoding
- Ice::Current::encoding
- Ice::OpaqueEndpointInfo::rawEncoding
- Ice::UnsupportedEncodingException::bad
- Ice::UnsupportedEncodingException::supported

#### Data Member Index

major  
minor

#### Data Members

byte major;

byte minor;

---

# Ice-Endpoint

---

## Ice::Endpoint

### Overview

#### local interface Endpoint

The user-level interface to an endpoint.

#### *Used By*

- `Ice::Connection::getEndpoint`
- `Ice::EndpointSeq`
- `Ice::Instrumentation::CommunicatorObserver::getConnectionEstablishmentObserver`
- `Ice::Instrumentation::CommunicatorObserver::getConnectionObserver`
- `Ice::Instrumentation::CommunicatorObserver::getEndpointLookupObserver`
- `Ice::Instrumentation::InvocationObserver::getRemoteObserver`

### Operation Index

`toString` — Return a string representation of the endpoint.

`getInfo` — Returns the endpoint information.

### Operations

#### string `toString()`

Return a string representation of the endpoint.

#### *Return Value*

The string representation of the endpoint.

#### `Ice::EndpointInfo` `getInfo()`

Returns the endpoint information.

#### *Return Value*

The endpoint information class.

---

## Ice-EndpointInfo

---

### Ice::EndpointInfo

#### Overview

#### local class EndpointInfo

Base class providing access to the endpoint details.

#### Derived Classes and Interfaces

- [Ice::IPEndpointInfo](#)
- [Ice::OpaqueEndpointInfo](#)

#### Used By

- [Ice::Endpoint::getInfo](#)

#### Operation Index

[type](#) — Returns the type of the endpoint.

[datagram](#) — Returns true if this endpoint is a datagram endpoint.

[secure](#) — Returns true if this endpoint is a secure endpoint.

#### Data Member Index

[timeout](#) — The timeout for the endpoint in milliseconds.

[compress](#) — Specifies whether or not compression should be used if available when using this endpoint.

#### Operations

##### short type()

Returns the type of the endpoint.

##### bool datagram()

Returns true if this endpoint is a datagram endpoint.

##### bool secure()

Returns true if this endpoint is a secure endpoint.

#### Data Members

##### int timeout;

The timeout for the endpoint in milliseconds. 0 means non-blocking, -1 means no timeout.

##### bool compress;

Specifies whether or not compression should be used if available when using this endpoint.

## Ice-EndpointParseException

---

### Ice::EndpointParseException

#### Overview

#### local exception EndpointParseException

This exception is raised if there was an error while parsing an endpoint.

#### Data Member Index

[str](#) — Describes the failure and includes the string that could not be parsed.

#### Data Members

**string str;**

Describes the failure and includes the string that could not be parsed.

---

## Ice-EndpointSelectionType

---

### Ice::EndpointSelectionType

#### Overview

#### enum EndpointSelectionType

Determines the order in which the Ice run time uses the endpoints in a proxy when establishing a connection.

#### Enumerator Index

[Random](#) — `Random` causes the endpoints to be arranged in a random order.

[Ordered](#) — `Ordered` forces the Ice run time to use the endpoints in the order they appeared in the proxy.

#### Enumerators

##### Random

`Random` causes the endpoints to be arranged in a random order.

##### Ordered

`Ordered` forces the Ice run time to use the endpoints in the order they appeared in the proxy.

---

## Ice-EndpointSelectionTypeParseException

---

### Ice::EndpointSelectionTypeParseException

#### Overview

#### local exception EndpointSelectionTypeParseException

This exception is raised if there was an error while parsing an endpoint selection type.

#### Data Member Index

[str](#) — Describes the failure and includes the string that could not be parsed.

#### Data Members

**string str;**

Describes the failure and includes the string that could not be parsed.

---

## Ice-FacetNotExistException

---

### Ice::FacetNotExistException

#### Overview

local exception `FacetNotExistException` extends [Ice::RequestFailedException](#)

This exception is raised if no facet with the given name exists, but at least one facet with the given identity exists.

---

## Ice-FeatureNotSupportedException

---

### Ice::FeatureNotSupportedException

#### Overview

#### local exception `FeatureNotSupportedException`

This exception is raised if an unsupported feature is used. The unsupported feature string contains the name of the unsupported feature

#### Data Member Index

`unsupportedFeature` — The name of the unsupported feature.

#### Data Members

`string unsupportedFeature;`

The name of the unsupported feature.

---

## Ice-FileException

---

### Ice::FileException

#### Overview

local exception FileException extends **Ice::SyscallException**

This exception indicates file errors.

#### Data Member Index

[path](#) — The path of the file responsible for the error.

#### Data Members

**string path;**

The path of the file responsible for the error.

---

## Ice-FixedProxyException

---

### Ice::FixedProxyException

#### Overview

local exception `FixedProxyException`

This exception indicates that an attempt has been made to change the connection properties of a fixed proxy.

---

## Ice-ForcedCloseConnectionException

---

### Ice::ForcedCloseConnectionException

#### Overview

local exception `ForcedCloseConnectionException` extends [Ice::ProtocolException](#)

This exception is raised by an operation call if the application forcefully closes the connection [Ice::Connection::close](#).

#### See Also

- [Ice::Connection::close](#)
-

## Ice-Identity

---

### Ice::Identity

#### Overview

#### struct Identity

The identity of an Ice object. In a proxy, an empty `name` denotes a nil proxy. An identity with an empty `name` and a non-empty `category` is illegal. You cannot add a servant with an empty name to the Active Servant Map.

#### Used By

- Freeze::BackgroundSaveEvictor::keepFacet
- Freeze::BackgroundSaveEvictor::keep
- Freeze::BackgroundSaveEvictor::releaseFacet
- Freeze::BackgroundSaveEvictor::release
- Freeze::Evictor::addFacet
- Freeze::Evictor::add
- Freeze::Evictor::hasFacet
- Freeze::Evictor::hasObject
- Freeze::Evictor::removeFacet
- Freeze::Evictor::remove
- Freeze::EvictorIterator::next
- Freeze::ServantInitializer::initialize
- Ice::Communicator::createAdmin
- Ice::Communicator::identityToString
- Ice::Communicator::stringToIdentity
- Ice::Connection::createProxy
- Ice::Current::id
- Ice::IdentitySeq
- Ice::IllegalIdentityException::id
- Ice::Locator::findObjectById
- Ice::ObjectAdapter::addFacet
- Ice::ObjectAdapter::add
- Ice::ObjectAdapter::createDirectProxy
- Ice::ObjectAdapter::createIndirectProxy
- Ice::ObjectAdapter::createProxy
- Ice::ObjectAdapter::findAllFacets
- Ice::ObjectAdapter::findFacet
- Ice::ObjectAdapter::find
- Ice::ObjectAdapter::removeAllFacets
- Ice::ObjectAdapter::removeFacet
- Ice::ObjectAdapter::remove
- Ice::ObjectDict
- Ice::RequestFailedException::id
- IceGrid::Admin::getObjectInfo
- IceGrid::Admin::removeObject
- IceGrid::AdminSession::setObserversByIdentity
- IceGrid::ObjectDescriptor::id
- IceGrid::ObjectExistsException::id
- IceGrid::ObjectNotRegisteredException::id
- IceGrid::ObjectObserver::objectRemoved
- IceGrid::ObserverAlreadyRegisteredException::id
- IceGrid::Query::findObjectById
- IceGrid::RegistryPluginFacade::getObjectInfo
- IceGrid::Session::allocateObjectById
- IceGrid::Session::releaseObject

#### See Also

- Ice::ServantLocator
- Ice::ObjectAdapter::addServantLocator

## Data Member Index

`name` — The name of the Ice object.  
`category` — The Ice object category.

## Data Members

**string name;**

The name of the Ice object.

**string category;**

The Ice object category.

---

## Ice-IdentityParseException

---

### Ice::IdentityParseException

#### Overview

#### local exception IdentityParseException

This exception is raised if there was an error while parsing a stringified identity.

#### Data Member Index

[str](#) — Describes the failure and includes the string that could not be parsed.

#### Data Members

**string str;**

Describes the failure and includes the string that could not be parsed.

---

## Ice-IllegalIdentityException

---

### Ice::IllegalIdentityException

#### Overview

#### local exception IllegalIdentityException

This exception is raised if an illegal identity is encountered.

#### Data Member Index

`id` — The illegal identity.

#### Data Members

**Ice::Identity** `id`;

The illegal identity.

---

## Ice-IllegalMessageSizeException

---

### Ice::IllegalMessageSizeException

#### Overview

local exception `IllegalMessageSizeException` extends `Ice::ProtocolException`

This exception indicates that a message size is less than the minimum required size.

---

## Ice-IllegalServantException

---

### Ice::IllegalServantException

#### Overview

#### local exception IllegalServantException

This exception is raised to reject an illegal servant (typically a null servant)

#### Data Member Index

[reason](#) — Describes why this servant is illegal.

#### Data Members

**string** `reason`;

Describes why this servant is illegal.

---

## Ice-ImplicitContext

---

### Ice::ImplicitContext

#### Overview

##### local interface ImplicitContext

An interface to associate implicit contexts with communicators. When you make a remote invocation without an explicit context parameter, Ice uses the per-proxy context (if any) combined with the `ImplicitContext` associated with the communicator.

Ice provides several implementations of `ImplicitContext`. The implementation used depends on the value of the `Ice.ImplicitContext` property.

`None` (default) — No implicit context at all.

`PerThread` — The implementation maintains a context per thread.

`Shared` — The implementation maintains a single context shared by all threads.

`ImplicitContext` also provides a number of operations to create, update or retrieve an entry in the underlying context without first retrieving a copy of the entire context. These operations correspond to a subset of the `java.util.Map` methods, with `java.lang.Object` replaced by `string` and null replaced by the empty-string.

##### Used By

- `Ice::Communicator::getImplicitContext`

#### Operation Index

`getContext` — Get a copy of the underlying context.

`setContext` — Set the underlying context.

`containsKey` — Check if this key has an associated value in the underlying context.

`get` — Get the value associated with the given key in the underlying context.

`put` — Create or update a key/value entry in the underlying context.

`remove` — Remove the entry for the given key in the underlying context.

#### Operations

##### `Ice::Context` `getContext()`

Get a copy of the underlying context.

##### Return Value

A copy of the underlying context.

##### `void` `setContext(Ice::Context newContext)`

Set the underlying context.

##### Parameters

`newContext` — The new context.

##### `bool` `containsKey(string key)`

Check if this key has an associated value in the underlying context.

##### Parameters

key — The key.

**Return Value**

True if the key has an associated value, False otherwise.

**string get(string key)**

Get the value associated with the given key in the underlying context. Returns an empty string if no value is associated with the key. [contains Key](#) allows you to distinguish between an empty-string value and no value at all.

**Parameters**

key — The key.

**Return Value**

The value associated with the key.

**string put(string key, string value)**

Create or update a key/value entry in the underlying context.

**Parameters**

key — The key.

value — The value.

**Return Value**

The previous value associated with the key, if any.

**string remove(string key)**

Remove the entry for the given key in the underlying context.

**Parameters**

key — The key.

**Return Value**

The value associated with the key, if any.

---

## Ice-InitializationException

---

### Ice::InitializationException

#### Overview

local exception InitializationException

This exception is raised when a failure occurs during initialization.

#### Data Member Index

`reason` — The reason for the failure.

#### Data Members

`string reason;`

The reason for the failure.

---

## Ice-Instrumentation

---

### Ice::Instrumentation

#### Overview

[ "objc:prefix:ICEINSTRUMENTATION" ] module Instrumentation

The Instrumentation local interfaces enable observing a number of Ice core internal components (threads, connections, etc).

#### Interface Index

[ChildInvocationObserver](#) — The child invocation observer to instrument remote or collocated invocations.

[CollocatedObserver](#) — The collocated observer to instrument invocations that are collocated.

[CommunicatorObserver](#) — The communicator observer interface used by the Ice run-time to obtain and update observers for its observable objects.

[ConnectionObserver](#) — The connection observer interface to instrument Ice connections.

[DispatchObserver](#) — The dispatch observer to instrument servant dispatch.

[InvocationObserver](#) — The invocation observer to instrument invocations on proxies.

[Observer](#) — The object observer interface used by instrumented objects to notify the observer of their existence.

[ObserverUpdater](#) — The observer updater interface.

[RemoteObserver](#) — The remote observer to instrument invocations that are sent over the wire.

[ThreadObserver](#) — The thread observer interface to instrument Ice threads.

#### Enumeration Index

[ConnectionState](#) — The state of an Ice connection.

[ThreadState](#) — The thread state enumeration keeps track of the different possible states of Ice threads.

---

## Ice-Instrumentation-ChildInvocationObserver

---

### Ice::Instrumentation::ChildInvocationObserver

#### Overview

***local interface ChildInvocationObserver extends Ice::Instrumentation::Observer***

The child invocation observer to instrument remote or collocated invocations.  
Derived Classes and Interfaces

- Ice::Instrumentation::CollocatedObserver
- Ice::Instrumentation::RemoteObserver

#### Operation Index

`reply` — Reply notification.

#### Operations

##### ***void reply(int size)***

Reply notification.  
Parameters

`size` — The size of the reply.

---

## Ice-Instrumentation-CollocatedObserver

---

### Ice::Instrumentation::CollocatedObserver

#### Overview

*local interface CollocatedObserver extends Ice::Instrumentation::ChildInvocationObserver*

The collocated observer to instrument invocations that are collocated.

Used By

- Ice::Instrumentation::InvocationObserver::getCollocatedObserver
-

## Ice-Instrumentation-CommunicatorObserver

---

### Ice::Instrumentation::CommunicatorObserver

#### Overview

#### *local interface CommunicatorObserver*

The communicator observer interface used by the Ice run-time to obtain and update observers for its observable objects. This interface should be implemented by add-ins that wish to observe Ice objects in order to collect statistics. An instance of this interface can be provided to the Ice run-time through the Ice communicator initialization data.

Used By

- [Ice::Communicator::getObserver](#)

#### Operation Index

[getConnectionEstablishmentObserver](#) — This method should return an observer for the given endpoint information and connector.  
[getEndpointLookupObserver](#) — This method should return an observer for the given endpoint information.  
[getConnectionObserver](#) — This method should return a connection observer for the given connection.  
[getThreadObserver](#) — This method should return a thread observer for the given thread.  
[getInvocationObserver](#) — This method should return an invocation observer for the given invocation.  
[getDispatchObserver](#) — This method should return a dispatch observer for the given dispatch.  
[setObserverUpdater](#) — The Ice run-time calls this method when the communicator is initialized.

#### Operations

#### ***Ice::Instrumentation::Observer*** [getConnectionEstablishmentObserver\(Ice::Endpoint endpt, string connector\)](#)

This method should return an observer for the given endpoint information and connector. The Ice run-time calls this method for each connection establishment attempt.

Parameters

`endpt` — The endpoint.

`connector` — The description of the connector. For IP transports, this is typically the IP address to connect to.

Return Value

The observer to instrument the connection establishment.

#### ***Ice::Instrumentation::Observer*** [getEndpointLookupObserver\(Ice::Endpoint endpt\)](#)

This method should return an observer for the given endpoint information. The Ice run-time calls this method to resolve an endpoint and obtain the list of connectors. For IP endpoints, this typically involves doing a DNS lookup to obtain the IP addresses associated with the DNS name.

Parameters

`endpt` — The endpoint.

Return Value

The observer to instrument the endpoint lookup.

#### ***Ice::Instrumentation::ConnectionObserver*** [getConnectionObserver\(Ice::ConnectionInfo c, Ice::Endpoint e, Ice::Instrumentation::ConnectionState s, Ice::Instrumentation::ConnectionObserver o\)](#)

This method should return a connection observer for the given connection. The Ice run-time calls this method for each new connection and for all the Ice communicator connections when `Ice::Instrumentation::ObserverUpdater::updateConnectionObservers` is called.

Parameters

`c` — The connection information.

`e` — The connection endpoint.

`s` — The state of the connection.

`o` — The old connection observer if one is already set or a null reference otherwise.  
Return Value

The connection observer to instrument the connection.

***Ice::Instrumentation::ThreadObserver* getThreadObserver(*string parent, string id, Ice::Instrumentation::ThreadState s, Ice::Instrumentation::ThreadObserver o*)**

This method should return a thread observer for the given thread. The Ice run-time calls this method for each new thread and for all the Ice communicator threads when `Ice::Instrumentation::ObserverUpdater::updateThreadObservers` is called.

Parameters

`parent` — The parent of the thread.  
`id` — The ID of the thread to observe.  
`s` — The state of the thread.  
`o` — The old thread observer if one is already set or a null reference otherwise.  
Return Value

The thread observer to instrument the thread.

***Ice::Instrumentation::InvocationObserver* getInvocationObserver(*Object\* prx, string operation, Ice::Context ctx*)**

This method should return an invocation observer for the given invocation. The Ice run-time calls this method for each new invocation on a proxy.

Parameters

`prx` — The proxy used for the invocation.  
`operation` — The name of the invocation.  
`ctx` — The context specified by the user.  
Return Value

The invocation observer to instrument the invocation.

***Ice::Instrumentation::DispatchObserver* getDispatchObserver(*Ice::Current c, int size*)**

This method should return a dispatch observer for the given dispatch. The Ice run-time calls this method each time it receives an incoming invocation to be dispatched for an Ice object.

Parameters

`c` — The current object as provided to the Ice servant dispatching the invocation.  
`size` — The size of the dispatch.  
Return Value

The dispatch observer to instrument the dispatch.

***void setObserverUpdater(Ice::Instrumentation::ObserverUpdater updater)***

The Ice run-time calls this method when the communicator is initialized. The add-in implementing this interface can use this object to get the Ice run-time to re-obtain observers for observed objects.

Parameters

`updater` — The observer updater object.

## Ice-Instrumentation-ConnectionObserver

---

### Ice::Instrumentation::ConnectionObserver

#### Overview

*local interface ConnectionObserver extends Ice::Instrumentation::Observer*

The connection observer interface to instrument Ice connections.

Used By

- Ice::Instrumentation::CommunicatorObserver::getConnectionObserver

#### Operation Index

[sentBytes](#) — Notification of sent bytes over the connection.

[receivedBytes](#) — Notification of received bytes over the connection.

#### Operations

##### ***void sentBytes(int num)***

Notification of sent bytes over the connection.

Parameters

`num` — The number of bytes sent.

##### ***void receivedBytes(int num)***

Notification of received bytes over the connection.

Parameters

`num` — The number of bytes received.

---

## Ice-Instrumentation-ConnectionState

---

### Ice::Instrumentation::ConnectionState

#### Overview

#### *local enum ConnectionState*

The state of an Ice connection.

Used By

- [CommunicatorObserver::getConnectionObserver](#)

#### Enumerator Index

[ConnectionStateValidating](#) — The connection is being validated.

[ConnectionStateHolding](#) — The connection is holding the reception of new messages.

[ConnectionStateActive](#) — The connection is active and can send and receive messages.

[ConnectionStateClosing](#) — The connection is being gracefully shutdown and waits for the peer to close its end of the connection.

[ConnectionStateClosed](#) — The connection is closed and waits for potential dispatch to be finished before being destroyed and detached from the observer.

#### Enumerators

#### *ConnectionStateValidating*

The connection is being validated.

#### *ConnectionStateHolding*

The connection is holding the reception of new messages.

#### *ConnectionStateActive*

The connection is active and can send and receive messages.

#### *ConnectionStateClosing*

The connection is being gracefully shutdown and waits for the peer to close its end of the connection.

#### *ConnectionStateClosed*

The connection is closed and waits for potential dispatch to be finished before being destroyed and detached from the observer.

---

## Ice-Instrumentation-DispatchObserver

---

### Ice::Instrumentation::DispatchObserver

#### Overview

*local interface DispatchObserver extends Ice::Instrumentation::Observer*

The dispatch observer to instrument servant dispatch.

Used By

- Ice::Instrumentation::CommunicatorObserver::getDispatchObserver

#### Operation Index

[userException](#) — Notification of a user exception.

[reply](#) — Reply notification.

#### Operations

##### ***void userException()***

Notification of a user exception.

##### ***void reply(int size)***

Reply notification.

Parameters

*size* — The size of the reply.

---

## Ice-Instrumentation-InvocationObserver

---

### Ice::Instrumentation::InvocationObserver

#### Overview

#### *local interface InvocationObserver extends Ice::Instrumentation::Observer*

The invocation observer to instrument invocations on proxies. A proxy invocation can either result in a collocated or remote invocation. If it results in a remote invocation, a sub-observer is requested for the remote invocation.

Used By

- [Ice::Instrumentation::CommunicatorObserver::getInvocationObserver](#)

#### Operation Index

[retried](#) — Notification of the invocation being retried.

[userException](#) — Notification of a user exception.

[getRemoteObserver](#) — Get a remote observer for this invocation.

[getCollocatedObserver](#) — Get a collocated observer for this invocation.

#### Operations

##### *void retried()*

Notification of the invocation being retried.

##### *void userException()*

Notification of a user exception.

##### *Ice::Instrumentation::RemoteObserver getRemoteObserver(Ice::ConnectionInfo con, Ice::Endpoint endpt, int requestId, int size)*

Get a remote observer for this invocation.

Parameters

`con` — The connection information.

`endpt` — The connection endpoint.

`requestId` — The ID of the invocation.

`size` — The size of the invocation.

Return Value

The observer to instrument the remote invocation.

##### *Ice::Instrumentation::CollocatedObserver getCollocatedObserver(Ice::ObjectAdapter adapter, int requestId, int size)*

Get a collocated observer for this invocation.

Parameters

`adapter` — The object adapter hosting the collocated Ice object.

`requestId` — The ID of the invocation.

`size` — The size of the invocation.

Return Value

The observer to instrument the collocated invocation.

---

## Ice-Instrumentation-Observer

---

### Ice::Instrumentation::Observer

#### Overview

#### *local interface Observer*

The object observer interface used by instrumented objects to notify the observer of their existence.  
Derived Classes and Interfaces

- `Ice::Instrumentation::ChildInvocationObserver`
- `Ice::Instrumentation::ConnectionObserver`
- `Ice::Instrumentation::DispatchObserver`
- `Ice::Instrumentation::InvocationObserver`
- `Ice::Instrumentation::ThreadObserver`

#### Used By

- `Ice::Instrumentation::CommunicatorObserver::getConnectionEstablishmentObserver`
- `Ice::Instrumentation::CommunicatorObserver::getEndpointLookupObserver`

#### Operation Index

`attach` — This method is called when the instrumented object is created or when the observer is attached to an existing object.  
`detach` — This method is called when the instrumented object is destroyed and as a result the observer detached from the object.  
`failed` — Notification of a failure.

#### Operations

##### *void attach()*

This method is called when the instrumented object is created or when the observer is attached to an existing object.

##### *void detach()*

This method is called when the instrumented object is destroyed and as a result the observer detached from the object.

##### *void failed(string exceptionName)*

Notification of a failure.

Parameters

`exceptionName` — The name of the exception.

---

## Ice-Instrumentation-ObserverUpdater

---

### Ice::Instrumentation::ObserverUpdater

#### Overview

#### *local interface ObserverUpdater*

The observer updater interface. This interface is implemented by the Ice run-time and an instance of this interface is provided by the Ice communicator on initialization to the `Ice::Instrumentation::CommunicatorObserver` object set with the communicator initialization data. The Ice communicator calls `Ice::Instrumentation::CommunicatorObserver::setObserverUpdater` to provide the observer updater. This interface can be used by add-ins implementing the `Ice::Instrumentation::CommunicatorObserver` interface to update the observers of connections and threads.

Used By

- `Ice::Instrumentation::CommunicatorObserver::setObserverUpdater`

#### Operation Index

`updateConnectionObservers` — Update connection observers associated with each of the Ice connection from the communicator and its object adapters.

`updateThreadObservers` — Update thread observers associated with each of the Ice thread from the communicator and its object adapters.

#### Operations

#### *void updateConnectionObservers()*

Update connection observers associated with each of the Ice connection from the communicator and its object adapters. When called, this method goes through all the connections and for each connection `Ice::Instrumentation::CommunicatorObserver::getConnectionObserver` is called. The implementation of `getConnectionObserver` has the possibility to return an updated observer if necessary.

#### *void updateThreadObservers()*

Update thread observers associated with each of the Ice thread from the communicator and its object adapters. When called, this method goes through all the threads and for each thread `Ice::Instrumentation::CommunicatorObserver::getThreadObserver` is called. The implementation of `getThreadObserver` has the possibility to return an updated observer if necessary.

---

## Ice-Instrumentation-RemoteObserver

---

### Ice::Instrumentation::RemoteObserver

#### Overview

*local interface RemoteObserver extends Ice::Instrumentation::ChildInvocationObserver*

The remote observer to instrument invocations that are sent over the wire.

Used By

- Ice::Instrumentation::InvocationObserver::getRemoteObserver
-

## Ice-Instrumentation-ThreadObserver

---

### Ice::Instrumentation::ThreadObserver

#### Overview

*local interface ThreadObserver extends Ice::Instrumentation::Observer*

The thread observer interface to instrument Ice threads. This can be threads from the Ice thread pool or utility threads used by the Ice core.  
Used By

- `Ice::Instrumentation::CommunicatorObserver::getThreadObserver`

#### Operation Index

`stateChanged` — Notification of thread state change.

#### Operations

***void stateChanged(Ice::Instrumentation::ThreadState oldState, Ice::Instrumentation::ThreadState newState)***

Notification of thread state change.

Parameters

`oldState` — The previous thread state.

`newState` — The new thread state.

---

## Ice-Instrumentation-ThreadState

---

### Ice::Instrumentation::ThreadState

#### Overview

#### *local enum ThreadState*

The thread state enumeration keeps track of the different possible states of Ice threads.

Used By

- [CommunicatorObserver::getThreadObserver](#)
- [ThreadObserver::stateChanged](#)

#### Enumerator Index

[ThreadStateIdle](#) — The thread is idle.

[ThreadStateInUseForIO](#) — The thread is in use performing reads or writes for Ice connections.

[ThreadStateInUseForUser](#) — The thread is calling user code (servant implementation, AMI callbacks).

[ThreadStateInUseForOther](#) — The thread is performing other internal activities (DNS lookups, timer callbacks, etc).

#### Enumerators

##### ***ThreadStateIdle***

The thread is idle.

##### ***ThreadStateInUseForIO***

The thread is in use performing reads or writes for Ice connections. This state is only for threads from an Ice thread pool.

##### ***ThreadStateInUseForUser***

The thread is calling user code (servant implementation, AMI callbacks). This state is only for threads from an Ice thread pool.

##### ***ThreadStateInUseForOther***

The thread is performing other internal activities (DNS lookups, timer callbacks, etc).

---

## Ice-InvalidReplicaGroupIdException

---

### Ice::InvalidReplicaGroupIdException

#### Overview

#### exception InvalidReplicaGroupIdException

This exception is raised if the replica group provided by the server is invalid.

#### *Used By*

- [Ice::LocatorRegistry::setReplicatedAdapterDirectProxy](#)
-

## Ice-InvocationCanceledException

---

### Ice::InvocationCanceledException

#### Overview

#### local exception InvocationCanceledException

This exception indicates that an asynchronous invocation failed because it was canceled explicitly by the user using the `Ice::AsyncResult::cancel` method.

---

## Ice-InvocationTimeoutException

---

### Ice::InvocationTimeoutException

#### Overview

local exception `InvocationTimeoutException` extends [Ice::TimeoutException](#)

This exception indicates that an invocation failed because it timed out.

---

## Ice-IPConnectionInfo

---

### Ice::IPConnectionInfo

#### Overview

local class `IPConnectionInfo` extends `Ice::ConnectionInfo`

Provides access to the connection details of an IP connection

#### *Derived Classes and Interfaces*

- `Ice::TCPConnectionInfo`
- `Ice::UDPConnectionInfo`
- `IceSSL::ConnectionInfo`

#### Data Member Index

`localAddress` — The local address.

`localPort` — The local port.

`remoteAddress` — The remote address.

`remotePort` — The remote port.

#### Data Members

**string localAddress;**

The local address.

**int localPort;**

The local port.

**string remoteAddress;**

The remote address.

**int remotePort;**

The remote port.

---

## Ice-IPEndpointInfo

---

### Ice::IPEndpointInfo

#### Overview

local class `IPEndpointInfo` extends `Ice::EndpointInfo`

Provides access to the address details of a IP endpoint.

#### *Derived Classes and Interfaces*

- `Ice::TCPEndpointInfo`
- `Ice::UDPEndpointInfo`
- `IceSSL::EndpointInfo`

#### *See Also*

- `Ice::Endpoint`

#### Data Member Index

`host` — The host or address configured with the endpoint.

`port` — The port number.

`sourceAddress` — The source IP address.

#### Data Members

**string** `host`;

The host or address configured with the endpoint.

**int** `port`;

The port number.

**string** `sourceAddress`;

The source IP address.

---

# Ice-Locator

---

## Ice::Locator

### Overview

#### interface Locator

The Ice locator interface. This interface is used by clients to lookup adapters and objects. It is also used by servers to get the locator registry proxy.

*The Ice::Locator interface is intended to be used by Ice internals and by locator implementations. Regular user code should not attempt to use any functionality of this interface directly.*

#### Derived Classes and Interfaces

- [IceGrid::Locator](#)

### Operation Index

[findObjectById](#) — Find an object by identity and return a proxy that contains the adapter ID or endpoints which can be used to access the object.

[findAdapterById](#) — Find an adapter by id and return a proxy that contains its endpoints.

[getRegistry](#) — Get the locator registry.

### Operations

[ "amd", "nonmutating" ] **Object\*** [findObjectById\(Ice::Identity id\)](#) throws **Ice::ObjectNotFoundException**

Find an object by identity and return a proxy that contains the adapter ID or endpoints which can be used to access the object.

#### Parameters

id — The identity.

#### Return Value

The proxy, or null if the object is not active.

#### Exceptions

[Ice::ObjectNotFoundException](#) — Raised if the object cannot be found.

[ "amd", "nonmutating" ] **Object\*** [findAdapterById\(string id\)](#) throws **Ice::AdapterNotFoundException**

Find an adapter by id and return a proxy that contains its endpoints.

#### Parameters

id — The adapter id.

#### Return Value

The adapter proxy, or null if the adapter is not active.

#### Exceptions

[Ice::AdapterNotFoundException](#) — Raised if the adapter cannot be found.

[ "nonmutating" ] **Ice::LocatorRegistry\*** getRegistry()

Get the locator registry.

***Return Value***

The locator registry.

---

## Ice-LocatorFinder

---

### Ice::LocatorFinder

#### Overview

#### interface LocatorFinder

This interface should be implemented by services implementing the Ice::Locator interface. It should be advertised through an Ice object with the identity 'Ice/LocatorFinder'. This allows clients to retrieve the locator proxy with just the endpoint information of the service.

#### Operation Index

`getLocator` — Get the locator proxy implemented by the process hosting this finder object.

#### Operations

##### Ice::Locator\* getLocator()

Get the locator proxy implemented by the process hosting this finder object. The proxy might point to several replicas.

##### *Return Value*

The locator proxy.

---

## Ice-LocatorRegistry

---

### Ice::LocatorRegistry

#### Overview

#### interface LocatorRegistry

The Ice locator registry interface. This interface is used by servers to register adapter endpoints with the locator.

*The `Ice::LocatorRegistry` interface is intended to be used by Ice internals and by locator implementations. Regular user code should not attempt to use any functionality of this interface directly.*

#### Operation Index

`setAdapterDirectProxy` — Set the adapter endpoints with the locator registry.  
`setReplicatedAdapterDirectProxy` — Set the adapter endpoints with the locator registry.  
`setServerProcessProxy` — Set the process proxy for a server.

#### Operations

[ "amd" ] void `setAdapterDirectProxy`(string id, Object\* proxy) throws `Ice::AdapterNotFoundException`, `Ice::AdapterAlreadyActiveException`

Set the adapter endpoints with the locator registry.

##### Parameters

`id` — The adapter id.  
`proxy` — The adapter proxy (a dummy direct proxy created by the adapter). The direct proxy contains the adapter endpoints.

##### Exceptions

`Ice::AdapterNotFoundException` — Raised if the adapter cannot be found, or if the locator only allows registered adapters to set their active proxy and the adapter is not registered with the locator.  
`Ice::AdapterAlreadyActiveException` — Raised if an adapter with the same id is already active.

[ "amd" ] void `setReplicatedAdapterDirectProxy`(string adapterId, string replicaGroupId, Object\* p) throws `Ice::AdapterNotFoundException`, `Ice::AdapterAlreadyActiveException`, `Ice::InvalidReplicaGroupIdException`

Set the adapter endpoints with the locator registry.

##### Parameters

`adapterId` — The adapter id.  
`replicaGroupId` — The replica group id.  
`p` — The adapter proxy (a dummy direct proxy created by the adapter). The direct proxy contains the adapter endpoints.

##### Exceptions

`Ice::AdapterNotFoundException` — Raised if the adapter cannot be found, or if the locator only allows registered adapters to set their active proxy and the adapter is not registered with the locator.  
`Ice::AdapterAlreadyActiveException` — Raised if an adapter with the same id is already active.  
`Ice::InvalidReplicaGroupIdException` — Raised if the given replica group doesn't match the one registered with the locator registry for this object adapter.

[ "amd" ] void **setServerProcessProxy**(string id, [Ice::Process\\*](#) proxy) throws [Ice::ServerNotFoundException](#)

Set the process proxy for a server.

**Parameters**

`id` — The server id.

`proxy` — The process proxy.

**Exceptions**

[Ice::ServerNotFoundException](#) — Raised if the server cannot be found.

---

# Ice-Logger

---

## Ice::Logger

### Overview

#### local interface `Logger`

The Ice message logger. Applications can provide their own logger by implementing this interface and installing it in a communicator.

#### *Used By*

- `Ice::Communicator::getLogger`
- `cloneWithPrefix`

### Operation Index

`print` — Print a message.  
`trace` — Log a trace message.  
`warning` — Log a warning message.  
`error` — Log an error message.  
`getPrefix` — Returns this logger's prefix.  
`cloneWithPrefix` — Returns a clone of the logger with a new prefix.

### Operations

#### `void print(string message)`

Print a message. The message is printed literally, without any decorations such as executable name or time stamp.

#### `void trace(string category, string message)`

Log a trace message.

#### *Parameters*

`category` — The trace category.  
`message` — The trace message to log.

#### `void warning(string message)`

Log a warning message.

#### *Parameters*

`message` — The warning message to log.

#### *See Also*

- `error`

#### `void error(string message)`

Log an error message.

#### *Parameters*

`message` — The error message to log.

**See Also**

- [warning](#)

**string getPrefix()**

Returns this logger's prefix.

**Return Value**

The prefix.

**Ice::Logger cloneWithPrefix(string prefix)**

Returns a clone of the logger with a new prefix.

**Parameters**

`prefix` — The new prefix for the logger.

---

## Ice-LoggerAdmin

---

### Ice::LoggerAdmin

#### Overview

#### interface LoggerAdmin

The interface of the admin object that allows an Ice application the attach its [Ice::RemoteLogger](#) to the [Ice::Logger](#) of this admin object's Ice communicator.

#### Operation Index

[attachRemoteLogger](#) — [attachRemoteLogger](#) is called to attach a [Ice::RemoteLogger](#) object to the local [Ice::Logger](#).  
[detachRemoteLogger](#) — [detachRemoteLogger](#) is called to detach a [Ice::RemoteLogger](#) object from the local [Ice::Logger](#).  
[getLog](#) — [getLog](#) retrieves log messages recently logged.

#### Operations

**void attachRemoteLogger([Ice::RemoteLogger](#)\* prx, [Ice::LogMessageTypeSeq](#) messageTypes, [Ice::StringSeq](#) traceCategories, int messageMax) throws [Ice::RemoteLoggerAlreadyAttachedException](#)**

[attachRemoteLogger](#) is called to attach a [Ice::RemoteLogger](#) object to the local [Ice::Logger](#). [attachRemoteLogger](#) calls [init](#) on the provided [Ice::RemoteLogger](#) proxy.

##### Parameters

[prx](#) — A proxy to the remote logger.  
[messageTypes](#) — The list of message types that the remote logger wishes to receive. An empty list means no filtering (send all message types).  
[traceCategories](#) — The categories of traces that the remote logger wishes to receive. This parameter is ignored if [messageTypes](#) is not empty and does not include trace. An empty list means no filtering (send all trace categories).  
[messageMax](#) — The maximum number of log messages (of all types) to be provided to [Ice::RemoteLogger::init](#). A negative value requests all messages available.

##### Exceptions

[Ice::RemoteLoggerAlreadyAttachedException](#) — Raised if this remote logger is already attached to this admin object.

**bool detachRemoteLogger([Ice::RemoteLogger](#)\* prx)**

[detachRemoteLogger](#) is called to detach a [Ice::RemoteLogger](#) object from the local [Ice::Logger](#).

##### Parameters

[prx](#) — A proxy to the remote logger.

##### Return Value

True if the provided remote logger proxy was detached, and false otherwise.

**[Ice::LogMessageSeq](#) getLog([Ice::LogMessageTypeSeq](#) messageTypes, [Ice::StringSeq](#) traceCategories, int messageMax, out string prefix)**

[getLog](#) retrieves log messages recently logged.

**Parameters**

`messageTypes` — The list of message types that the caller wishes to receive. An empty list means no filtering (send all message types).  
`traceCategories` — The categories of traces that caller wish to receive. This parameter is ignored if `messageTypes` is not empty and does not include trace. An empty list means no filtering (send all trace categories).  
`messageMax` — The maximum number of log messages (of all types) to be returned. A negative value requests all messages available.  
`prefix` — The prefix of the associated local `Ice::Logger`.

**Return Value**

The Log messages.

---

## Ice-LogMessage

---

### Ice::LogMessage

#### Overview

#### struct LogMessage

A complete log message.

#### Used By

- [Ice::LogMessageSeq](#)
- [Ice::RemoteLogger::log](#)

#### Data Member Index

[type](#) — The type of message sent to the [Ice::Logger](#).

[timestamp](#) — The date and time when the [Ice::Logger](#) received this message, expressed as the number of microseconds since the Unix Epoch (00:00:00 UTC on 1 January 1970)

[traceCategory](#) — For a message of type trace, the trace category of this log message; otherwise, the empty string.

[message](#) — The log message itself.

#### Data Members

##### **Ice::LogMessageType** type;

The type of message sent to the [Ice::Logger](#).

##### **long** timestamp;

The date and time when the [Ice::Logger](#) received this message, expressed as the number of microseconds since the Unix Epoch (00:00:00 UTC on 1 January 1970)

##### **string** traceCategory;

For a message of type trace, the trace category of this log message; otherwise, the empty string.

##### **string** message;

The log message itself.

---

## Ice-LogMessageType

---

### Ice::LogMessageType

#### Overview

#### enum LogMessageType

An enumeration representing the different types of log messages.

#### *Used By*

- [LogMessage::type](#)
- [LogMessageTypeSeq](#)

#### Enumerator Index

[PrintMessage](#) — The [Logger](#) received a print message.  
[TraceMessage](#) — The [Logger](#) received a trace message.  
[WarningMessage](#) — The [Logger](#) received a warning message.  
[ErrorMessage](#) — The [Logger](#) received an error message.

#### Enumerators

##### PrintMessage

The [Logger](#) received a print message.

##### TraceMessage

The [Logger](#) received a trace message.

##### WarningMessage

The [Logger](#) received a warning message.

##### ErrorMessage

The [Logger](#) received an error message.

---

## Ice-MarshallException

---

### Ice::MarshalException

#### Overview

local exception `MarshalException` extends `Ice::ProtocolException`

This exception is raised for errors during marshaling or unmarshaling data.

#### *Derived Exceptions*

- `Ice::EncapsulationException`
  - `Ice::MemoryLimitException`
  - `Ice::NoObjectFactoryException`
  - `Ice::ProxyUnmarshalException`
  - `Ice::StringConversionException`
  - `Ice::UnexpectedObjectException`
  - `Ice::UnmarshalOutOfBoundsException`
-

## Ice-MemoryLimitException

---

### Ice::MemoryLimitException

#### Overview

local exception `MemoryLimitException` extends `Ice::MarshalException`

This exception is raised when Ice receives a request or reply message whose size exceeds the limit specified by the `Ice.MessageSizeMax` property.

---

## Ice-NoEndpointException

---

### Ice::NoEndpointException

#### Overview

#### local exception NoEndpointException

This exception is raised if no suitable endpoint is available.

#### Data Member Index

[proxy](#) — The stringified proxy for which no suitable endpoint is available.

#### Data Members

**string proxy;**

The stringified proxy for which no suitable endpoint is available.

---

## Ice-NoObjectFactoryException

---

### Ice::NoObjectFactoryException

#### Overview

local exception `NoObjectFactoryException` extends `Ice::MarshalException`

This exception is raised if no suitable object factory was found during unmarshaling of a Slice class instance.

#### See Also

- `Ice::ObjectFactory`
- `Ice::Communicator::addObjectFactory`
- `Ice::Communicator::findObjectFactory`

#### Data Member Index

`type` — The Slice type ID of the class instance for which no no factory could be found.

#### Data Members

`string type;`

The Slice type ID of the class instance for which no no factory could be found.

---

## Ice-NotRegisteredException

---

### Ice::NotRegisteredException

#### Overview

#### local exception NotRegisteredException

An attempt was made to find or deregister something that is not registered with the Ice run time or Ice locator. This exception is raised if an attempt is made to remove a servant, servant locator, facet, object factory, plug-in, object adapter, object, or user exception factory that is not currently registered. It's also raised if the Ice locator can't find an object or object adapter when resolving an indirect proxy or when an object adapter is activated.

#### Data Member Index

`kindOfObject` — The kind of object that could not be removed: "servant", "servant locator", "object factory", "plug-in", "object adapter", "object", or "user exception factory".

`id` — The ID (or name) of the object that could not be removed.

#### Data Members

`string kindOfObject;`

The kind of object that could not be removed: "servant", "servant locator", "object factory", "plug-in", "object adapter", "object", or "user exception factory".

`string id;`

The ID (or name) of the object that could not be removed.

---

## Ice-ObjectAdapter

---

### Ice::ObjectAdapter

#### Overview

#### local interface ObjectAdapter

The object adapter provides an up-call interface from the Ice run time to the implementation of Ice objects. The object adapter is responsible for receiving requests from endpoints, and for mapping between servants, identities, and proxies.

#### Used By

- [Freeze::ServantInitializer::initialize](#)
- [Ice::Communicator::createAdmin](#)
- [Ice::Communicator::createObjectAdapterWithEndpoints](#)
- [Ice::Communicator::createObjectAdapterWithRouter](#)
- [Ice::Communicator::createObjectAdapter](#)
- [Ice::Connection::getAdapter](#)
- [Ice::Connection::setAdapter](#)
- [Ice::Current::adapter](#)
- [Ice::Instrumentation::InvocationObserver::getCollocatedObserver](#)

#### See Also

- [Ice::Communicator](#)
- [Ice::ServantLocator](#)

#### Operation Index

[getName](#) — Get the name of this object adapter.

[getCommunicator](#) — Get the communicator this object adapter belongs to.

[activate](#) — Activate all endpoints that belong to this object adapter.

[hold](#) — Temporarily hold receiving and dispatching requests.

[waitForHold](#) — Wait until the object adapter holds requests.

[deactivate](#) — Deactivate all endpoints that belong to this object adapter.

[waitForDeactivate](#) — Wait until the object adapter has deactivated.

[isDeactivated](#) — Check whether object adapter has been deactivated.

[destroy](#) — Destroys the object adapter and cleans up all resources held by the object adapter.

[add](#) — Add a servant to this object adapter's Active Servant Map.

[addFacet](#) — Like [add](#), but with a facet.

[addWithUUID](#) — Add a servant to this object adapter's Active Servant Map, using an automatically generated UUID as its identity.

[addFacetWithUUID](#) — Like [addWithUUID](#), but with a facet.

[addDefaultServant](#) — Add a default servant to handle requests for a specific category.

[remove](#) — Remove a servant (that is, the default facet) from the object adapter's Active Servant Map.

[removeFacet](#) — Like [remove](#), but with a facet.

[removeAllFacets](#) — Remove all facets with the given identity from the Active Servant Map.

[removeDefaultServant](#) — Remove the default servant for a specific category.

[find](#) — Look up a servant in this object adapter's Active Servant Map by the identity of the Ice object it implements.

[findFacet](#) — Like [find](#), but with a facet.

[findAllFacets](#) — Find all facets with the given identity in the Active Servant Map.

[findByProxy](#) — Look up a servant in this object adapter's Active Servant Map, given a proxy.

[addServantLocator](#) — Add a Servant Locator to this object adapter.

[removeServantLocator](#) — Remove a Servant Locator from this object adapter.

[findServantLocator](#) — Find a Servant Locator installed with this object adapter.

[findDefaultServant](#) — Find the default servant for a specific category.

[createProxy](#) — Create a proxy for the object with the given identity.

[createDirectProxy](#) — Create a direct proxy for the object with the given identity.

[createIndirectProxy](#) — Create an indirect proxy for the object with the given identity.

[setLocator](#) — Set an Ice locator for this object adapter.

[getLocator](#) — Get the Ice locator used by this object adapter.

[refreshPublishedEndpoints](#) — Refresh the set of published endpoints.

[getEndpoints](#) — Get the set of endpoints configured with this object adapter.

[getPublishedEndpoints](#) — Get the set of endpoints that proxies created by this object adapter will contain.

## Operations

### string getName()

Get the name of this object adapter.

#### *Return Value*

This object adapter's name.

### Ice::Communicator getCommunicator()

Get the communicator this object adapter belongs to.

#### *Return Value*

This object adapter's communicator.

#### *See Also*

- [Ice::Communicator](#)

### void activate()

Activate all endpoints that belong to this object adapter. After activation, the object adapter can dispatch requests received through its endpoints.

#### *See Also*

- [hold](#)
- [deactivate](#)

### void hold()

Temporarily hold receiving and dispatching requests. The object adapter can be reactivated with the [activate](#) operation.

*Holding is not immediate, i.e., after [hold](#) returns, the object adapter might still be active for some time. You can use [waitForHold](#) to wait until holding is complete.*

#### *See Also*

- [activate](#)
- [deactivate](#)
- [waitForHold](#)

### void waitForHold()

Wait until the object adapter holds requests. Calling [hold](#) initiates holding of requests, and [waitForHold](#) only returns when holding of requests has been completed.

#### *See Also*

- [hold](#)
- [waitForDeactivate](#)
- [Ice::Communicator::waitForShutdown](#)

**void deactivate()**

Deactivate all endpoints that belong to this object adapter. After deactivation, the object adapter stops receiving requests through its endpoints. Object adapters that have been deactivated must not be reactivated again, and cannot be used otherwise. Attempts to use a deactivated object adapter raise `Ice::ObjectAdapterDeactivatedException`; however, attempts to `deactivate` an already deactivated object adapter are ignored and do nothing. Once deactivated, it is possible to destroy the adapter to clean up resources and then create and activate a new adapter with the same name.

*After `deactivate` returns, no new requests are processed by the object adapter. However, requests that have been started before `deactivate` was called might still be active. You can use `waitForDeactivate` to wait for the completion of all requests for this object adapter.*

**See Also**

- [activate](#)
- [hold](#)
- [waitForDeactivate](#)
- [Ice::Communicator::shutdown](#)

**void waitForDeactivate()**

Wait until the object adapter has deactivated. Calling `deactivate` initiates object adapter deactivation, and `waitForDeactivate` only returns when deactivation has been completed.

**See Also**

- [deactivate](#)
- [waitForHold](#)
- [Ice::Communicator::waitForShutdown](#)

**bool isDeactivated()**

Check whether object adapter has been deactivated.

**Return Value**

Whether adapter has been deactivated.

**See Also**

- [Ice::Communicator::shutdown](#)

**void destroy()**

Destroys the object adapter and cleans up all resources held by the object adapter. If the object adapter has not yet been deactivated, `destroy` implicitly initiates the deactivation and waits for it to finish. Subsequent calls to `destroy` are ignored. Once `destroy` has returned, it is possible to create another object adapter with the same name.

**See Also**

- [deactivate](#)
- [waitForDeactivate](#)
- [Ice::Communicator::destroy](#)

**Object\* add(Object servant, Ice::Identity id)**

Add a servant to this object adapter's Active Servant Map. Note that one servant can implement several Ice objects by registering the servant with multiple identities. Adding a servant with an identity that is in the map already throws `Ice::AlreadyRegisteredException`.

**Parameters**

`servant` — The servant to add.

`id` — The identity of the Ice object that is implemented by the servant.

**Return Value**

A proxy that matches the given identity and this object adapter.

**See Also**

- [Ice::Identity](#)
- [addFacet](#)
- [addWithUUID](#)
- [remove](#)
- [find](#)

**Object\* addFacet(Object servant, Ice::Identity id, string facet)**

Like [add](#), but with a facet. Calling `add(servant, id)` is equivalent to calling [addFacet](#) with an empty facet.

**Parameters**

`servant` — The servant to add.

`id` — The identity of the Ice object that is implemented by the servant.

`facet` — The facet. An empty facet means the default facet.

**Return Value**

A proxy that matches the given identity, facet, and this object adapter.

**See Also**

- [Ice::Identity](#)
- [add](#)
- [addFacetWithUUID](#)
- [removeFacet](#)
- [findFacet](#)

**Object\* addWithUUID(Object servant)**

Add a servant to this object adapter's Active Servant Map, using an automatically generated UUID as its identity. Note that the generated UUID identity can be accessed using the proxy's `ice_getIdentity` operation.

**Parameters**

`servant` — The servant to add.

**Return Value**

A proxy that matches the generated UUID identity and this object adapter.

**See Also**

- [Ice::Identity](#)
- [add](#)
- [addFacetWithUUID](#)
- [remove](#)
- [find](#)

**Object\* addFacetWithUUID(Object servant, string facet)**

Like [addWithUUID](#), but with a facet. Calling `addWithUUID(servant)` is equivalent to calling [addFacetWithUUID](#) with an empty facet.

**Parameters**

`servant` — The servant to add.

`facet` — The facet. An empty facet means the default facet.

**Return Value**

A proxy that matches the generated UUID identity, facet, and this object adapter.

**See Also**

- [Ice::Identity](#)
- [addFacet](#)
- [addWithUUID](#)
- [removeFacet](#)
- [findFacet](#)

**void addDefaultServant(Object servant, string category)**

Add a default servant to handle requests for a specific category. Adding a default servant for a category for which a default servant is already registered throws [Ice::AlreadyRegisteredException](#). To dispatch operation calls on servants, the object adapter tries to find a servant for a given Ice object identity and facet in the following order:

1. The object adapter tries to find a servant for the identity and facet in the Active Servant Map.
2. If no servant has been found in the Active Servant Map, the object adapter tries to find a default servant for the category component of the identity.
3. If no servant has been found by any of the preceding steps, the object adapter tries to find a default servant for an empty category, regardless of the category contained in the identity.
4. If no servant has been found by any of the preceding steps, the object adapter gives up and the caller receives [Ice::ObjectNotExistException](#) or [Ice::FacetNotExistException](#).

**Parameters**

`servant` — The default servant.

`category` — The category for which the default servant is registered. An empty category means it will handle all categories.

**See Also**

- [removeDefaultServant](#)
- [findDefaultServant](#)

**Object remove(Ice::Identity id)**

Remove a servant (that is, the default facet) from the object adapter's Active Servant Map.

**Parameters**

`id` — The identity of the Ice object that is implemented by the servant. If the servant implements multiple Ice objects, [remove](#) has to be called for all those Ice objects. Removing an identity that is not in the map throws [Ice::NotRegisteredException](#).

**Return Value**

The removed servant.

**See Also**

- [Ice::Identity](#)
- [add](#)
- [addWithUUID](#)

**Object removeFacet(Ice::Identity id, string facet)**

Like [remove](#), but with a facet. Calling `remove(id)` is equivalent to calling [removeFacet](#) with an empty facet.

**Parameters**

`id` — The identity of the Ice object that is implemented by the servant.

`facet` — The facet. An empty facet means the default facet.

**Return Value**

The removed servant.

**See Also**

- [Ice::Identity](#)
- [addFacet](#)
- [addFacetWithUUID](#)

**Ice::FacetMap removeAllFacets(Ice::Identity id)**

Remove all facets with the given identity from the Active Servant Map. The operation completely removes the Ice object, including its default facet. Removing an identity that is not in the map throws [Ice::NotRegisteredException](#).

**Parameters**

`id` — The identity of the Ice object to be removed.

**Return Value**

A collection containing all the facet names and servants of the removed Ice object.

**See Also**

- [remove](#)
- [removeFacet](#)

**Object removeDefaultServant(string category)**

Remove the default servant for a specific category. Attempting to remove a default servant for a category that is not registered throws [Ice::NotRegisteredException](#).

**Parameters**

`category` — The category of the default servant to remove.

**Return Value**

The default servant.

**See Also**

- [addDefaultServant](#)
- [findDefaultServant](#)

**Object find(Ice::Identity id)**

Look up a servant in this object adapter's Active Servant Map by the identity of the Ice object it implements.

*This operation only tries to look up a servant in the Active Servant Map. It does not attempt to find a servant by using any installed [Ice::ServantLocator](#).*

**Parameters**

`id` — The identity of the Ice object for which the servant should be returned.

**Return Value**

The servant that implements the Ice object with the given identity, or null if no such servant has been found.

**See Also**

- [Ice::Identity](#)
- [findFacet](#)
- [findByProxy](#)

### Object [findFacet\(Ice::Identity id, string facet\)](#)

Like [find](#), but with a facet. Calling `find(id)` is equivalent to calling [findFacet](#) with an empty facet.

#### Parameters

`id` — The identity of the Ice object for which the servant should be returned.

`facet` — The facet. An empty facet means the default facet.

#### Return Value

The servant that implements the Ice object with the given identity and facet, or null if no such servant has been found.

#### See Also

- [Ice::Identity](#)
- [find](#)
- [findByProxy](#)

### [Ice::FacetMap](#) [findAllFacets\(Ice::Identity id\)](#)

Find all facets with the given identity in the Active Servant Map.

#### Parameters

`id` — The identity of the Ice object for which the facets should be returned.

#### Return Value

A collection containing all the facet names and servants that have been found, or an empty map if there is no facet for the given identity.

#### See Also

- [find](#)
- [findFacet](#)

### Object [findByProxy\(Object\\* proxy\)](#)

Look up a servant in this object adapter's Active Servant Map, given a proxy.

*This operation only tries to lookup a servant in the Active Servant Map. It does not attempt to find a servant by using any installed [Ice::ServantLocator](#).*

#### Parameters

`proxy` — The proxy for which the servant should be returned.

#### Return Value

The servant that matches the proxy, or null if no such servant has been found.

#### See Also

- [find](#)
- [findFacet](#)

### `void addServantLocator(Ice::ServantLocator locator, string category)`

Add a Servant Locator to this object adapter. Adding a servant locator for a category for which a servant locator is already registered throws `Ice::AlreadyRegisteredException`. To dispatch operation calls on servants, the object adapter tries to find a servant for a given Ice object identity and facet in the following order:

1. The object adapter tries to find a servant for the identity and facet in the Active Servant Map.
2. If no servant has been found in the Active Servant Map, the object adapter tries to find a servant locator for the category component of the identity. If a locator is found, the object adapter tries to find a servant using this locator.
3. If no servant has been found by any of the preceding steps, the object adapter tries to find a locator for an empty category, regardless of the category contained in the identity. If a locator is found, the object adapter tries to find a servant using this locator.
4. If no servant has been found by any of the preceding steps, the object adapter gives up and the caller receives `Ice::ObjectNotExistException` or `Ice::FacetNotExistException`.

*Only one locator for the empty category can be installed.*

#### Parameters

`locator` — The locator to add.

`category` — The category for which the Servant Locator can locate servants, or an empty string if the Servant Locator does not belong to any specific category.

#### See Also

- [Ice::Identity](#)
- [removeServantLocator](#)
- [findServantLocator](#)
- [Ice::ServantLocator](#)

### **Ice::ServantLocator** `removeServantLocator(string category)`

Remove a Servant Locator from this object adapter.

#### Parameters

`category` — The category for which the Servant Locator can locate servants, or an empty string if the Servant Locator does not belong to any specific category.

#### Return Value

The Servant Locator, or throws `Ice::NotRegisteredException` if no Servant Locator was found for the given category.

#### See Also

- [Ice::Identity](#)
- [addServantLocator](#)
- [findServantLocator](#)
- [Ice::ServantLocator](#)

### **Ice::ServantLocator** `findServantLocator(string category)`

Find a Servant Locator installed with this object adapter.

#### Parameters

`category` — The category for which the Servant Locator can locate servants, or an empty string if the Servant Locator does not belong to any specific category.

#### Return Value

The Servant Locator, or null if no Servant Locator was found for the given category.

#### See Also

- [Ice::Identity](#)
- [addServantLocator](#)
- [removeServantLocator](#)

- [Ice::ServantLocator](#)

### Object `findDefaultServant(string category)`

Find the default servant for a specific category.

#### *Parameters*

`category` — The category of the default servant to find.

#### *Return Value*

The default servant or null if no default servant was registered for the category.

#### *See Also*

- [addDefaultServant](#)
- [removeDefaultServant](#)

### Object\* `createProxy(Ice::Identity id)`

Create a proxy for the object with the given identity. If this object adapter is configured with an adapter id, the return value is an indirect proxy that refers to the adapter id. If a replica group id is also defined, the return value is an indirect proxy that refers to the replica group id. Otherwise, if no adapter id is defined, the return value is a direct proxy containing this object adapter's published endpoints.

#### *Parameters*

`id` — The object's identity.

#### *Return Value*

A proxy for the object with the given identity.

#### *See Also*

- [Ice::Identity](#)

### Object\* `createDirectProxy(Ice::Identity id)`

Create a direct proxy for the object with the given identity. The returned proxy contains this object adapter's published endpoints.

#### *Parameters*

`id` — The object's identity.

#### *Return Value*

A proxy for the object with the given identity.

#### *See Also*

- [Ice::Identity](#)

### Object\* `createIndirectProxy(Ice::Identity id)`

Create an indirect proxy for the object with the given identity. If this object adapter is configured with an adapter id, the return value refers to the adapter id. Otherwise, the return value contains only the object identity.

#### *Parameters*

`id` — The object's identity.

**Return Value**

A proxy for the object with the given identity.

**See Also**

- [Ice::Identity](#)

**void setLocator(Ice::Locator\* loc)**

Set an Ice locator for this object adapter. By doing so, the object adapter will register itself with the locator registry when it is activated for the first time. Furthermore, the proxies created by this object adapter will contain the adapter identifier instead of its endpoints. The adapter identifier must be configured using the AdapterId property.

**Parameters**

loc — The locator used by this object adapter.

**See Also**

- [createDirectProxy](#)
- [Ice::Locator](#)
- [Ice::LocatorRegistry](#)

**Ice::Locator\* getLocator()**

Get the Ice locator used by this object adapter.

**Return Value**

The locator used by this object adapter, or null if no locator is used by this object adapter.

**See Also**

- [Ice::Locator](#)
- [setLocator](#)

**void refreshPublishedEndpoints()**

Refresh the set of published endpoints. The run time re-reads the PublishedEndpoints property if it is set and re-reads the list of local interfaces if the adapter is configured to listen on all endpoints. This operation is useful to refresh the endpoint information that is published in the proxies that are created by an object adapter if the network interfaces used by a host changes.

**Ice::EndpointSeq getEndpoints()**

Get the set of endpoints configured with this object adapter.

**Return Value**

The set of endpoints.

**See Also**

- [Ice::Endpoint](#)

**Ice::EndpointSeq getPublishedEndpoints()**

Get the set of endpoints that proxies created by this object adapter will contain.

**Return Value**

The set of published endpoints.

**See Also**

- [refreshPublishedEndpoints](#)
  - [Ice::Endpoint](#)
-

## Ice-ObjectAdapterDeactivatedException

---

### Ice::ObjectAdapterDeactivatedException

#### Overview

#### local exception `ObjectAdapterDeactivatedException`

This exception is raised if an attempt is made to use a deactivated [Ice::ObjectAdapter](#).

#### See Also

- [Ice::ObjectAdapter::deactivate](#)
- [Ice::Communicator::shutdown](#)

#### Data Member Index

`name` — Name of the adapter.

#### Data Members

`string name;`

Name of the adapter.

---

## Ice-ObjectAdapterIdInUseException

---

### Ice::ObjectAdapterIdInUseException

#### Overview

#### local exception ObjectAdapterIdInUseException

This exception is raised if an `Ice::ObjectAdapter` cannot be activated. This happens if the `Ice::Locator` detects another active `Ice::ObjectAdapter` with the same adapter id.

#### Data Member Index

`id` — Adapter ID.

#### Data Members

`string id;`

Adapter ID.

---

# Ice-ObjectFactory

---

## Ice::ObjectFactory

### Overview

#### local interface ObjectFactory

A factory for objects. Object factories are used in several places, for example, when receiving "objects by value" and when Freeze restores a persistent object. Object factories must be implemented by the application writer, and registered with the communicator.

#### Used By

- [Ice::Communicator::addObjectFactory](#)
- [Ice::Communicator::findObjectFactory](#)

### Operation Index

[create](#) — Create a new object for a given object type.

[destroy](#) — Called when the factory is removed from the communicator, or if the communicator is destroyed.

### Operations

#### Object create(string type)

Create a new object for a given object type. The type is the absolute Slice type id, i.e., the id relative to the unnamed top-level Slice module. For example, the absolute Slice type id for interfaces of type `Bar` in the module `Foo` is `::Foo::Bar`.

*The leading "::" is required.*

#### Parameters

`type` — The object type.

#### Return Value

The object created for the given type, or nil if the factory is unable to create the object.

#### void destroy()

Called when the factory is removed from the communicator, or if the communicator is destroyed.

#### See Also

- [Ice::Communicator::destroy](#)
-

## Ice-ObjectNotExistException

---

### Ice::ObjectNotExistException

#### Overview

local exception `ObjectNotExistException` extends `Ice::RequestFailedException`

This exception is raised if an object does not exist on the server, that is, if no facets with the given identity exist.

---

## Ice-ObjectNotFoundException

---

### Ice::ObjectNotFoundException

#### Overview

exception `ObjectNotFoundException`

This exception is raised if an object cannot be found.

#### *Used By*

- `Ice::Locator::findObjectById`
-

## Ice-OpaqueEndpointInfo

---

### Ice::OpaqueEndpointInfo

#### Overview

local class `OpaqueEndpointInfo` extends `Ice::EndpointInfo`

Provides access to the details of an opaque endpoint.

#### See Also

- `Ice::Endpoint`

#### Data Member Index

`rawEncoding` — The encoding version of the opaque endpoint (to decode or encode the `rawBytes`).  
`rawBytes` — The raw encoding of the opaque endpoint.

#### Data Members

`Ice::EncodingVersion` `rawEncoding`;

The encoding version of the opaque endpoint (to decode or encode the `rawBytes`).

`Ice::ByteSeq` `rawBytes`;

The raw encoding of the opaque endpoint.

---

## Ice-OperationInterruptedException

---

### Ice::OperationInterruptedException

#### Overview

local exception `OperationInterruptedException`

This exception indicates a request was interrupted.

---

## Ice-OperationMode

---

### Ice::OperationMode

#### Overview

#### enum OperationMode

The `OperationMode` determines the retry behavior an invocation in case of a (potentially) recoverable error.

#### Used By

- `Current::mode`

#### Enumerator Index

**Normal** — Ordinary operations have `Normal` mode.

**Nonmutating** — Operations that use the Slice `nonmutating` keyword must not modify object state.

**Idempotent** — Operations that use the Slice `idempotent` keyword can modify object state, but invoking an operation twice in a row must result in the same object state as invoking it once.

#### Enumerators

##### Normal

Ordinary operations have `Normal` mode. These operations modify object state; invoking such an operation twice in a row has different semantics than invoking it once. The Ice run time guarantees that it will not violate at-most-once semantics for `Normal` operations.

##### Nonmutating

Operations that use the Slice `nonmutating` keyword must not modify object state. For C++, nonmutating operations generate `const` member functions in the skeleton. In addition, the Ice run time will attempt to transparently recover from certain run-time errors by re-issuing a failed request and propagate the failure to the application only if the second attempt fails.

*Nonmutating is deprecated; Use the `idempotent` keyword instead. For C++, to retain the mapping of nonmutating operations to C++ `const` member functions, use the `["cpp:const"]` metadata directive.*

##### Idempotent

Operations that use the Slice `idempotent` keyword can modify object state, but invoking an operation twice in a row must result in the same object state as invoking it once. For example, `x = 1` is an idempotent statement, whereas `x += 1` is not. For idempotent operations, the Ice run-time uses the same retry behavior as for nonmutating operations in case of a potentially recoverable error.

---

## Ice-OperationNotExistException

---

### Ice::OperationNotExistException

#### Overview

local exception `OperationNotExistException` extends [Ice::RequestFailedException](#)

This exception is raised if an operation for a given object does not exist on the server. Typically this is caused by either the client or the server using an outdated Slice specification.

---

## Ice-Plugin

---

### Ice::Plugin

#### Overview

##### local interface Plugin

A communicator plug-in. A plug-in generally adds a feature to a communicator, such as support for a protocol. The communicator loads its plug-ins in two stages: the first stage creates the plug-ins, and the second stage invokes [initialize](#) on each one.

##### *Used By*

- [Ice::PluginManager::addPlugin](#)
- [Ice::PluginManager::getPlugin](#)

#### Operation Index

[initialize](#) — Perform any necessary initialization steps.

[destroy](#) — Called when the communicator is being destroyed.

#### Operations

##### **void initialize()**

Perform any necessary initialization steps.

##### **void destroy()**

Called when the communicator is being destroyed.

---

## Ice-PluginInitializationException

---

### Ice::PluginInitializationException

#### Overview

#### local exception PluginInitializationException

This exception indicates that a failure occurred while initializing a plug-in.

#### Data Member Index

`reason` — The reason for the failure.

#### Data Members

`string reason;`

The reason for the failure.

---

## Ice-PluginManager

---

### Ice::PluginManager

#### Overview

#### local interface PluginManager

Each communicator has a plug-in manager to administer the set of plug-ins.

#### Used By

- [Ice::Communicator::getPluginManager](#)

#### Operation Index

[initializePlugins](#) — Initialize the configured plug-ins.  
[getPlugins](#) — Get a list of plugins installed.  
[getPlugin](#) — Obtain a plug-in by name.  
[addPlugin](#) — Install a new plug-in.  
[destroy](#) — Called when the communicator is being destroyed.

#### Operations

##### void initializePlugins()

Initialize the configured plug-ins. The communicator automatically initializes the plug-ins by default, but an application may need to interact directly with a plug-in prior to initialization. In this case, the application must set `Ice.InitPlugins=0` and then invoke [initializePlugins](#) manually. The plug-ins are initialized in the order in which they are loaded. If a plug-in raises an exception during initialization, the communicator invokes [destroy](#) on the plug-ins that have already been initialized.

#### Exceptions

[Ice::InitializationException](#) — Raised if the plug-ins have already been initialized.

##### Ice::StringSeq getPlugins()

Get a list of plugins installed.

#### Return Value

The names of the plugins installed.

#### See Also

- [getPlugin](#)

##### Ice::Plugin getPlugin(string name)

Obtain a plug-in by name.

#### Parameters

`name` — The plug-in's name.

#### Return Value

The plug-in.

**Exceptions**

[Ice::NotRegisteredException](#) — Raised if no plug-in is found with the given name.

**void addPlugin(string name, [Ice::Plugin](#) pi)**

Install a new plug-in.

**Parameters**

*name* — The plug-in's name.

*pi* — The plug-in.

**Exceptions**

[Ice::AlreadyRegisteredException](#) — Raised if a plug-in already exists with the given name.

**void destroy()**

Called when the communicator is being destroyed.

---

## Ice-Process

---

### Ice::Process

#### Overview

#### interface Process

An administrative interface for process management. Managed servers must implement this interface.

*A servant implementing this interface is a potential target for denial-of-service attacks, therefore proper security precautions should be taken. For example, the servant can use a UUID to make its identity harder to guess, and be registered in an object adapter with a secured endpoint.*

#### Operation Index

[shutdown](#) — Initiate a graceful shut-down.

[writeMessage](#) — Write a message on the process' stdout or stderr.

#### Operations

##### void shutdown()

Initiate a graceful shut-down.

##### See Also

- [Ice::Communicator::shutdown](#)

##### void writeMessage(string message, int fd)

Write a message on the process' stdout or stderr.

##### Parameters

`message` — The message.

`fd` — 1 for stdout, 2 for stderr.

---

## Ice-Properties

---

### Ice::Properties

#### Overview

#### local interface Properties

A property set used to configure Ice and Ice applications. Properties are key/value pairs, with both keys and values being strings. By convention, property keys should have the form *application-name[.category[.sub-category]].name*.

#### Used By

- [Ice::Communicator::getProperties](#)
- [clone](#)

#### Operation Index

[getProperty](#) — Get a property by key.  
[getPropertyWithDefault](#) — Get a property by key.  
[getPropertyAsInt](#) — Get a property as an integer.  
[getPropertyAsIntWithDefault](#) — Get a property as an integer.  
[getPropertyAsList](#) — Get a property as a list of strings.  
[getPropertyAsListWithDefault](#) — Get a property as a list of strings.  
[getPropertiesForPrefix](#) — Get all properties whose keys begins with *prefix*.  
[setProperty](#) — Set a property.  
[getCommandLineOptions](#) — Get a sequence of command-line options that is equivalent to this property set.  
[parseCommandLineOptions](#) — Convert a sequence of command-line options into properties.  
[parseIceCommandLineOptions](#) — Convert a sequence of command-line options into properties.  
[load](#) — Load properties from a file.  
[clone](#) — Create a copy of this property set.

#### Operations

##### string getProperty(string key)

Get a property by key. If the property is not set, an empty string is returned.

#### Parameters

`key` — The property key.

#### Return Value

The property value.

#### See Also

- [setProperty](#)

##### string getPropertyWithDefault(string key, string value)

Get a property by key. If the property is not set, the given default value is returned.

#### Parameters

`key` — The property key.

`value` — The default value to use if the property does not exist.

**Return Value**

The property value or the default value.

**See Also**

- [setProperty](#)

**int getPropertyAsInt(string key)**

Get a property as an integer. If the property is not set, 0 is returned.

**Parameters**

`key` — The property key.

**Return Value**

The property value interpreted as an integer.

**See Also**

- [setProperty](#)

**int getPropertyAsIntWithDefault(string key, int value)**

Get a property as an integer. If the property is not set, the given default value is returned.

**Parameters**

`key` — The property key.

`value` — The default value to use if the property does not exist.

**Return Value**

The property value interpreted as an integer, or the default value.

**See Also**

- [setProperty](#)

**Ice::StringSeq getPropertyAsList(string key)**

Get a property as a list of strings. The strings must be separated by whitespace or comma. If the property is not set, an empty list is returned. The strings in the list can contain whitespace and commas if they are enclosed in single or double quotes. If quotes are mismatched, an empty list is returned. Within single quotes or double quotes, you can escape the quote in question with `\`, e.g. O'Reilly can be written as O'Reilly, "O'Reilly" or 'O'Reilly'.

**Parameters**

`key` — The property key.

**Return Value**

The property value interpreted as a list of strings.

**See Also**

- [setProperty](#)

**Ice::StringSeq getPropertyAsListWithDefault(string key, Ice::StringSeq value)**

Get a property as a list of strings. The strings must be separated by whitespace or comma. If the property is not set, the default list is returned. The strings in the list can contain whitespace and commas if they are enclosed in single or double quotes. If quotes are mismatched, the default list is returned. Within single quotes or double quotes, you can escape the quote in question with `\`, e.g. O'Reilly can be written as O'Reilly, "O'Reilly" or 'O'Reilly'.

**Parameters**

`key` — The property key.  
`value` — The default value to use if the property is not set.

**Return Value**

The property value interpreted as list of strings, or the default value.

**See Also**

- [setProperty](#)

**Ice::PropertyDict getPropertiesForPrefix(string prefix)**

Get all properties whose keys begins with `prefix`. If `prefix` is an empty string, then all properties are returned.

**Parameters**

`prefix` — The prefix to search for (empty string if none).

**Return Value**

The matching property set.

**void setProperty(string key, string value)**

Set a property. To unset a property, set it to the empty string.

**Parameters**

`key` — The property key.  
`value` — The property value.

**See Also**

- [getProperty](#)

**Ice::StringSeq getCommandLineOptions()**

Get a sequence of command-line options that is equivalent to this property set. Each element of the returned sequence is a command-line option of the form `--key=value`.

**Return Value**

The command line options for this property set.

**Ice::StringSeq parseCommandLineOptions(string prefix, Ice::StringSeq options)**

Convert a sequence of command-line options into properties. All options that begin with `--prefix.` are converted into properties. If the prefix is empty, all options that begin with `--` are converted to properties.

**Parameters**

`prefix` — The property prefix, or an empty string to convert all options starting with `--`.  
`options` — The command-line options.

**Return Value**

The command-line options that do not start with the specified prefix, in their original order.

**Ice::StringSeq parseIceCommandLineOptions(Ice::StringSeq options)**

Convert a sequence of command-line options into properties. All options that begin with one of the following prefixes are converted into properties: `--Ice`, `--IceBox`, `--IceGrid`, `--IcePatch2`, `--IceSSL`, `--IceStorm`, `--Freeze`, and `--Glacier2`.

**Parameters**

`options` — The command-line options.

**Return Value**

The command-line options that do not start with one of the listed prefixes, in their original order.

**void load(string file)**

Load properties from a file.

**Parameters**

`file` — The property file.

**Ice::Properties clone()**

Create a copy of this property set.

**Return Value**

A copy of this property set.

---

## Ice-PropertiesAdmin

---

### Ice::PropertiesAdmin

#### Overview

#### interface PropertiesAdmin

The PropertiesAdmin interface provides remote access to the properties of a communicator.

#### Operation Index

[getProperty](#) — Get a property by key.

[getPropertiesForPrefix](#) — Get all properties whose keys begin with *prefix*.

[setProperty](#) — Update the communicator's properties with the given property set.

#### Operations

##### string getProperty(string key)

Get a property by key. If the property is not set, an empty string is returned.

##### Parameters

*key* — The property key.

##### Return Value

The property value.

##### [ "java:type:java.util.TreeMap<String, String>" ] Ice::PropertyDict getPropertiesForPrefix(string prefix)

Get all properties whose keys begin with *prefix*. If *prefix* is an empty string then all properties are returned.

##### Parameters

*prefix* — The prefix to search for (empty string if none).

##### Return Value

The matching property set.

##### [ "amd" ] void setProperties(Ice::PropertyDict newProperties)

Update the communicator's properties with the given property set.

##### Parameters

*newProperties* — Properties to be added, changed, or removed. If an entry in *newProperties* matches the name of an existing property, that property's value is replaced with the new value. If the new value is an empty string, the property is removed. Any existing properties that are not modified or removed by the entries in *newProperties* are retained with their original values.

---

## Ice-ProtocolException

---

### Ice::ProtocolException

#### Overview

#### local exception ProtocolException

A generic exception base for all kinds of protocol error conditions.

#### *Derived Exceptions*

- Ice::BadMagicException
- Ice::CloseConnectionException
- Ice::CompressionException
- Ice::ConnectionNotValidatedException
- Ice::DatagramLimitException
- Ice::ForcedCloseConnectionException
- Ice::IllegalMessageSizeException
- Ice::MarshalException
- Ice::UnknownMessageException
- Ice::UnknownReplyStatusException
- Ice::UnknownRequestIdException
- Ice::UnsupportedEncodingException
- Ice::UnsupportedProtocolException

#### Data Member Index

`reason` — The reason for the failure.

#### Data Members

`string reason;`

The reason for the failure.

---

## Ice-ProtocolVersion

---

### Ice::ProtocolVersion

#### Overview

#### struct ProtocolVersion

A version structure for the protocol version.

#### *Used By*

- Ice::UnsupportedProtocolException::bad
- Ice::UnsupportedProtocolException::supported

#### Data Member Index

major  
minor

#### Data Members

byte major;

byte minor;

---

## Ice-ProxyParseException

---

### Ice::ProxyParseException

#### Overview

#### local exception ProxyParseException

This exception is raised if there was an error while parsing a stringified proxy.

#### Data Member Index

[str](#) — Describes the failure and includes the string that could not be parsed.

#### Data Members

**string str;**

Describes the failure and includes the string that could not be parsed.

---

## Ice-ProxyUnmarshalException

---

### Ice::ProxyUnmarshalException

#### Overview

local exception ProxyUnmarshalException extends **Ice::MarshalException**

This exception is raised if inconsistent data is received while unmarshaling a proxy.

---

## Ice-RemoteLogger

---

### Ice::RemoteLogger

#### Overview

#### interface RemoteLogger

The Ice remote logger interface. An application can implement a RemoteLogger to receive the log messages sent to the local `Ice::Logger` of another Ice application.

#### Operation Index

`init` — `init` is called by `Ice::LoggerAdmin::attachRemoteLogger` when a RemoteLogger proxy is attached.  
`log` — Log a `Ice::LogMessage`.

#### Operations

##### `void init(string prefix, Ice::LogMessageSeq logMessages)`

`init` is called by `Ice::LoggerAdmin::attachRemoteLogger` when a RemoteLogger proxy is attached.

##### *Parameters*

`prefix` — The prefix of the associated local `Ice::Logger`  
`logMessages` — Old log messages generated before "now".

##### *See Also*

- `Ice::LoggerAdmin::attachRemoteLogger`

##### `void log(Ice::LogMessage message)`

Log a `Ice::LogMessage`. Note that `log` may be called by `Ice::LoggerAdmin` before `init`.

##### *Parameters*

`message` — The message to log.

##### *See Also*

- `Ice::Logger`
-

## Ice-RemoteLoggerAlreadyAttachedException

---

### Ice::RemoteLoggerAlreadyAttachedException

#### Overview

#### exception RemoteLoggerAlreadyAttachedException

An exception thrown by `Ice::LoggerAdmin::attachRemoteLogger` to report that the provided `Ice::RemoteLogger` was previously attached to this `Ice::LoggerAdmin`.

#### *Used By*

- `Ice::LoggerAdmin::attachRemoteLogger`
-

## Ice-RequestFailedException

---

### Ice::RequestFailedException

#### Overview

#### local exception RequestFailedException

This exception is raised if a request failed. This exception, and all exceptions derived from [Ice::RequestFailedException](#), are transmitted by the Ice protocol, even though they are declared `local`.

#### *Derived Exceptions*

- [Ice::FacetNotExistException](#)
- [Ice::ObjectNotExistException](#)
- [Ice::OperationNotExistException](#)

#### Data Member Index

`id` — The identity of the Ice Object to which the request was sent.

`facet` — The facet to which the request was sent.

`operation` — The operation name of the request.

#### Data Members

##### **Ice::Identity** `id`;

The identity of the Ice Object to which the request was sent.

##### **string** `facet`;

The facet to which the request was sent.

##### **string** `operation`;

The operation name of the request.

---

## Ice-ResponseSentException

---

### Ice::ResponseSentException

#### Overview

local exception `ResponseSentException`

Indicates that the response to a request has already been sent; re-dispatching such a request is not possible.

---

# Ice-Router

---

## Ice::Router

### Overview

#### interface Router

The Ice router interface. Routers can be set either globally with `Ice::Communicator::setDefaultRouter`, or with `ice_router` on specific proxies.

#### Derived Classes and Interfaces

- [Glacier2::Router](#)

### Operation Index

[getClientProxy](#) — Get the router's client proxy, i.e., the proxy to use for forwarding requests from the client to the router.  
[getServerProxy](#) — Get the router's server proxy, i.e., the proxy to use for forwarding requests from the server to the router.  
[addProxies](#) — Add new proxy information to the router's routing table.

### Operations

#### [ "nonmutating" ] Object\* getClientProxy()

Get the router's client proxy, i.e., the proxy to use for forwarding requests from the client to the router. If a null proxy is returned, the client will forward requests to the router's endpoints.

#### Return Value

The router's client proxy.

#### [ "nonmutating" ] Object\* getServerProxy()

Get the router's server proxy, i.e., the proxy to use for forwarding requests from the server to the router.

#### Return Value

The router's server proxy.

#### Ice::ObjectProxySeq addProxies(Ice::ObjectProxySeq proxies)

Add new proxy information to the router's routing table.

#### Parameters

`proxies` — The proxies to add.

#### Return Value

Proxies discarded by the router.

---

## Ice-RouterFinder

---

### Ice::RouterFinder

#### Overview

#### interface RouterFinder

This interface should be implemented by services implementing the Ice::Router interface. It should be advertised through an Ice object with the identity 'Ice/RouterFinder'. This allows clients to retrieve the router proxy with just the endpoint information of the service.

#### Operation Index

`getRouter` — Get the router proxy implemented by the process hosting this finder object.

#### Operations

##### Ice::Router\* getRouter()

Get the router proxy implemented by the process hosting this finder object. The proxy might point to several replicas.

##### *Return Value*

The router proxy.

---

## Ice-SecurityException

---

### Ice::SecurityException

#### Overview

#### local exception SecurityException

This exception indicates a failure in a security subsystem, such as the IceSSL plug-in.

#### Data Member Index

`reason` — The reason for the failure.

#### Data Members

`string reason;`

The reason for the failure.

---

# Ice-ServantLocator

---

## Ice::ServantLocator

### Overview

#### local interface ServantLocator

A servant locator is called by an object adapter to locate a servant that is not found in its active servant map.

#### Derived Classes and Interfaces

- [Freeze::Evictor](#)

#### Used By

- [Ice::ObjectAdapter::addServantLocator](#)
- [Ice::ObjectAdapter::findServantLocator](#)
- [Ice::ObjectAdapter::removeServantLocator](#)

#### See Also

- [Ice::ObjectAdapter](#)
- [Ice::ObjectAdapter::addServantLocator](#)
- [Ice::ObjectAdapter::findServantLocator](#)

### Operation Index

**locate** — Called before a request is dispatched if a servant cannot be found in the object adapter's active servant map.

**finished** — Called by the object adapter after a request has been made.

**deactivate** — Called when the object adapter in which this servant locator is installed is destroyed.

### Operations

#### Object **locate**([Ice::Current](#) curr, out [LocalObject](#) cookie)

Called before a request is dispatched if a servant cannot be found in the object adapter's active servant map. Note that the object adapter does not automatically insert the returned servant into its active servant map. This must be done by the servant locator implementation, if this is desired. `locate` can throw any user exception. If it does, that exception is marshaled back to the client. If the Slice definition for the corresponding operation includes that user exception, the client receives that user exception; otherwise, the client receives [Ice::UnknownUserException](#). If `locate` throws any exception, the Ice run time does *not* call `finished`.

*If you call `locate` from your own code, you must also call `finished` when you have finished using the servant, provided that `locate` returned a non-null servant; otherwise, you will get undefined behavior if you use servant locators such as the [Freeze Evictor](#).*

#### Parameters

`curr` — Information about the current operation for which a servant is required.

`cookie` — A "cookie" that will be passed to `finished`.

#### Return Value

The located servant, or null if no suitable servant has been found.

#### See Also

- [Ice::ObjectAdapter](#)
- [Ice::Current](#)
- [finished](#)

**void finished(Ice::Current curr, Object servant, LocalObject cookie)**

Called by the object adapter after a request has been made. This operation is only called if `locate` was called prior to the request and returned a non-null servant. This operation can be used for cleanup purposes after a request. `finished` can throw any user exception. If it does, that exception is marshaled back to the client. If the Slice definition for the corresponding operation includes that user exception, the client receives that user exception; otherwise, the client receives `Ice::UnknownUserException`. If both the operation and `finished` throw an exception, the exception thrown by `finished` is marshaled back to the client.

**Parameters**

`curr` — Information about the current operation call for which a servant was located by `locate`.  
`servant` — The servant that was returned by `locate`.  
`cookie` — The cookie that was returned by `locate`.

**See Also**

- [Ice::ObjectAdapter](#)
- [Ice::Current](#)
- [locate](#)

**void deactivate(string category)**

Called when the object adapter in which this servant locator is installed is destroyed.

**Parameters**

`category` — Indicates for which category the servant locator is being deactivated.

**See Also**

- [Ice::ObjectAdapter::destroy](#)
  - [Ice::Communicator::shutdown](#)
  - [Ice::Communicator::destroy](#)
-

## Ice-ServerNotFoundException

---

### Ice::ServerNotFoundException

#### Overview

exception `ServerNotFoundException`

This exception is raised if a server cannot be found.

#### *Used By*

- `Ice::LocatorRegistry::setServerProcessProxy`
-

## Ice-SocketException

---

### Ice::SocketException

#### Overview

local exception `SocketException` extends `Ice::SyscallException`

This exception indicates socket errors.

#### *Derived Exceptions*

- `Ice::ConnectFailedException`
  - `Ice::ConnectionLostException`
-

## Ice-StringConversionException

---

### Ice::StringConversionException

#### Overview

local exception `StringConversionException` extends `Ice::MarshalException`

This exception is raised when a string conversion to or from UTF-8 fails during marshaling or unmarshaling.

---

## Ice-SyscallException

---

### Ice::SyscallException

#### Overview

#### local exception SyscallException

This exception is raised if a system error occurred in the server or client process. There are many possible causes for such a system exception. For details on the cause, `error` should be inspected.

#### *Derived Exceptions*

- [Ice::FileException](#)
- [Ice::SocketException](#)

#### Data Member Index

`error` — The error number describing the system exception.

#### Data Members

`int error;`

The error number describing the system exception. For C++ and Unix, this is equivalent to `errno`. For C++ and Windows, this is the value returned by `GetLastError()` or `WSAGetLastError()`.

---

## Ice-TCPConnectionInfo

---

### Ice::TCPConnectionInfo

#### Overview

local class TCPConnectionInfo extends [Ice::IPConnectionInfo](#)

Provides access to the connection details of a TCP connection

#### *Derived Classes and Interfaces*

- [Ice::WSConnectionInfo](#)
-

## Ice-TCPEndpointInfo

---

### Ice::TCPEndpointInfo

#### Overview

local class `TCPEndpointInfo` extends `Ice::IPEndpointInfo`

Provides access to a TCP endpoint information.

#### *Derived Classes and Interfaces*

- `Ice::WSEndpointInfo`

#### *See Also*

- `Ice::Endpoint`
-

## Ice-TimeoutException

---

### Ice::TimeoutException

#### Overview

#### local exception TimeoutException

This exception indicates a timeout condition.

#### *Derived Exceptions*

- Ice::CloseTimeoutException
  - Ice::ConnectTimeoutException
  - Ice::ConnectionTimeoutException
  - Ice::InvocationTimeoutException
-

## Ice-TwowayOnlyException

---

### Ice::TwowayOnlyException

#### Overview

#### local exception TwowayOnlyException

The operation can only be invoked with a twoway request. This exception is raised if an attempt is made to invoke an operation with `ice_oneway`, `ice_batchOneway`, `ice_datagram`, or `ice_batchDatagram` and the operation has a return value, out-parameters, or an exception specification.

#### Data Member Index

`operation` — The name of the operation that was invoked.

#### Data Members

`string operation;`

The name of the operation that was invoked.

---

## Ice-UDPConnectionInfo

---

### Ice::UDPConnectionInfo

#### Overview

local class `UDPConnectionInfo` extends `Ice::IPConnectionInfo`

Provides access to the connection details of a UDP connection

#### Data Member Index

`mcastAddress` — The multicast address.

`mcastPort` — The multicast port.

#### Data Members

`string mcastAddress;`

The multicast address.

`int mcastPort;`

The multicast port.

---

## Ice-UDPEndpointInfo

---

### Ice::UDPEndpointInfo

#### Overview

local class `UDPEndpointInfo` extends `Ice::IPEndpointInfo`

Provides access to an UDP endpoint information.

#### See Also

- `Ice::Endpoint`

#### Data Member Index

`mcastInterface` — The multicast interface.

`mcastTtl` — The multicast time-to-live (or hops).

#### Data Members

`string mcastInterface;`

The multicast interface.

`int mcastTtl;`

The multicast time-to-live (or hops).

---

## Ice-UnexpectedObjectException

---

### Ice::UnexpectedObjectException

#### Overview

local exception `UnexpectedObjectException` extends `Ice::MarshalException`

This exception is raised if the type of an unmarshaled Slice class instance does not match its expected type. This can happen if client and server are compiled with mismatched Slice definitions or if a class of the wrong type is passed as a parameter or return value using dynamic invocation. This exception can also be raised if IceStorm is used to send Slice class instances and an operation is subscribed to the wrong topic.

#### Data Member Index

`type` — The Slice type ID of the class instance that was unmarshaled.  
`expectedType` — The Slice type ID that was expected by the receiving operation.

#### Data Members

`string type;`

The Slice type ID of the class instance that was unmarshaled.

`string expectedType;`

The Slice type ID that was expected by the receiving operation.

---

## Ice-UnknownException

---

### Ice::UnknownException

#### Overview

#### local exception UnknownException

This exception is raised if an operation call on a server raises an unknown exception. For example, for C++, this exception is raised if the server throws a C++ exception that is not directly or indirectly derived from `Ice::LocalException` or `Ice::UserException`.

#### *Derived Exceptions*

- [Ice::UnknownLocalException](#)
- [Ice::UnknownUserException](#)

#### Data Member Index

`unknown` — This field is set to the textual representation of the unknown exception if available.

#### Data Members

`string unknown;`

This field is set to the textual representation of the unknown exception if available.

---

## Ice-UnknownLocalException

---

### Ice::UnknownLocalException

#### Overview

local exception `UnknownLocalException` extends [Ice::UnknownException](#)

This exception is raised if an operation call on a server raises a local exception. Because local exceptions are not transmitted by the Ice protocol, the client receives all local exceptions raised by the server as `Ice::UnknownLocalException`. The only exception to this rule are all exceptions derived from `Ice::RequestFailedException`, which are transmitted by the Ice protocol even though they are declared `local`.

---

## Ice-UnknownMessageException

---

### Ice::UnknownMessageException

#### Overview

local exception `UnknownMessageException` extends `Ice::ProtocolException`

This exception indicates that an unknown protocol message has been received.

---

## Ice-UnknownReplyStatusException

---

### Ice::UnknownReplyStatusException

#### Overview

local exception `UnknownReplyStatusException` extends `Ice::ProtocolException`

This exception indicates that an unknown reply status has been received.

---

## Ice-UnknownRequestIdException

---

### Ice::UnknownRequestIdException

#### Overview

local exception `UnknownRequestIdException` extends `Ice::ProtocolException`

This exception indicates that a response for an unknown request ID has been received.

---

## Ice-UnknownUserException

---

### Ice::UnknownUserException

#### Overview

local exception `UnknownUserException` extends `Ice::UnknownException`

An operation raised an incorrect user exception. This exception is raised if an operation raises a user exception that is not declared in the exception's `throws` clause. Such undeclared exceptions are not transmitted from the server to the client by the Ice protocol, but instead the client just gets an `Ice::UnknownUserException`. This is necessary in order to not violate the contract established by an operation's signature: Only local exceptions and user exceptions declared in the `throws` clause can be raised.

---

## Ice-UnmarshalOutOfBoundsException

---

### Ice::UnmarshalOutOfBoundsException

#### Overview

local exception `UnmarshalOutOfBoundsException` extends `Ice::MarshalException`

This exception is raised if an out-of-bounds condition occurs during unmarshaling.

---

## Ice-UnsupportedEncodingException

---

### Ice::UnsupportedEncodingException

#### Overview

local exception `UnsupportedEncodingException` extends `Ice::ProtocolException`

This exception indicates an unsupported data encoding version.

#### Data Member Index

`bad` — The version of the unsupported encoding.

`supported` — The version of the encoding that is supported.

#### Data Members

`Ice::EncodingVersion bad;`

The version of the unsupported encoding.

`Ice::EncodingVersion supported;`

The version of the encoding that is supported.

---

## Ice-UnsupportedProtocolException

---

### Ice::UnsupportedProtocolException

#### Overview

local exception `UnsupportedProtocolException` extends `Ice::ProtocolException`

This exception indicates an unsupported protocol version.

#### Data Member Index

`bad` — The version of the unsupported protocol.

`supported` — The version of the protocol that is supported.

#### Data Members

`Ice::ProtocolVersion bad;`

The version of the unsupported protocol.

`Ice::ProtocolVersion supported;`

The version of the protocol that is supported.

---

## Ice-VersionMismatchException

---

### Ice::VersionMismatchException

#### Overview

local exception `VersionMismatchException`

This exception is raised if the Ice library version does not match the version in the Ice header files.

---

## Ice-VersionParseException

---

### Ice::VersionParseException

#### Overview

#### local exception `VersionParseException`

This exception is raised if there was an error while parsing a version.

#### Data Member Index

`str` — Describes the failure and includes the string that could not be parsed.

#### Data Members

`string str;`

Describes the failure and includes the string that could not be parsed.

---

## Ice-WSConnectionInfo

---

### Ice::WSConnectionInfo

#### Overview

local class `WSConnectionInfo` extends `Ice::TCPConnectionInfo`

Provides access to the connection details of a WebSocket connection

#### Data Member Index

`headers` — The headers from the HTTP upgrade request.

#### Data Members

`Ice::HeaderDict headers;`

The headers from the HTTP upgrade request.

---

## Ice-WSEndpointInfo

---

### Ice::WSEndpointInfo

#### Overview

local class `WSEndpointInfo` extends `Ice::TCPEndpointInfo`

Provides access to a WebSocket endpoint information.

#### Data Member Index

`resource` — The URI configured with the endpoint.

#### Data Members

`string resource;`

The URI configured with the endpoint.

---

# IceSSL Slice API

---

## IceSSL

### Overview

[ "objc:prefix:ICESSL" ] module IceSSL

IceSSL provides a secure transport for Ice.

### Class Index

[ConnectionInfo](#) — Provides access to the connection details of an SSL connection

[EndpointInfo](#) — Provides access to an SSL endpoint information.

[WSSConnectionInfo](#) — Provides access to the connection details of a secure WebSocket connection

[WSSEndpointInfo](#) — Provides access to a secure WebSocket endpoint information.

### Constant Index

[EndpointType](#) — Uniquely identifies SSL endpoints.

### Constants

**const short EndpointType = 2;**

Uniquely identifies SSL endpoints.

---

## IceSSL-ConnectionInfo

---

### IceSSL::ConnectionInfo

#### Overview

local class `ConnectionInfo` extends `Ice::IPConnectionInfo`

Provides access to the connection details of an SSL connection

#### *Derived Classes and Interfaces*

- `IceSSL::WSSConnectionInfo`

#### Data Member Index

`cipher` — The negotiated cipher suite.

`certs` — The certificate chain.

`verified` — The certificate chain verification status.

#### Data Members

**string** `cipher`;

The negotiated cipher suite.

**Ice::StringSeq** `certs`;

The certificate chain.

**bool** `verified`;

The certificate chain verification status.

---

## IceSSL-EndpointInfo

---

### IceSSL::EndpointInfo

#### Overview

local class EndpointInfo extends [Ice::IPEndpointInfo](#)

Provides access to an SSL endpoint information.

#### *Derived Classes and Interfaces*

- [IceSSL::WSEndpointInfo](#)
-

## IceSSL-WSSConnectionInfo

---

### IceSSL::WSSConnectionInfo

#### Overview

local class `WSSConnectionInfo` extends `IceSSL::ConnectionInfo`

Provides access to the connection details of a secure WebSocket connection

#### Data Member Index

`headers` — The headers from the HTTP upgrade request.

#### Data Members

`Ice::HeaderDict headers;`

The headers from the HTTP upgrade request.

---

## IceSSL-WSSseEndpointInfo

---

### IceSSL::WSSseEndpointInfo

#### Overview

local class `WSSseEndpointInfo` extends `IceSSL::EndpointInfo`

Provides access to a secure WebSocket endpoint information.

#### Data Member Index

`resource` — The URI configured with the endpoint.

#### Data Members

`string resource;`

The URI configured with the endpoint.

---

# IceStorm Slice API

---

## IceStorm

### Overview

#### [ "objc:prefix:ICESTORM" ] module IceStorm

A messaging service with support for federation. In contrast to most other messaging or event services, IceStorm supports typed events, meaning that broadcasting a message over a federation is as easy as invoking a method on an interface.

### Interface Index

[Finder](#) — This interface is advertised by the IceStorm service through the Ice object with the identity `IceStorm/Finder`.

[Topic](#) — Publishers publish information on a particular topic.

[TopicManager](#) — A topic manager manages topics, and subscribers to topics.

### Exception Index

[AlreadySubscribed](#) — This exception indicates that an attempt was made to subscribe a proxy for which a subscription already exists.

[BadQoS](#) — This exception indicates that a subscription failed due to an invalid QoS.

[InvalidSubscriber](#) — This exception indicates that an attempt was made to subscribe a proxy that is null.

[LinkExists](#) — This exception indicates that an attempt was made to create a link that already exists.

[NoSuchLink](#) — This exception indicates that an attempt was made to remove a link that does not exist.

[NoSuchTopic](#) — This exception indicates that an attempt was made to retrieve a topic that does not exist.

[TopicExists](#) — This exception indicates that an attempt was made to create a topic that already exists.

### Structure Index

[LinkInfo](#) — Information on the topic links.

### Sequence Index

[LinkInfoSeq](#) — A sequence of [LinkInfo](#) objects.

### Dictionary Index

[QoS](#) — This dictionary represents quality of service parameters.

[TopicDict](#) — Mapping of topic name to topic proxy.

### Sequences

#### sequence<[LinkInfo](#)> [LinkInfoSeq](#)

A sequence of [LinkInfo](#) objects.

#### Used By

- [Topic::getLinkInfoSeq](#)

### Dictionaries

## **dictionary<string, string> QoS**

This dictionary represents quality of service parameters.

### **Used By**

- [Topic::subscribeAndGetPublisher](#)

### **See Also**

- [Topic::subscribeAndGetPublisher](#)

## **dictionary<string, [Topic\\*](#)> TopicDict**

Mapping of topic name to topic proxy.

### **Used By**

- [TopicManager::retrieveAll](#)
-

## IceStorm-AlreadySubscribed

---

### IceStorm::AlreadySubscribed

#### Overview

#### exception AlreadySubscribed

This exception indicates that an attempt was made to subscribe a proxy for which a subscription already exists.

#### *Used By*

- `IceStorm::Topic::subscribeAndGetPublisher`
-

## IceStorm-BadQoS

---

### IceStorm::BadQoS

#### Overview

#### exception BadQoS

This exception indicates that a subscription failed due to an invalid QoS.

#### *Used By*

- `IceStorm::Topic::subscribeAndGetPublisher`

#### Data Member Index

`reason` — The reason for the failure.

#### Data Members

`string reason;`

The reason for the failure.

---

## IceStorm-Finder

---

### IceStorm::Finder

#### Overview

#### interface Finder

This interface is advertised by the IceStorm service through the Ice object with the identity `IceStorm/Finder`. This allows clients to retrieve the topic manager with just the endpoint information of the IceStorm service.

#### Operation Index

[getTopicManager](#) — Get the topic manager proxy.

#### Operations

##### **IceStorm::TopicManager\*** [getTopicManager\(\)](#)

Get the topic manager proxy. The proxy might point to several replicas.

##### *Return Value*

The topic manager proxy.

---

## IceStorm-InvalidSubscriber

---

### IceStorm::InvalidSubscriber

#### Overview

#### exception InvalidSubscriber

This exception indicates that an attempt was made to subscribe a proxy that is null.

#### *Used By*

- [IceStorm::Topic::subscribeAndGetPublisher](#)

#### Data Member Index

[reason](#) — The reason for the failure.

#### Data Members

**string** [reason](#);

The reason for the failure.

---

## IceStorm-LinkExists

---

### IceStorm::LinkExists

#### Overview

#### exception LinkExists

This exception indicates that an attempt was made to create a link that already exists.

#### *Used By*

- `IceStorm::Topic::link`

#### Data Member Index

`name` — The name of the linked topic.

#### Data Members

`string name;`

The name of the linked topic.

---

## IceStorm-LinkInfo

---

### IceStorm::LinkInfo

#### Overview

#### struct LinkInfo

Information on the topic links.

#### *Used By*

- [IceStorm::LinkInfoSeq](#)

#### Data Member Index

[theTopic](#) — The linked topic.

[name](#) — The name of the linked topic.

[cost](#) — The cost of traversing this link.

#### Data Members

**IceStorm::Topic\*** [theTopic](#);

The linked topic.

**string** [name](#);

The name of the linked topic.

**int** [cost](#);

The cost of traversing this link.

---

## IceStorm-NoSuchLink

---

### IceStorm::NoSuchLink

#### Overview

#### exception NoSuchLink

This exception indicates that an attempt was made to remove a link that does not exist.

#### *Used By*

- [IceStorm::Topic::unlink](#)

#### Data Member Index

`name` — The name of the link that does not exist.

#### Data Members

`string name;`

The name of the link that does not exist.

### IceStorm::Topic

#### Overview

#### interface Topic

Publishers publish information on a particular topic. A topic logically represents a type.

#### See Also

- [IceStorm::TopicManager](#)

#### Operation Index

[getName](#) — Get the name of this topic.

[getPublisher](#) — Get a proxy to a publisher object for this topic.

[getNonReplicatedPublisher](#) — Get a non-replicated proxy to a publisher object for this topic.

[subscribeAndGetPublisher](#) — Subscribe with the given `qos` to this topic.

[unsubscribe](#) — Unsubscribe the given `subscriber`.

[link](#) — Create a link to the given topic.

[unlink](#) — Destroy the link from this topic to the given topic `linkTo`.

[getLinkInfoSeq](#) — Retrieve information on the current links.

[getSubscribers](#) — Retrieve the list of subscribers for this topic.

[destroy](#) — Destroy the topic.

#### Operations

##### [ "nonmutating" ] string getName()

Get the name of this topic.

#### Return Value

The name of the topic.

#### See Also

- [IceStorm::TopicManager::create](#)

##### [ "nonmutating" ] Object\* getPublisher()

Get a proxy to a publisher object for this topic. To publish data to a topic, the publisher calls [getPublisher](#) and then casts to the topic type. An unchecked cast must be used on this proxy. If a replicated IceStorm deployment is used this call may return a replicated proxy.

#### Return Value

A proxy to publish data on this topic.

##### [ "nonmutating" ] Object\* getNonReplicatedPublisher()

Get a non-replicated proxy to a publisher object for this topic. To publish data to a topic, the publisher calls [getPublisher](#) and then casts to the topic type. An unchecked cast must be used on this proxy.

#### Return Value

A proxy to publish data on this topic.

**Object\* subscribeAndGetPublisher(IceStorm::QoS theQoS, Object\* subscriber) throws IceStorm::AlreadySubscribed, IceStorm::InvalidSubscriber, IceStorm::BadQoS**

Subscribe with the given `qoS` to this topic. A per-subscriber publisher object is returned.

**Parameters**

`theQoS` — The quality of service parameters for this subscription.  
`subscriber` — The subscriber's proxy.

**Return Value**

The per-subscriber publisher object.

**Exceptions**

`IceStorm::AlreadySubscribed` — Raised if the subscriber object is already subscribed.  
`NullSubscriber` — Raised if the subscriber object is null.  
`IceStorm::BadQoS` — Raised if the requested quality of service is unavailable or invalid.

**See Also**

- [unsubscribe](#)

**void unsubscribe(Object\* subscriber)**

Unsubscribe the given `subscriber`.

**Parameters**

`subscriber` — The proxy of an existing subscriber.

**See Also**

- [subscribeAndGetPublisher](#)

**void link(IceStorm::Topic\* linkTo, int cost) throws IceStorm::LinkExists**

Create a link to the given topic. All events originating on this topic will also be sent to `linkTo`.

**Parameters**

`linkTo` — The topic to link to.  
`cost` — The cost to the linked topic.

**Exceptions**

`IceStorm::LinkExists` — Raised if a link to the same topic already exists.

**void unlink(IceStorm::Topic\* linkTo) throws IceStorm::NoSuchLink**

Destroy the link from this topic to the given topic `linkTo`.

**Parameters**

`linkTo` — The topic to destroy the link to.

**Exceptions**

`IceStorm::NoSuchLink` — Raised if a link to the topic does not exist.

[ "nonmutating" ] `IceStorm::LinkInfoSeq` `getLinkInfoSeq()`

Retrieve information on the current links.

*Return Value*

A sequence of `LinkInfo` objects.

[ "nonmutating" ] `Ice::IdentitySeq` `getSubscribers()`

Retrieve the list of subscribers for this topic.

*Return Value*

The sequence of Ice identities for the subscriber objects.

`void destroy()`

Destroy the topic.

---

## IceStorm-TopicExists

---

### IceStorm::TopicExists

#### Overview

#### exception TopicExists

This exception indicates that an attempt was made to create a topic that already exists.

#### *Used By*

- [IceStorm::TopicManager::create](#)

#### Data Member Index

`name` — The name of the topic that already exists.

#### Data Members

`string name;`

The name of the topic that already exists.

---

## IceStorm-TopicManager

---

### IceStorm::TopicManager

#### Overview

#### interface TopicManager

A topic manager manages topics, and subscribers to topics.

#### See Also

- [IceStorm::Topic](#)

#### Operation Index

[create](#) — Create a new topic.

[retrieve](#) — Retrieve a topic by name.

[retrieveAll](#) — Retrieve all topics managed by this topic manager.

[getSliceChecksums](#) — Returns the checksums for the IceStorm Slice definitions.

#### Operations

##### **IceStorm::Topic\*** [create](#)(string name) throws **IceStorm::TopicExists**

Create a new topic. The topic name must be unique, otherwise [IceStorm::TopicExists](#) is raised.

#### *Parameters*

name — The name of the topic.

#### *Return Value*

A proxy to the topic instance.

#### *Exceptions*

[IceStorm::TopicExists](#) — Raised if a topic with the same name already exists.

##### [ "nonmutating" ] **IceStorm::Topic\*** [retrieve](#)(string name) throws **IceStorm::NoSuchTopic**

Retrieve a topic by name.

#### *Parameters*

name — The name of the topic.

#### *Return Value*

A proxy to the topic instance.

#### *Exceptions*

[IceStorm::NoSuchTopic](#) — Raised if the topic does not exist.

##### [ "nonmutating" ] **IceStorm::TopicDict** [retrieveAll](#)()

Retrieve all topics managed by this topic manager.

***Return Value***

A dictionary of string, topic proxy pairs.

**[ "nonmutating" ] Ice::SliceChecksumDict getSliceChecksums()**

Returns the checksums for the IceStorm Slice definitions.

***Return Value***

A dictionary mapping Slice type ids to their checksums.
